ion sources can, in mass-separated ion-beam columns, provide ions of B, As, or Si. Separation is usually performed by use of a Wien filter, which consists of crossed (perpendicular) magnetic and electrostatic fields. The needles are typically 1–5 μm in diameter and can be fabricated from any conductor which will not be corroded by the liquid metal. The liquid metals are restricted to those that have vapor pressures low enough (Swanson and Bell, 1989) for the ion source to have a reasonably long life.

Emitted ions are characterized by energy spreads that are low enough ($\sim$5 eV) (Swanson, 1982) for LMIS to be of use in focused ion beam applications.

2. DEVICES AND INSTRUMENTS

2.1 Emitters

Points suitable for field-emission experiments with radii in the range 20–200 nm are easily fabricated by electrochemical etching of small-diameter (0.25 mm) metal wires. Usually, the process of drawing wires causes the wire to form crystals of the metal with a preferred orientation along the wire axis. For tungsten this is the (110) direction. Other orientations may be produced by zone melting of the wire in contact with a suitable seed crystal. For tungsten, electrochemical etching can be performed either with a positive potential of a few volts dc applied to the metal or with a few volts ac using sodium hydroxide as the electrolyte.

Room-temperature operation of field emitters requires ultrahigh vacuum because ions formed by electron impact return to the emitter and cause formation of rough, atomic-scale features over which enhanced electric fields exist. Electron emission increases at these sites and can run away leading to a vacuum arc that can destroy the emitter.

High-temperature operation of the emitter greatly enhances emitter life by causing increased surface self-diffusion of the emitter material. This causes the rough surface features to smooth away by surface diffusion. This healing mechanism is utilized in the 1800-K operation of (100)-oriented field emitters of W coated with a highly stable compound of zirconium and oxygen. Such emitters have lowered sticking coefficients for gases which would also otherwise change the I/V characteristics of the needle by adsorption-induced work-function changes. Because of the lowered work function of the W(100) plane due to the adsorbed ZrO overlayer at the needle apex of such emitters, there is an additional advantage: electron emission is confined to a cone of half angle $\sim$13 vs 30° for a clean emitter. Beam confinement is especially useful for electron optical applications.

Points suitable for field ionization experiments typically have radii in the range 10–100 nm. FI emitters are initially shaped by the same electrochemical etching techniques used for field-emission emitters. The final shaping of an FI emitter is performed in an FI microscope (see Sec. 2.3). As the voltage applied to an electrochemically etched emitter is gradually raised, the field strength over local protuberances increases until they are stripped away by field evaporation. The process is continued until the apex of the emitter attains a so-called field-evaporation end form in which the surface is atomically smooth and representative of the metal's crystallographic structure.

2.2 Field-Emission Microscope

In 1937, Mueller introduced the field-emission projection microscope (FEM) in which an image of the emitter surface was projected onto a fluorescent screen with a magnification M given approximately by the ratio of screen to emitter radii: R/r.

Actual magnification is reduced from this value by about 30% because of compression of the trajectories of the electrons due to the difference between the electric-field distribution for a sphere, for which the above expression is exact, and the actual field distribution for a needle-shaped emitter. The resolution of the microscope is about 1 nm and is limited by the fact that the electrons emerge from the emitter surface with a variation in velocities in the plane perpendicular to the emitter surface's normal. This results in the production of a blurred spot at the fluorescent screen that limits the ability of a viewer to distinguish between the projected images of adjacent surface features on the emitter.

A FEM image of a clean tungsten surface is shown in Fig. 8. When the needle is annealed, the point develops an end form that minimizes the surface energy of the needle. This

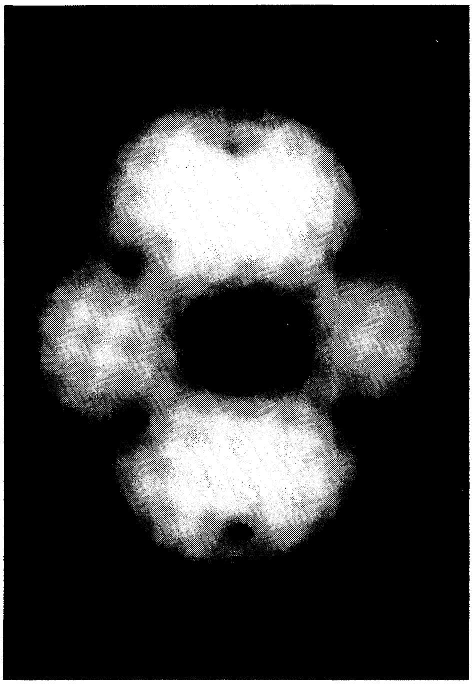

FIG. 8. Image of a field-emission pattern of a tungsten (110)-oriented needle. (Courtesy of L. W. Swanson, FEI Corp., Beaverton, Oregon.)

results in a mostly hemispherical shape on which low-energy, low-index planes of the metal exist as flats joined together by curved regions of the emitter surface.

The dark areas of the projected field-emission pattern correspond to the low-index planes, which have high work functions. These planes are distributed on the needle surface in a way that is determined by the crystal symmetry of the needle material. Hence the symmetry of the field-emission image is a reflection of the symmetry of the crystal structure of the tungsten needle. The FEM has been used extensively for the study of adsorption phenomena on clean, well-defined crystal surfaces.

2.3 Field-Ion Microscope

Mueller showed that, if a needle suitable for field-emission experiments is subjected to a reverse electric field, i.e., the needle was positive with respect to the extractor electrode, and a gas at low pressure was present, then ions are formed from the gas by field ionization. If, in addition, the needle is cooled to temperatures less than ~100 K, a projection image of the surface is formed on a fluorescent screen, as in the field-emission microscope case, with a resolution, however, that is sufficiently high to allow individual atoms of the surface to be distinguished. This can be seen in Fig. 9 which shows an image of a W needle, cooled to 20 K, in the presence of helium at 10-μm pressure.

The contrast mechanism is due to the fact that higher electric fields exist above the atoms compared to that between them so that the bright spots on the photograph correspond to individual atoms. The interiors of the single-crystal planes are not visible because the electric fields are too low.

Cooling of the needle causes an increase in ion current because gas atoms that hit the needle and are trapped there by polarization forces make jumps on the surface of the needle to a height that decreases with gas temperature. Consequently, they spend a longer time in the critical ionization zone, just above the needle surface, and so are more likely to be ionized at lower needle temperatures and thereby produce an increased current.

The resolution of the field-ion microscope, δ, is dependent on the needle apex radius r_t, needle temperature T, electric field at the emitter apex, F_0, gas atom atomic weight M, and gas atom size δ_0:

$$\delta = A(r_t/MF_0)^{1/2} + B(r_tT/F_0) + \delta_0, \qquad (30)$$

where A and B are constants. The above formula was derived in the book by Mueller and Tsong (1969). It can be seen that resolution is favored by low temperatures, high gas ionization fields F_0, small needle radii, and small gas molecule size. This is the reason that resolution is highest for helium, which has the highest value for F_0 and the smallest diameter. Helium also permits operation at temperatures <20 K where most other gases would freeze out as solids.

2.4 Scanning Tunneling Microscope

The atomic-resolution scanning tunneling microscope (STM), developed in 1981 by Binnig and Rohrer at IBM Zurich, Switzerland (see Binnig *et al.*, 1982), represents a revolutionary advance in microscope technology. The resolution in the plane of the sample is ~0.2 nm and much better in the vertical direction. This is good enough for imaging of

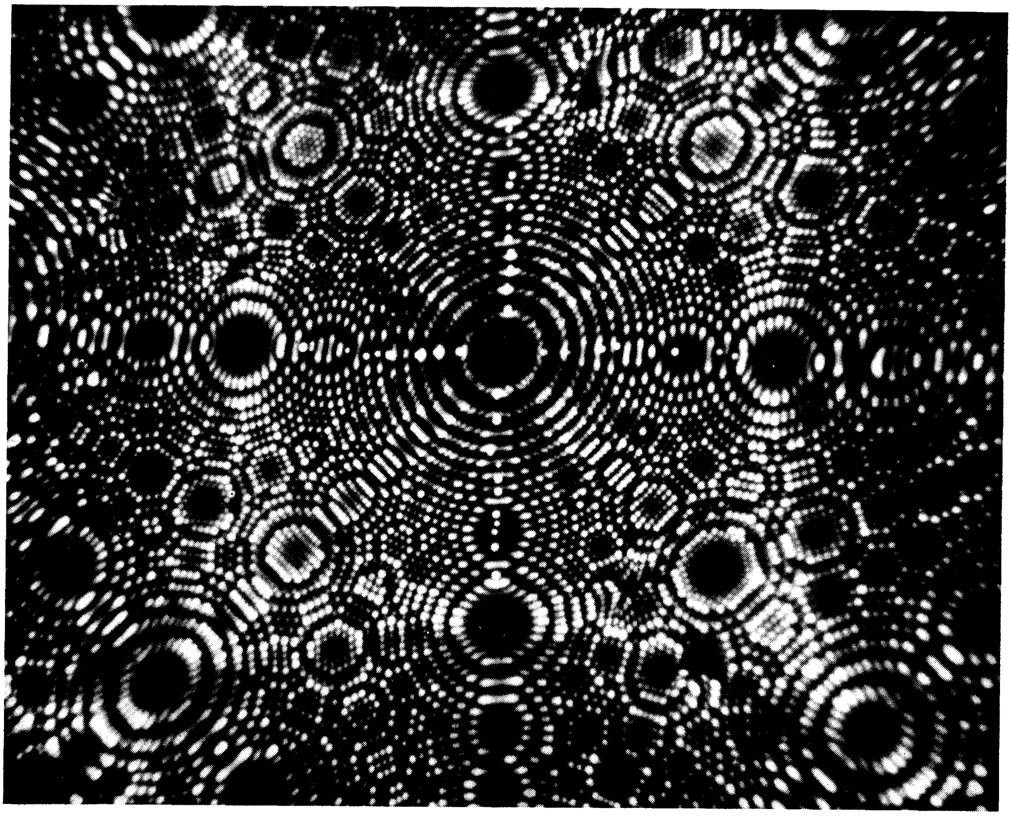

FIG. 9. Image of a field-ion microscope pattern of an iridium single crystal in which individual atoms at the edges of the single-crystal planes can be seen. In some cases, the atoms of small-diameter planes can be seen even in the interior of the planes.

individual atoms, as can be seen for the image in Fig. 10 of the surface of a Si(111)7×7 crystal. Because of the closeness of the electron source—the emitter tip—to the sample, the presence of gases at atmospheric pressure does not prevent operation of the STM, although it does present a problem for surface science studies involving clean surfaces which would rapidly become contaminated in the presence of atmospheric gases. The contrast in the STM image arises from the overlap of the wave function of an atom at the apex of the STM needle with that of a surface atom. This is often greater over a surface atom than that between atoms.

The success of the STM and its rapid development during the last decade are due in large part to the fact that STM workers have found techniques to overcome the following problems:

1. vibrations that tend to cause tip-damaging collisions between the tip and surface,
2. difficult to control tip-surface distances, and
3. conversion of STM data into useful surface images.

As discussed by Pohl (1986), vibrational problems have been greatly reduced by reducing the dimensions of the STM and making compact rigid devices. Tip-surface distances are being controlled to less than 0.1 nm by means of piezoelectric drivers. The development of superb graphics imaging software, mostly by IBM workers, has contributed greatly to the acceptance of STM technology.

2.5 Flash X-Ray Technology

If current densities are too high at the field emitter surface, the emitter end vaporizes and turns into a plasma that, in a period of ~10 ns, expands to fill the space between anode and

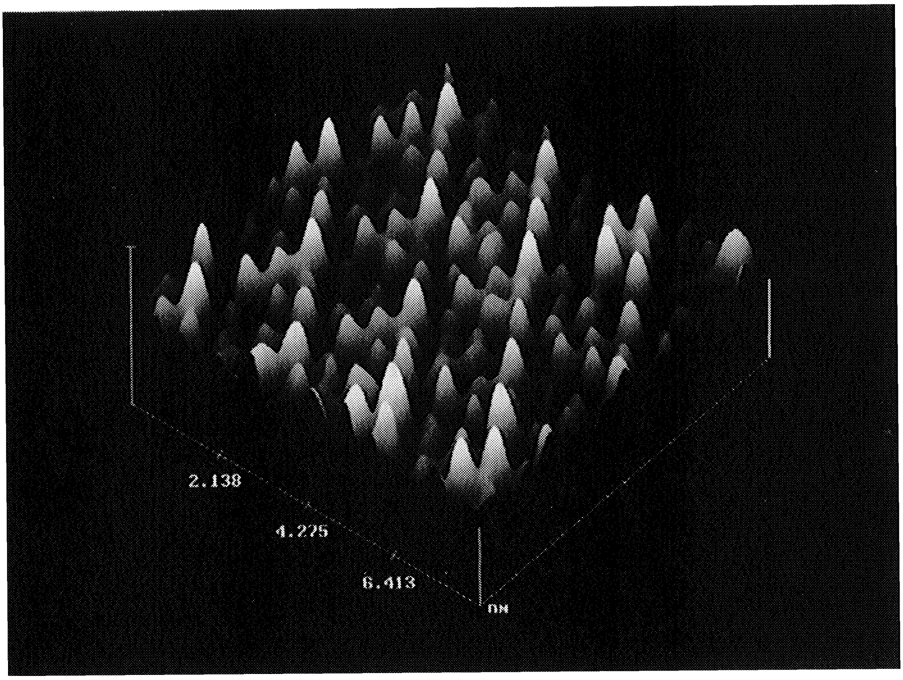

FIG. 10. A scanning tunneling microscope image of silicon showing the 7×7 reconstruction of the Si (111) surface. (Courtesy of Jeff Tetzlaff, Perkin Elmer Corp., Electronics Division.)

extractor electrode. This causes a tip-destroying arc. If, on the other hand, the field emission extraction voltage is turned off in time, the expanding plasma does not have time to reach the extractor and short out the electrodes. This is the basis of a flash x-ray technology for producing ultrahigh-power, short pulse-length, x-ray sources. By using extractor voltage pulses of ~10 ns or less, x-ray systems using electron bursts of up to 10 000 A and 2 MeV were developed by Dyke and co-workers (see Charbonnier *et al.*, 1963) at Femcor, now Hewlett Packard in McMinnville, Oregon.

2.6 Electron-Beam Lithography

The printing of patterns on resist-coated silicon wafers by passing light through lithographic masks is a key process in integrated-circuit manufacture. The mask layout, on the other hand, can also be created by using computer-directed, finely focused electron beams. Recently, field-emission sources using the zirconiated tungsten cathodes, discussed above in Sec. 2.1, have been used for high-performance electron-beam lithography systems devoted to the production of application-specific integrated circuits.

2.7 Flat-Panel Field-Emission Display (FED) Technology

A very promising recent application of field emission has emerged: the use of individually addressable field-emitter arrays for flat panel displays. A high-resolution color display using field-emission sources was recently demonstrated by Meyer and co-workers (see Meyer, 1991) at Leti Ceng, Grenoble, France. In a 256×256-line, 2-mm-thick, 6-in. diagonal monochrome display, lifetimes of >5000 h have been demonstrated. Intrinsic contrasts of >100:1 were attained with a brightness of 150–300 cd/m^2. The average power consumption for the screen was 1 W/dm^2.

The individual emitters of, presumably, molybdenum, deposited on a glass substrate, were 1.2 μm high and arranged 10 000/mm^2, allowing about 1000 emitters per pixel, thus providing a very high level of redundancy should individual emitters fail. A problem with field-emitter arrays is that only a small fraction contribute to emission because the emission current, as seen earlier, is exponentially dependent on emitter radius. Thus sharper emitters dominate emission because they emit at lower voltage than duller ones. An attempt to increase voltage to allow emission from duller tips leads to catastrophically high emission from the sharp emitters which fail through generation of a vacuum arc which can destroy a large fraction of all array emitters simultaneously. Leti workers overcame this problem by incorporating a resistive strip in the base of each emitter so that at high currents the voltage on an emitter was substantially less than that across low-emitting blunt emitters. This solution also greatly reduced the degree of flicker in the display.

According to Kuo (1992), the field-emission flat-panel display may play a prominent part in new flat-panel display developments because of its apparent advantage over competing display technologies of requiring fewer manufacturing steps.

2.8 Field-Emission Microwave Generation

Another promising application of the field-emission array technology, discussed in the previous section, is for generation of high-power microwaves in the frequency range 10–100 GHz. The first unequivocal demonstration of the possibility of microwave modulation of field-emission tungsten emitter arrays was carried out by Charbonnier *et al.* (1963) using a two-cavity device which these authors called the femitron: field-emission microwave generator. The analysis and experimental results of this work indicate that field-emission microwave amplifiers promise higher power than solid state devices, offer instant turn-on, unlike thermionic electron devices, and hold out the possibilities of much higher efficiencies than thermionic devices.

More recent discussions of the potentialities of field emission for microwave generation and amplification have been described at meetings of the recently instituted international conferences on vacuum microelectronics in which new developments of miniaturized field-emission devices are discussed.

GLOSSARY

Electron-Beam Lithography: The use of a focused beam of electrons to create patterns in resist materials in order to facilitate the fabrication of fine features for integrated-circuit fabrication.

Fermi Level: The maximum energy level of electrons in a metal at absolute zero or the energy for which the electron occupancy probability is 0.5. It is also the electrochemical potential of an electron in a solid.

Field Desorption: Removal of an adsorbed atom from a surface by application of a high electric field.

Field Emission: Extraction of electrons from a solid by tunneling.

Field-Emission Microscope: A high-resolution (~ 1 nm) point-projection microscope utilizing the emission of electrons by tunneling of the electrons through a field-deformed potential energy barrier.

Field Evaporation: Removal of an atom from a surface by application of a high electric field. This process was described by Mueller as a special case of field desorption.

Field-Ion Microscope: A point-projection microscope of atomic resolution utilizing atom ionization by the high electric field at the surface of a conductive needle.

Field Ionization: The process of ionization of an atom by tunneling of an electron from it through the electric-field–deformed potential energy barrier.

Image Force: The force between an electric charge and its induced opposite (image) charge in a conductor or semiconductor.

Liquid-Metal Ion Source: A novel high-intensity ion source generated by the application of a high electric potential to a liquid conductor coating a needle.

Scanning Tunneling Miscroscope: A recently developed microscope of atomic resolution which is based on the principle of tunneling of electrons from atom(s) of an atomically sharp conductive needle to adjacent surface atoms on the surface of a conductor or semiconductor.

Thermionic Emission: Emission of electrons brought about by heating.

Tunneling: Removal of an atomic-sized particle, in this case an electron, from an atom or a solid by utilizing the wavelike properties of very small particles which can then pass through a potential energy barrier if it is sufficiently thin.

Work Function: Energy required to remove an electron from a metal to a position just outside it.

INTRODUCTION

The field-ion microscope was invented by the late Erwin W. Müller (Müller, 1951). Four years later, the first direct images of individual atoms on a solid surface were obtained with this instrument (Müller, 1956a). For nearly 20 years thereafter, the field-ion microscope had the distinction of being the only microscope capable of atomic resolution. Although it is now possible to resolve individual atoms in the high-resolution electron microscope (Crewe *et al.*, 1970) and scanning tunneling microscope (Binnig *et al.*, 1983), the field-ion microscope remains a powerful basic research tool for the investigation of atomic processes at solid surfaces.

The physical process that underlies the operation of the field-ion microscope is field ionization. In a high electric field, electrons may tunnel from gas-phase atoms or molecules to the surface of a solid. The loss of electrons results in the formation of positive ions. It is these "field ions" that produce direct images of the surface atoms in the field-ion microscope. In a related process known as field desorption, the surface atoms themselves are removed from the solid as positive ions. The discovery of field desorption led to the development of the atom-probe (Müller *et al.*, 1968), an instrument that is used to identify selected atoms observed in the field-ion microscope. Together, the field-ion microscope and atom-probe have been used to investigate a wide variety of problems in materials science and solid-state physics.

In this article the principles and applications of the field-ion microscope and atom-probe are reviewed. The processes that underlie the operation of the instruments, namely field ionization and field desorption, are discussed first. The emphasis in this section is placed on physical concepts rather than mathematical detail. A more extensive mathematical description can be found in the article FIELD EMISSION AND FIELD IONIZATION. Next, the design and operation of the instruments are reviewed. Included are discussions of the basic design of a field-ion microscope, methods of sample preparation, and the interpretation of field-ion microscope images. The different types of atom-probes currently in operation and the methods used to interpret atom-probe data are also discussed. Finally, selected applications of the instruments in the areas of surface science, metallurgy, and materials science are reviewed.

1. PHYSICAL PROCESSES

1.1. Field Ionization

Field ionization is a process in which an atom or molecule loses one or more electrons by the application of a high electric field. The strength of the electric field required for field ionization is of the order of tens of V/nm. In the field-ion microscope the field-ionization process takes place near the surface of a solid sample (either a metal or a semiconductor). The high electric field is achieved by forming the sample into a sharply pointed needle (called a tip) and applying a positive voltage. The radius of curvature at the tip apex is of the order of tens of nm and the applied voltage is typically 3–20 kV.

Field ionization relies on the quantum-mechanical process of tunneling, for which there is no classical analog. The potential-energy diagram shown in Fig. 1 indicates how field ionization of an atom occurs at a metal surface. The metal is represented by a free-electron model with electronic states filled to the Fermi level. The uppermost electronic level of an atom near the metal surface is raised above the Fermi level of the metal by the application of a high electric field. If the width of the potential barrier between the atom and metal is sufficiently narrow (the width decreases as the height of the atomic level is increased above the Fermi level), an electron can tunnel from the gas atom to the metal. This tunneling process produces a positive ion next to the positively charged metal surface. Electrostatic repulsion accelerates the ion away from the surface to the fluorescent screen of the field-ion microscope.

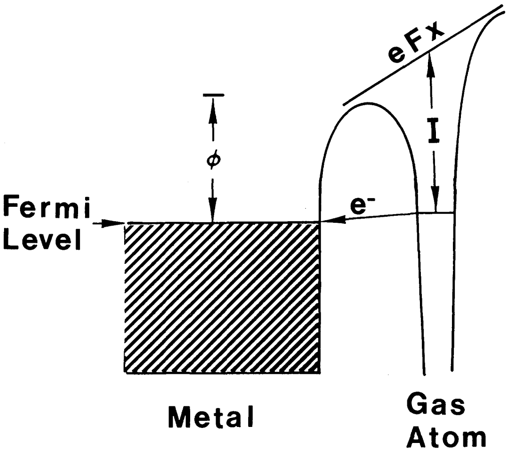

FIG. 1. Electron potential-energy diagram for an atom near a metal surface in the presence of an electric field *F*. In field ionization an electron tunnels from the gas atom to the metal.

In general, the tunneling probability increases as the atom moves closer to the surface and the barrier narrows. However, if the highest filled energy level of the atom falls below the Fermi level of the metal, tunneling cannot occur because there are no unoccupied states to receive the electron. This condition defines the critical distance of field ionization, x_c, given by

$$eFx_c = I - \Phi, \qquad (1)$$

where e is the electron charge, F is the applied field, I is the ionization potential of the atom, and Φ is the work function of the metal. At distances smaller than x_c field ionization is forbidden. Beyond the critical distance the field falls off very rapidly, resulting in a narrow zone in which field ionization can occur. It should be noted that the above relationship neglects contributions of the image potential and polarization effects, which are assumed to be small in comparison to I and Φ. For the typical case of helium ionized above a tungsten surface, Eq. (1) predicts that the critical distance of field ionization is approximately 0.4 nm.

The most widely accepted theoretical treatment of field ionization at a metal surface was originated by Inghram and Gomer (1954) and involves the application of the Wentzel-Kramers-Brillouin (WKB) method to determine the tunneling probability. The barrier penetration is given by an expression that depends on the potential and total energies of the tunneling electron. Various approximations for the electron potential energy have led to both numerical and analytic solutions for the tunneling probability. The total ion current, which is a product of this probability and the gas supply to the emitter apex, can be calculated and compared to experiment. Measurements of the energy distributions of field-ionized gases and the total ion current as a function of electric field have, in general, established the validity of this approach. Detailed discussions of field-ionization theory can be found in books by Gomer (1961), Müller and Tsong (1969), and Tsong (1990).

Atomic resolution with the field-ion microscope was achieved following the discovery that the lateral resolution increases dramatically at lower temperatures. It is observed experimentally that a temperature of approximately 20 K produces the best resolution (see Sec. 3.1). This observation, along with the fact that field ionization occurs away from the surface at the critical distance of field ionization, indicates that the gas atoms are not field ionized upon a single impact with the surface, but are thermally accommodated, i.e., their kinetic energy is reduced to that of the thermal energy of the surface atoms. Without thermal accommodation, there would be no temperature dependence of the resolution. The accommodation process involves a large number of hops from one impact site to another for each gas atom. Polarization attraction causes the atoms to return to the surface after each impact and concomitant loss of kinetic energy. Derivations of the theoretical resolution of the field-ion microscope assume that the gas atoms are fully accommodated to the sample temperature. The hopping-gas model has been used successfully to explain the measured ion current-voltage relationship.

It is now generally accepted that, in addition to the hopping-gas atoms above the sample surface, there is also a layer of adsorbed atoms on the surface. Inert gases such as He or Ne, which are typically used for imaging in the field-ion microscope, are weakly bound to the surface in the presence of a high electric field at low temperatures. The term used to describe this phenomenon is field adsorption. The binding has been described as an attraction between the field-induced dipole of the gas atom and its image dipole (Tsong and Müller, 1970). More recently, it has been suggested that the applied electric field raises the electronic levels of the gas atoms to a point where chemisorption may occur (Nath *et al.*, 1986). In either case, the binding is relatively weak compared to ordinary chemisorption, and the atoms are released at temperatures above 100–150 K. Atomic-resolution images of metal surfaces by the thermal-induced desorption of field-adsorbed gas atoms has been reported (Kellogg and Tsong, 1981).

1.2 Field Evaporation and Field Desorption

In addition to ionizing gas-phase atoms above a surface, the high electric field used in the field-ion microscope may also induce the removal of substrate surface atoms and adsorbates. The process is known as field evaporation when referring to removal of substrate atoms or, more generally, field desorption when referring to removal of either substrate surface atoms or adsorbates. In field-ion microscopy the imaging gas is typically chosen such that the field required for field ionization is somewhat less than the substrate evaporation field. Under these conditions, it is possible to raise the field to remove atoms for sample preparation (cleaning) purposes and then reduce the field for imaging. As a result, field desorption (evaporation) is used routinely in field-ion microscopy. As discussed later, field desorption is also the process that underlies the operation of the atom-probe field-ion microscope.

The process of field desorption is understood qualitatively in terms of one-dimensional potential-energy diagrams as shown in Fig. 2. The curve shown in Fig. 2(a) represents an atom at a surface in the absence of an applied electric field. The quantity λ is either the sublimation energy for field evaporation of a protruding atom at the edge of a plane or the binding energy for field desorption of an adsorbate. To remove the atom as an n-fold charged ion requires an energy given by

$$Q_0=\lambda+\sum_n I_n-n\Phi, \tag{2}$$

where I_n is the nth ionization potential of the atom and Φ is the work function of the surface. The situation is illustrated in Fig. 2(b). In an applied electric field, the ionic potential-energy curve is given by the superposition of the curve shown in Fig. 2(b) and the potential due to the field, $-neFx$. The result of this superposition is shown in Fig. 2(c). Field desorption is viewed as a thermal activation of the surface atom or adsorbate over the barrier indicated in Fig. 2(c). The activation energy for field desorption is therefore given by $Q_n(F)$, the height of the barrier.

In Müller's "image hump" model of field evaporation (Müller, 1956b), the ionic potential is approximated by a simple image potential, $-ne^2/4x$. The superposition of this curve with the field potential $-neFx$ results in a

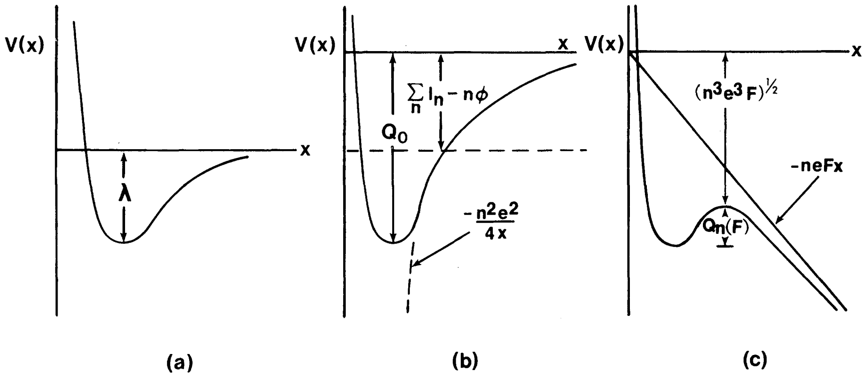

FIG. 2. Atomic and ionic potential-energy curves related to field desorption. (a) Atomic potential-energy curve for an atom held on the surface with a binding (or sublimation) energy λ. (b) Ionic potential-energy curve for an n-fold charged ion approximated by a simple image potential. (c) Ionic potential energy for the same ion in an applied field F. The energy required to remove the atom as an n-fold charged ion is $Q_n(F)$.

"Schottky saddle" with a maximum at $(n^3e^3F)^{1/2}$ below the zero-field maximum. The activation energy $Q(F)$ is given by the zero-field energy (the energy to remove the ion in the absence of a field) reduced by the energy at the Schottky maximum, i.e.,

$$Q_n(F) = Q_0 - (n^3e^3F)^{1/2}. \qquad (3)$$

In more refined models the difference in polarizability between the atom and the ion is included in the expression for $Q_n(F)$. Despite the simplicity of this model, it predicts the low-temperature evaporation fields and the ionic charge states of many metals with surprising accuracy.

In Gomer's "charge-exchange" model (Gomer, 1959), it is the crossing point of the atomic and ionic potential-energy curves that defines the maximum of the activation barrier. The activation energy is given by the difference between this intersection point and the minimum of the atomic potential-energy curve. Although the charge-exchange model is considered to be more realistic than the image-hump model (the image potential is not well defined at such small distances), it is less convenient for the calculation of measurable parameters because the exact forms of the curves are generally not known. However, by making suitable approximations, investigators have used this model successfully to analyze data on the field-evaporation rates of several metals.

More recently, quantum-mechanical models of field desorption have begun to emerge (McMullen and Perdew, 1987; Kreuzer and Nath, 1987). In the model of Kreuzer and Nath, the electronic properties of the metal are calculated within a tight-binding cluster model and the local electric field is taken from self-consistent jellium calculations (see COLLECTIVE PHENOMENA IN SOLIDS). A scaling law is derived from this approach which predicts experimentally measured evaporation fields to within 10%–20%, which is really no better than the above phenomenological models. However, the quantum-mechanical calculations are found to predict the field dependence of the activation energy for field evaporation of W and Rh much better than the image-hump model.

2. INSTRUMENTATION AND PRINCIPLES OF OPERATION

2.1 Field-Ion Microscope

The basic design of the field-ion microscope is surprisingly simple, given its ability to resolve individual atoms at a solid surface. The essential requirements are a vacuum system that can be charged with a low pressure of an inert gas (the imaging gas), a sharply pointed needle (the tip) cooled to 77 K or lower, a fluorescent screen, and a means to apply a high positive voltage to the tip. These requirements can be met by the simple design shown in Fig. 3. Although stainless-steel vacuum systems are standard nowadays, glass systems similar to this design were common prior to the 1970s.

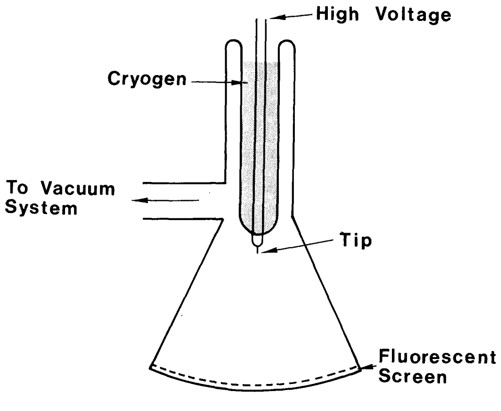

FIG. 3. Schematic diagram showing the essential components of a field-ion microscope. The voltage is referenced to the fluorescent screen, which is deposited on a conductive film.

The standard method for the preparation of sample tips used in field-ion microscopy is electrochemical etching. The starting material for metals is typically a piece of wire of 0.1–0.2 mm diameter. The wire is dipped (by hand or manipulator) into an appropriate chemical solution and a current is passed through it. Semiconductor samples are prepared from thin whiskers or slices of wafers and are sharpened in chemical solutions. Over the years, researchers have developed etching recipes for a variety of semiconductor and metal samples. Many of the polishing solutions are taken from those developed for the etching of thin-field transmission electron-microscope samples. Several tables of tip-polishing recipes are published in the literature (Müller and Tsong, 1969; Bowkett and Smith, 1970; Miller and Smith, 1989; Tsong, 1990).

The field-ion microscope was developed as an extension of the earlier field- (electron-) emission microscope (Müller, 1936). In fact, the same system design used for field-ion microscopy (e.g., Fig. 3) may also be used for field-emission microscopy. In field-emission microscopy a negative voltage is applied to the tip in ultrahigh vacuum. The required voltage for the field-emission microscope is about a factor of 10 lower than that needed for the field-ion microscope (see below). The negative electric field at the tip apex ejects electrons in a process known as field emission (the electrons tunnel out from the solid) and these electrons form an image of the tip surface on the fluorescent screen. Although simpler to operate than the field-ion microscope, the field-emission microscope has a resolution of 3–4 nm, not sufficient to resolve individual atoms.

To operate a field-ion microscope, the chamber is evacuated to a pressure in the 10^{-6} Pa range or lower and several tenths of a Pa of the imaging gas is introduced (He and Ne are common). The tip is cooled with a cryogen and a positive voltage in the range of 3–20 kV is applied to the emitter. The high electric field at the tip apex (20–50 V/nm) ionizes imaging gas atoms as discussed above and projects them to the fluorescent screen. The pattern of spots that forms on the screen is a direct image of the protruding surface atoms.

Contrast variations in the field-ion microscope result from the fact that field ionization occurs preferentially above the protruding surface atoms. The enhanced electric field above the protruding atoms causes the hopping-gas atoms (see above) to have a higher probability of ionization in these localized regions. Ions formed above the atoms follow the nearly radial electric field lines to the fluorescent screen and produce a highly magnified image of the surface.

An example of a field-ion image from a rhodium tip is shown in Fig. 4. The small spots in this micrograph correspond to individual surface atoms. It is clear from Fig. 4 that there are regions on the surface where the atoms do not protrude sufficiently to be imaged (the dark circular areas). These regions correspond to the low-index (smooth) single-crystal planes of the multifaceted surface. The atoms within these planes do not protrude out far enough to cause local field variations and

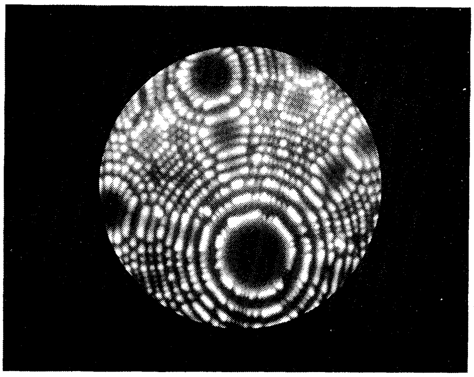

FIG. 4. An example of a field-ion microscope image from a sample of rhodium.

differences in contrast. The concentric rings of spots that surround the dark regions correspond to the edge atoms of successively deeper atomic layers. The edge atoms of the different low-index planes join each other to form the higher-index planes. The field-ion image is a stereographic projection of the hemispherical tip surface. From the symmetry of the spot patterns and the known crystallographic structure of the sample (e.g., pure metals), it is relatively easy to determine the Miller indices of the different crystal faces observed in the image. For alloy samples and more complicated structures, computer simulations of field-ion images are very useful for obtaining the crystal structure.

The field-ion microscope is a point-projection microscope and therefore has a magnification given by

$$M=D/\beta r, \tag{4}$$

where D is the tip-to-screen distance, r is the tip radius, and β is an image compression factor that accounts for the fact that the electric field lines do not follow exactly the radial direction from the tip to the screen (the field lines are compressed by the presence of the tip shank). The value of β typically is in the range from 1.5 to 1.8. Thus, a magnification of several million is obtained from a tip with a radius of curvature of a few tens of nm. Because the ions are generated very close to the tip surface, there is no relative motion of the surface with respect to the beam of field ions. As a result, external vibrations are not magnified as in conventional electron microscopes or scanning tunneling microscopes and means to isolate the system from such vibrations are not required.

The resolution of the field-ion microscope is determined by three factors: the spatial extent of the region above the protruding surface atom where ionization occurs, the lateral velocity component of the emerging ions, and diffraction effects due to the finite de Broglie wavelengths of the field ions. The spatial extent of the ionization zone is defined by the overlap region of the protruding surface atom and imaging gas atom. The lateral velocity component of the field ions and the diffraction effects have been calculated, and an expression for the overall resolution has been derived (see, for example, Müller and Tsong, 1969; Miller and Smith, 1989; Tsong, 1990). From this expression it has been found that the resolution of the field-ion microscope improves with increasing field strength, decreasing temperature, and decreasing tip radius. On the basis of these criteria, He is the best choice for an imaging gas because it has the highest ionization field and can be used at low temperatures without condensation onto the sample surface. However, as discussed below, many materials cannot withstand the high fields required for imaging in He.

The processes of field evaporation and field desorption are used routinely in field-ion microscopy to obtain the smooth, nearly hemispherical end forms required to obtain images like the one in Fig. 4. When one first views a sample in the field-ion microscope, there are usually asperities, crystallographic irregularities, oxides, and other surface contaminants left from the electrochemical etching process. With increasing field, the surface contaminants are field desorbed and the asperities and irregularities are removed by field evaporation. Once a smooth end form is obtained, the field-evaporation process proceeds in a uniform fashion. Atoms in the vicinity of the low-index planes are removed from the edge of the plane inward, one atomic layer at a time. Thus, it is possible both to clean the surface and to probe into the bulk of the sample with the use of field desorption and evaporation.

The field strength at which the sharpest image is produced in the field-ion microscope is known as the best image field. In order to obtain stable images, the evaporation field of the material under investigation must be higher than the best image field. Although somewhat subjective, the best image fields for the common imaging gases are generally agreed to be 44 V/nm for He, 37 V/nm for Ne, and 22 V/nm for H_2 and Ar. It has been found that only the most refractory metals have evaporation fields higher than the 44 V/nm required for imaging in He. Many other materials are suitable for imaging in Ne or Ar, but the heavier ions have a much lower efficiency for exciting the phosphor of the fluorescent screen.

A major breakthrough in field-ion microscopy came with the development of channel-plate image intensifiers. A channel plate, placed just in front of the fluorescent screen, converts the relatively weak ion image into an intense electron image by an electron multiplication process. The electron image is proximity focused onto the fluorescent screen without loss of resolution. With channel plates it is now possible to apply the technique to almost all metals and alloys, most semiconductors, and even a few exotic materials such as the recently discovered ceramic superconductors.

2.2 Atom-Probe Mass Spectrometer

Except for very special conditions, the field-ion microscope provides an image of the atomic structure only. However, the chemical identity of atoms observed in the field-ion microscope can be determined with a related instrument known as the atom-probe. The atom-probe is a time-of-flight mass spectrometer that analyzes ions generated at the surface of a field-ion tip by field evaporation or desorption. With the atom-probe, field-ion microscope combination, it is possible to image individual atoms on a solid surface, to remove selected atoms in a controlled layer-by-layer fashion, and to determine the chemical identity of the atoms as they are removed. Given these capabilities, it is clear that the atom-probe field-ion microscope is a microanalytical probe unsurpassed in sensitivity.

The first atom-probe was introduced in 1968 (Müller *et al.*, 1968) and is now known as the probe-hole atom-probe or conventional atom-probe. Shown schematically in Fig. 5, the probe-hole atom-probe is a field-ion microscope that has been modified to permit time-of-flight mass analysis of field-desorbed surface atoms. The tip is mounted on a manipulator allowing preselected atoms to be aligned with a small hole in the viewing screen. Surface atoms are removed as positive ions by field desorption. The desorption takes place over a very short interval of time (tens of ns) with the application of a high-voltage (0.5–3.0 kV) pulse to the tip. The tip voltage is added to the dc imaging voltage such that the sum of the two voltages removes surface atoms at a reasonable rate. The ions of interest travel through the probe hole and along a drift tube to a detector sensitive to the impact of individual ions. From the known drift length (l) and measured flight time (t), the mass-to-charge ratios (m/n) of the desorbed ions are determined from the simple expression

$$m/n = (2e/l^2)(V_t + V_p)t^2, \tag{5}$$

where e is the elementary charge and V_t and V_p are the applied dc and pulse voltage, respectively. The mass-to-charge ratio specifies (although sometimes not uniquely) the chemical identity of the desorbed ions.

In most applications the atom-probe is not used to identify individual surface atoms, but rather to probe the composition of a selected volume of the sample material. In this case the probe hole covers an area extending a few nm over the tip surface and the tip is pulsed repetitively. As atoms are removed, the analysis extends into the bulk of the sample. Data obtained in this manner (the ion flight times) may be expressed in several forms. The most common procedure is to plot a simple mass spectrum, i.e., a histogram of the ion signal intensity (the number of ions of a given m/n ratio) versus the m/n ratio. The intensities may be plotted either linearly or logarithmically, the latter having the advantage of emphasizing the low-concentration species. An example of an atom-probe mass spectrum from a $YBa_2Cu_3O_{7-x}$ sample is shown in Fig. 6.

Ion signals may also be plotted as "ladder diagrams" or "cumulative profiles." In these forms of data representation the number of ions of a given mass-to-charge ratio is plotted against the number of ions of a different species (ladder diagram) or the total number

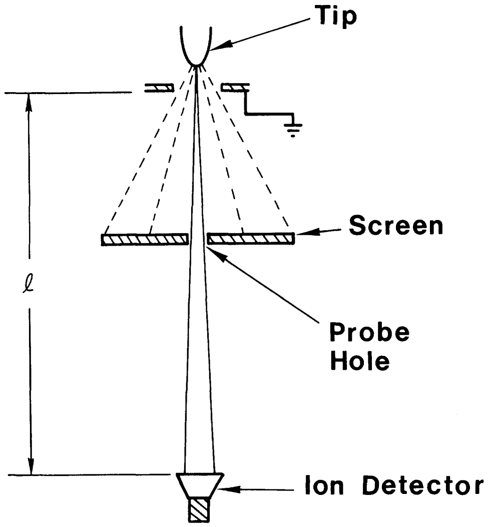

FIG. 5. Schematic diagram of a probe-hole time-of-flight atom-probe field-ion microscope.

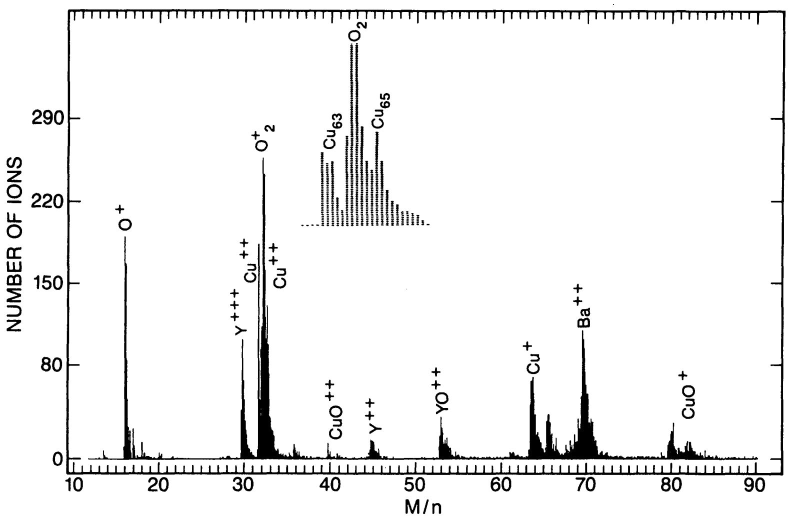

FIG. 6. An example of a time-of-flight mass spectrum taken from a sample of $YBa_2Cu_3O_{7-x}$. [From Kellogg and Brenner (1987).]

of ions detected (cumulative profile). The slopes of these plots can be used as a quick visual aid to determine how the concentration of a given species varies with respect to another species or with all species through the probed region. An example of a ladder diagram from atom-probe analysis of an oxidized Rh sample is shown in Fig. 7.

The probe-hole atom-probe described above has two major limitations. The first is its mass resolution, which is limited primarily by the energy spread of the ions as they enter the drift region. The energy spread arises from premature field desorption (ions that are desorbed before the voltage pulse reaches its maximum value). The resolution of the conventional atom probe is typically $M/\Delta M \sim 250$. The second limitation is the small extent of the probe area over which ions are collected. These restrictions have led researchers to develop a number of variations of the original atom-probe design.

One way to improve the mass resolution of the atom-probe is to use a magnetic-sector (instead of a time-of-flight) mass spectrometer to analyze the desorbed ions. An instru-

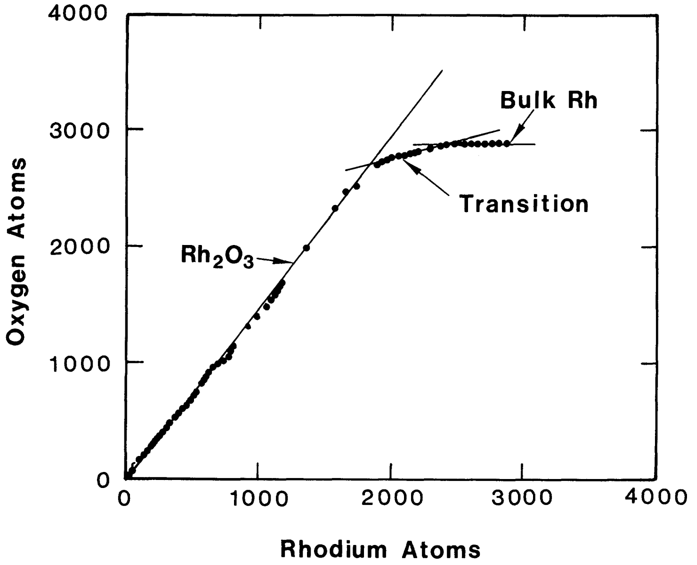

FIG. 7. An example of a ladder diagram resulting from atom-probe analysis of an oxidized rhodium tip. [From Kellogg (1987b).]

ment based on this concept was developed by Barofski and Müller (1968) and improved by Müller and Sakurai (1974). Although the resolution ($M/\Delta M \sim 2000$) is much better than that of the conventional probe-hole atom-probe, the magnetic-sector instrument suffers from a narrow mass range and low transmission coefficient. As a result, it has seen only limited application.

A more common way to improve the mass resolution of the conventional atom-probe is to replace the straight drift tube with an energy-compensating lens (Müller and Krishnaswami, 1974). The lens system used in most atom-probes is based on a 163° sector design developed for other applications by Poschenrieder (1971). The mass resolution of the energy-compensated atom-probe is better than $M/\Delta M = 2000$. This system also has the advantage that noise signals from the background imaging gas are filtered out and accurate elemental analysis can be carried out while viewing the field-ion microscope image. The energy-compensated atom-probe is the state-of-the-art system for applications in metallurgy and materials science.

A third method to improve the mass resolution of the atom-probe is to eliminate the high-voltage pulse entirely and replace it with a dc voltage and a short-duration laser pulse. In the pulsed-laser atom-probe, the dc voltage is set below the evaporation field of the material, and the thermal stimulation provided by the laser pulse initiates the field-evaporation process. Time-of-flight mass analysis is carried out the same as in the conventional atom-probe. With the use of laser pulses, the kinetic energy spread of the desorbed ions is negligible. Although the first pulsed-laser atom-probe systems, introduced independently by Kellogg and Tsong (1980) and Drachsel *et al.* (1980), were not designed for high mass resolution, subsequent versions with a straight drift-tube configuration were able to achieve mass resolution better than even the energy-compensated atom-probe (Tsong *et al.*, 1982). The pulsed-laser atom-probe has the additional advantage of being able to analyze materials whose electrical resistivity is too high to transmit the nanosecond pulses in the voltage-pulsed atom-probe. This capability has greatly facilitated atom-probe investigations of semiconductor materials. The ability to induce desorption at lower field strengths has also stimulated investigations of surface chemical reactions with the pulsed-laser technique. A general review of the pulsed-laser atom probe technique and its applications has been given by Kellogg (1987a).

In all of the atom-probe designs mentioned above, the diameter of the probed area on the surface is just a few nm. This design is particularly well suited for the study of impurities at lattice defects, etc., but poses a limitation for adsorption studies because the total number of ions collected is very small. This limitation can be addressed with the use of the imaging atom-probe (Panitz, 1973). In this design the viewing screen of the field-ion microscope is replaced with a set of channel-plate ion detectors. By stacking two plates in series, the impact of individual ions may be detected. The drift region in this system is the tip-to-screen region, i.e., there is no separate drift tube. Ions desorbed from anywhere within the imaged area of the surface produce both a current signal that can be used for time-of-flight mass analysis and an image spot on the screen. The imaging feature of this atom-probe makes it possible to obtain elemental maps of selected surface species. The association of a given chemical species with a specific structural feature or defect is easily seen in these elemental maps. However, the shorter flight path imposes an inherent mass resolution of $M/\Delta M < 100$.

Elemental maps may also be obtained with the position-sensitive atom-probe developed by Cerezo *et al.* (1988). As with the imaging atom-probe, ions are collected from the entire imaged area of the surface (no probe hole). However, instead of a fluorescent screen behind the image intensifier, this instrument uses a position-sensitive anode (wedge-and-strip) to record the arrival of ions. If the desorption rate is maintained at less than one ion per pulse, the chemical identity and position of each ion arriving at the detector can be determined and stored in a computer. After field evaporation through the near-surface region, a three-dimensional map of each element in the analyzed volume can be reconstructed from the stored data.

In general, the choice of a particular atom-probe design is based on its intended application. The conventional (probe-hole) and energy-compensated designs are used most often in metallurgical applications. The ability to carry out chemical analysis in a highly localized region of the sample makes the atom-probe an ideal instrument to investigate impurity segregation to defects, precipitate formation in alloys, and other atomic-level phenomena. The imaging atom-probe is better suited to investigations of adsorption and surface reaction processes than the probe-hole instruments, but has seen applications in both areas. The pulsed-laser atom-probe is used for semiconductor studies and also adsorption studies where the ability to vary the electric field over a wide range is important. The position-sensitive atom-probe is a relatively new instrument, but should develop into a useful tool for investigations of a wide range of problems in metallurgy and materials science.

3. APPLICATIONS OF THE FIELD-ION MICROSCOPE AND ATOM-PROBE

3.1 Surface Science

The most impressive feature of the field-ion microscope is its ability to obtain beautiful, atomically resolved images of metal surfaces. It would seem therefore, that an obvious application of the instrument would be the determination of surface atomic structure. Since the bulk structure for the common metals examined in field-ion microscopy is known from x-ray diffraction, the field-ion microscope should be able to determine if the surface atomic structure is a simple termination of the bulk structure or if the surface atoms are displaced from their bulk positions. A surface whose atomic structure differs from the bulk-terminated structure is said to be "reconstructed." Unfortunately, for many of the surface planes of interest (primarily atomically smooth planes having low Miller indices), the interior atoms are not resolved and no information on atomic structure is available. Even for those crystal planes that are fully resolved, there is a concern that the applied electric field may have an influence on the atomic structure, and the imaged positions of the atoms may not reflect the true positions of the surface atoms under equilibrium conditions. As a result, the field-ion microscope has not seen widespread application over the years as a probe of surface atomic structure.

Within the past several years, however, researchers have begun to investigate certain types of surface reconstructions with the field-ion microscope. The uncertainty with respect to the electric field mentioned above is alleviated by studying systems for which the reconstructed surface is energetically very stable and transformations from the bulk-terminated to the reconstructed atomic structure can be observed. An example is the (110) surface of Pt. Field evaporation at low temperatures (77 K or less) produces the bulk-terminated structure, which, in the case of an fcc (110) plane, is a periodic array of close-packed atomic rows. The bulk-terminated structure is stable only at these very low temperatures. Upon heating to room temperature (or above) in the absence of any applied fields, the surface atoms rearrange to form the equilibrium structure. This structure can be "frozen in" by quenching the surface back to 77 K or less. For the Pt(110) plane, imaging with the field-ion microscope reveals that the equilibrium surface structure is the so-called missing-row reconstruction, in which every other close-packed row of atoms is absent (Kellogg, 1985a). This observation confirms atomic models of the reconstruction of macroscopic Pt(110) surfaces based on low-energy electron-diffraction and ion-scattering studies. Moreover, the results demonstrate that such reconstructions exist even for very small clusters of atoms (as few as five) and involve very short-ranged atomic interactions. Field-ion microscopy has been used subsequently for similar studies of reconstructions on other surfaces. The results of these investigations are reviewed in detail in Chap. 4 of the recent book by Tsong (1990).

An area of surface science where the field-ion microscope has seen much more extensive application is the investigation of the diffusion and clustering of individual atoms on top of perfectly ordered solid surfaces. In surface diffusion studies, the movement of a single atom on a perfectly ordered surface is tracked as a function of time and temperature. As an example, Fig. 8 shows snapshots of a nickel atom as it moves around on the (110) surface of tungsten. In studies of atomic interactions, the motion of two or more atoms is examined. Pioneered by Ehrlich in the mid-1960s (Ehrlich and Hudda, 1966), field-ion microscope studies have provided diffusion parameters and interaction energies for a large number of atom-surface combinations. Although atomic resolution has been achieved with other techniques, the field-ion micro-

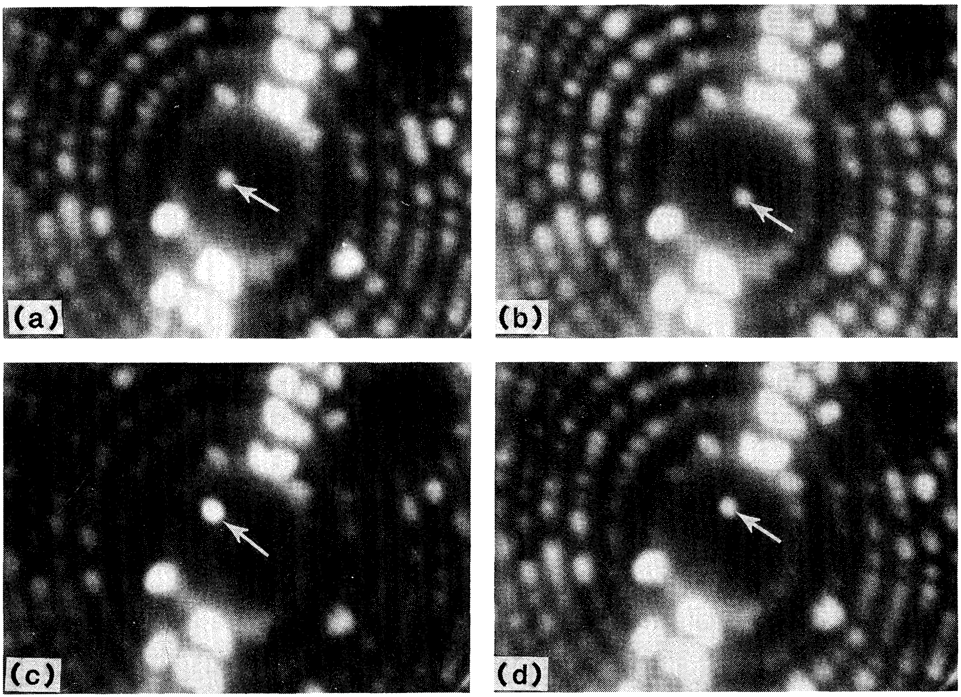

FIG. 8. Field-ion micrographs showing the migration of a nickel atom on the (110) plane of tungsten. The images were recorded with the tip at 77 K. Between each micrograph the tip was heated to a temperature of 200 K for 1 min. The arrow points to the nickel atom, which performs a two-dimensional random walk. [From Kellogg (1987c).]

paralleled in its ability to obtain quantitative data on the diffusion and interaction of individual atoms on surfaces. Field-ion microscope studies of surface diffusion and atomic interactions have been reviewed in articles by Kellogg *et al.* (1978), Ehrlich and Stolt (1980), Bassett (1983), and Tsong (1988, 1990).

A surprising discovery that has resulted from field-ion microscope investigations of single-atom surface diffusion is that the migration of single atoms on certain surfaces does not take place by the site-to-site hopping process one would expect intuitively. Instead, the atom migrates by a series of exchange displacements with atoms in the top layer of the substrate. First observed on the grooved (110) surfaces of Pt (Bassett and Webber, 1978) and Ir (Wrigley and Ehrlich, 1980), exchange displacements have recently been shown to occur on the smooth (100) surfaces of these same metals (Kellogg and Feibelman, 1990; Chen and Tsong, 1990). The exchange mechanism on the fcc (100) surfaces is deduced from maps of the sites visited by the migrating atom. Diffusion by the exchange process produces different maps than does diffusion by ordinary hopping. The exchange-diffusion mechanism has important implications in various crystal and epitaxial growth processes.

The investigation of small clusters of atoms with the field-ion microscope has also provided fundamental insight concerning the interaction of atoms at surfaces. Especially noteworthy is the finding that atomic interactions cannot be modeled by simple pairwise interactions. This discovery is clearly demonstrated by the observation that Re atoms on the W(110) surface do not form stable two-atom clusters, but readily form stable three-atom clusters (Fink and Ehrlich, 1984). Three-body or higher-order interactions are required to explain this observation. Many-body interactions are also needed to explain the stability of atomic configurations observed in cluster nuclei on the (100) surfaces of Ir and Pt (Schwoebel and Kellogg, 1988; Schwoebel *et al.*, 1989). On Pt(100), for example, field-ion microscopic observations show that the stable configuration oscillates between a linear chain and a two-dimensional island as the number of atoms in the cluster is increased of atoms in the cluster is increased from three to six. Theoretical calculations indicate that up to four-body interactions are needed to explain this observation (Schwoebel *et al.*, 1989).

The chemical analytical capabilities of the atom-probe mass spectrometer have extended applications of the field-ion microscope to other areas of surface science. One example is surface segregation in metal alloy systems. Often it is found that under equilibrium conditions the surface and near-surface layers of an alloy are enriched or depleted in one of the alloy components. With the atom-probe field-ion microscope and controlled field evaporation, it is possible to obtain composition profiles with single-atomic-layer depth resolution. Investigations by Tsong and co-workers have shown that in certain alloy systems the concentration of the segregant changes from enrichment to depletion upon removal of successive layers of surface atoms (Tsong *et al.*, 1978; Ng *et al.*, 1979). The atomic-layer depth resolution of the atom-probe is essential to observe this behavior experimentally.

The atom-probe and field-ion microscope have also been used to investigate the reaction of gas-phase adsorbates on metal surfaces. Information on surface morphological and compositional changes induced by various reaction processes including surface oxidation have been obtained in studies with the field-ion microscope and atom-probe, respectively. For example, in one such study the inhibition of the CO oxidation reaction on Rh by the formation of a surface oxide was clearly demonstrated (Kellogg, 1985b). Detailed studies of the kinetics of several reaction processes have been carried out with a pulsed field-desorption technique developed by Block and co-workers (Block *et al.*, 1986). Field-ion–related techniques are particularly attractive for the study of surface reactions related to catalysis because the analyzed area of a field-emitter tip is quite similar to the surface of commercial catalyst particles.

3.2 Metallurgy and Materials Science

Although the field-ion microscope and atom-probe are considered surface-sensitive probes, the ability to field evaporate into the bulk of the sample has led to numerous investigations of problems in physical metallurgy. A few examples of applications in this area are mentioned in the following paragraphs. For more extensive discussions of these applications, the reader is referred to a review by Brenner (1978) and books by Hren and Ranganathan (1968), Müller and Tsong (1969), Bowkett and Smith (1970), Miller and Smith (1980), and Tsong (1990).

One obvious metallurgical application of the field-ion microscope is the investigation of structural defects in pure metals. Point defects (vacancies and interstitials), which are beyond the resolution of conventional electron microscopes, are easily detected in the field-ion microscope. As early as 1959, the field-ion microscope was used to examine the thermal vacancy concentration in an annealed Pt wire (Müller, 1959). Line and planar defects (dislocations, stacking faults, twin boundaries, etc.) have also been investigated extensively with the field-ion microscope (Bowkett and Smith, 1970). In addition, the field-ion microscope has made significant contributions to our understanding of interface structures in metals. A particularly noteworthy accomplishment in this area was the clarification of the structure of high-angle grain boundaries (Müller, 1963; Brandon *et al.*, 1964).

A considerable amount of field-ion microscope research has been carried out related to the crystal and defect structure of ordered alloys. The early work in this field was directed towards image interpretation. In certain alloy materials it was discovered that only one of the constituent elements produced image spots in the field-ion microscope. Although it caused some confusion at first, this phenomenon proved to be useful to examine defect structures. Later, field-ion microscope studies provided valuable information concerning disorder-order transitions in platinum-cobalt (Tsong and Müller, 1966), nickel-molybdenum (Yamamoto *et al.*, 1974) and nickel-iron (Taunt and Ralph, 1975) alloys.

The field-ion microscope and atom-probe have made significant contributions to our understanding of decomposition processes in metal alloys. Precipitate formation in various Fe-, Al-, and Ni-based alloys has been a fruitful area of investigation. The techniques are particularly suited to the study of precipitates smaller than ~10 nm. In some alloy systems small precipitates image very clearly in the field-ion microscope and their number and size distributions are easily obtained. In other systems this information must be inferred from statistical analysis of atom-probe data. Composition modulations in spinodally decomposed alloys have also been investigated in atomic detail with the field-ion microscope and atom-probe. Extensive references to the original work in precipitation and other alloy decomposition processes can be found in the reviews cited above.

Another important application of field-ion microscopy has been the investigation of radiation damage induced by the bombardment of various forms of energetic particles. For example, studies by Seidman and co-workers (Seidman, 1978) have provided detailed information concerning the range profile of the impinging particles, the extent and structure of depleted zones, the type and size distributions of defects, and the removal of these defects by thermal processing.

In recent years materials science applications of the field-ion microscope and atom-probe have gone beyond studies of metals and alloys and now include semiconductor materials. Detailed investigations of metal-silicide interfaces were first reported by Nishikawa *et al.* (1983), and many similar studies of silicon-metal and compound semiconductor-metal interfaces have followed. The atom-probe is shown to be ideally suited for the investigation of compositional variations across the interface with single-atom-layer depth resolution. Studies of semiconductors are not confined to metal-semiconductor interfaces. For example, three-dimensional composition maps, compiled from analysis with the position-sensitive atom-probe, have been obtained from GaInGa/InP quantum-well heterostructures (Liddle *et al.*, 1989).

3.3 Novel Materials and Special Applications

The field-ion microscope and atom-probe have been used in the analysis of some very interesting and "novel" materials. For example, the atomic structure of the icosohedral alloy Al–12% Mn was investigated by Melmed and Klein (1986). The results indicate that there is long-range icosohedral order and that the fivefold symmetry is not due to microtwinning. Attempts to examine amorphous alloys (metallic glasses) have also been reported (Jacobaeus *et al.*, 1980; Piller and Haasen, 1982). As in the case of ordered alloys, it is found that some of the component atoms do not produce image spots, which makes quantitative structural determinations difficult. More recently, field-ion microscopy has been used to investigate the structure of high-T_c superconducting ceramic oxides (Kellogg and Brenner, 1987; Melmed *et al.*, 1988). Interesting patterns consisting of parallel rows of atoms are observed in the field-ion images, and atom-probe analysis yields a composition fairly consistent with the known stoichiometry of the material. Field-ion–related techniques have been developed to examine the morphology of biological molecules deposited on a metal surface (Panitz, 1982). Quasi three-dimensional images of several biological molecules (e.g., ferritin) deposited on a tungsten surface have been obtained with benzene as the imaging gas. The field-ion microscope and atom-probe have also been involved in the development of field emission, field-ion, and liquid-metal ion sources. Although these developments have considerable technological interest, a discussion of field-electron and ion sources is beyond the scope of this article.

4. SUMMARY

Over the past 40 years, the field-ion microscope has grown from a curiosity instrument capable of resolving the surface atoms of a few refractory metals under very special conditions to a basic research tool with widespread applications in the areas of surface and materials science. This growth is due, in part, to numerous advancements in the instrumentation associated with the field-ion microscope. Certainly, the ability to conduct chemical analysis with the atom-probe and its many variations has contributed to the widespread materials applications of the technique. In recent years, the development of new techniques with atomic resolution such as the high-resolution electron microscope and scanning tunneling microscope have rekindled an interest in viewing matter at the atomic level. This interest combined with an ever-increasing drive to fabricate new materials with unique and tailorable properties by manipulating matter at the atomic level should provide a long-range incentive for continued fundamental and applied research with the field-ion microscope and related instruments.

GLOSSARY

Atom-Probe: A field-ion microscope combined with a time-of-flight mass spectrometer, used to determine the chemical identity of ions generated at the surface of an emitter tip.

Channel Plate: A device placed in front of the fluorescent screen in a field-ion microscope used to convert the relatively weak ion image into an intense electron image by a process of electron multiplication.

Critical Distance of Field Ionization: The shortest distance from a surface for which field ionization may occur. Within this distance, the uppermost ionization level of the gas atom or molecule falls below the Fermi energy of the surface and tunneling is forbidden.

Energy-Compensated Atom-Probe: A variation of the time-of-flight atom-probe in which a electrostatic lens is used to improve mass resolution by compensating for the distribution in the initial kinetic energies of field desorbed ions.

Field Adsorption: The binding of gas atoms or molecules (usually inert-gas atoms) to a solid surface induced by the presence of a high electric field.

Field Desorption: The removal of atoms or molecules from a surface as ions by the application of a high electric field.

Field-Electron Microscope: An instrument in which a negative voltage is applied to an emitter tip to eject electrons and form an image on a fluorescent screen. Unable to achieve atomic resolution, the field-electron microscope was the predecessor to the field-ion microscope.

Field Evaporation: A special case of field desorption in which atoms of the emitter material itself are removed by a high electric field.

Field-Ion Microscope: An instrument in which the field-ionization process is used to obtain atomic-resolution images of solid surfaces.

Field Ionization: The ionization of gas atoms or molecules in a high electric field by an electron tunneling process.

Imaging Gas: A gas (usually inert) admitted to a field-ion microscope to produce the image. The gas atoms are ionized above the tip surface and accelerated to an imaging detector.

Imaging Atom-Probe: A variation of the time-of-flight atom-probe in which a large-area, imaging, single-ion detector is used to obtain elemental maps of preselected atomic or molecular species.

Magnetic-Sector Atom-Probe: An atom-probe that uses a magnetic-sector mass spectrometer to determine the identity of field desorbed ions or molecules.

Position-Sensitive Atom-Probe: A variation of the time-of-flight atom-probe in which the identity and spatial location of each atom removed is recorded. Full three-dimensional reconstructions of the removed material are obtained with this instrument.

Pulsed-Laser Atom-Probe: A variation of the time-of-flight atom-probe in which ions are generated by the combination of a dc electric field and a short-duration laser pulse. It is used to examine low-conductivity materials and to investigate field-desorption phenomena as a function of electric field.

Thermal Accommodation: The loss of kinetic energy of impinging gas-phase atoms by successive hops across a cryogenically cooled sample surface. The spatial resolution of the field-ion microscope is greatly improved by this process.

Tip: A sharply pointed wire sample or whisker whose apex surface is examined in the field-ion microscope and atom-probe.

INTRODUCTION AND SCOPE

Fluid dynamics is a continuum science that deals with a sufficient number of molecules so that meaningful averages of density, mass-averaged velocity, internal energy, pressure, temperature, and so forth may be formed. A fluid dynamic event must have length and time scales large enough to conceptually form these averages.

It is a tacit assumption that if we subtract the average velocity from each molecular velocity, the remaining random components will still have a Maxwellian distribution. This

means that equilibrium thermodynamics prevails locally. In cases where rarefied gases are involved this assumption is sometimes modified.

1. SIMPLE COMPRESSIBLE SUBSTANCE

A simple compressible substance is a fluid that receives reversible work only from pressure forces. This article will deal only with fluids of this type. The thermodynamics of a simple compressible substance is completely described by two equations of state: a pressure-density-temperature relation and a specific-heat function of density and temperature (see THERMODYNAMICS, EQUILIBRIUM). Thus fluids with anisotropic structure or electrical and magnetic properties are excluded. Occasionally liquids are characterized as incompressible substances. Then density and pressure are no longer thermodynamic variables, and one equation of state for the specific heat as a function of temperature describes the liquid. Transport laws for the molecular migration of chemical species, momentum, or internal energy contain coefficients that depend on the thermodynamic state. These coefficients, namely the diffusion coefficients, viscosity, and thermal conductivity, are in this sense thermodynamic properties of the fluid.

If a shear stress is applied to a fluid it continues to deform as long as the stress is applied. On the other hand, application of a shear stress to a solid produces only a small strain that generates internal forces which resist the force and produce an equilibrium. Removal of the force in a perfectly elastic solid recovers the energy used to deform the solid. On the other hand, the shearing work in a fluid cannot be recovered and becomes random molecular motion in the form of internal energy. In fluid mechanics, solids are frequently idealized as rigid objects.

2. KINEMATICS

The *Eulerian* viewpoint is to analyze fluid flows from a fixed coordinate system where properties are functions of position $\mathbf{x}$ and time t. The *substantial* or *material derivative*, first introduced by Stokes, is defined as

$$\frac{D(\ )}{Dt}=\frac{\partial(\ )}{\partial t}+\mathbf{v}\cdot\nabla(\ ). \tag{1}$$

As applied to an Eulerian function this derivative has the interpretation of the rate of change as one moves along with a fluid particle. If $\mathbf{r}$ is the position vector of a material particle, $D\mathbf{r}/Dt=\mathbf{v}$ is the velocity and $D\mathbf{v}/Dt=\mathbf{a}$ is the acceleration. Consider two neighboring material particles P and P', separated by an increment $\delta\mathbf{r}$, and imagine following the motion of P' relative to P. Then the material derivative of $\delta\mathbf{r}$ is the difference in their velocities,

$$\frac{D(\delta\mathbf{r})}{Dt}=d\mathbf{v}=\delta\mathbf{r}\cdot\nabla\mathbf{v}. \tag{2}$$

Using definitions below and tensor identities, Eq. (2) can be changed into

$$\frac{D(\delta\mathbf{r})}{Dt}=\delta\mathbf{r}\cdot\mathbf{S}+\tfrac{1}{2}\boldsymbol{\omega}\times\delta\mathbf{r}. \tag{3}$$

Here, the *strain rate* tensor is defined as

$$\mathbf{S}=\tfrac{1}{2}\nabla\mathbf{v}+\tfrac{1}{2}(\nabla\mathbf{v})^{\mathrm{T}}, \tag{4}$$

and the *vorticity* vector is defined as

$$\boldsymbol{\omega}=\nabla\times\mathbf{v}. \tag{5}$$

The vorticity is equal to twice the solid-body rotation of P' about P while all the deformation motions (both angular and extensional) are produced by $\mathbf{S}$. The trace of $\mathbf{S}$, that is $\nabla\cdot\mathrm{v}$, is the *rate of expansion* of a unit volume. Flow regions where $\boldsymbol{\omega}=\mathbf{0}$ are called *irrotational.*

At any given instant in time *streamlines* are defined as lines that are everywhere parallel to the velocity vectors. Similarly *vortex lines* are at any instant everywhere parallel to the vorticity vectors (the term "line vortex" has a distinctly different use). *Particle path* is the term for the trajectory of a fluid particle of fixed identity. In *steady flow,* a field that is independent of time, the streamlines and the particle paths coincide; otherwise they are distinct.

3. LOCAL CONSERVATION LAWS

3.1 Continuity, Momentum, and Energy

Any flow field is governed by three independent conservation laws. The conservation of mass, usually called the *continuity equation,* governs the density ρ:

$$\frac{1}{\rho}\frac{D\rho}{Dt}=-\nabla\cdot v. \tag{6}$$

The fractional rate of change of density is equal to the rate of expansion.

The *momentum equation* attributes acceleration to pressure forces, viscous forces, and gravity:

$$\rho\frac{D\mathbf{v}}{Dt}=-\nabla p+\nabla\cdot\tau+\rho\mathbf{g}. \tag{7}$$

Here p is the pressure, the viscous stress tensor is τ, and the gravity vector is $\mathbf{g}$.

The total energy equation governs the sum of internal energy e and macroscopic kinetic energy $\frac{1}{2}v^2$:

$$\rho\frac{D}{Dt}(e+\tfrac{1}{2}v^2)$$
$$=-\nabla\cdot q-\nabla\cdot(p\mathbf{v})+\nabla\cdot(\tau\cdot v)+\rho\mathbf{v}\cdot g. \tag{8}$$

Microscopic energy transfer mechanisms that have no discernible force are called heat. The symbol $\mathbf{q}$ is the *heat flux.* Conduction, radiation, and diffusion (in a mixture of chemical species) are in this category. Macroscopic energy transfers are the total work rate (force times velocity) of surface forces and gravity forces. An alternative perspective is to introduce a gravitational potential energy (*gh,* where h is the vertical distance above a reference level and g the magnitude of $\mathbf{g}$) and delete the work of the gravity force $\rho\mathbf{v}\cdot\mathbf{g}$.

3.2 Angular Momentum, Kinetic Energy, and Thermal Energy

If $\mathbf{r}$ is the particle position from an arbitrary origin, the macroscopic *angular momentum* about that origin is $\mathbf{r}\times\mathbf{v}$. An equation governing this quantity can be derived by taking the vector product of $\mathbf{r}$ and the linear momentum equation, Eq. (7). This relation is called the moment-of-momentum equation.

When angular momentum is transported and stored at the molecular level (a preferred orientation of spinning microscopic particles), one must also propose an angular momentum conservation law and provide an angular momentum transport tensor. For such fluids Dahler and Scriven (1961) summarize the results, which include a stress tensor that is not symmetric. This approach is needed only for exotic fluids such as ferromagnetic fluids (iron filings suspended in oil).

Homogeneous isotropic fluids have no net molecular angular momentum; that is, the molecular angular momentum is randomly oriented. In this case comparing the angular momentum conservation law and the moment-of-momentum equation shows that the stress tensor is symmetric and the equations become identical, namely

$$\rho\frac{D(\mathbf{r}\times\mathbf{v})}{Dt}=-\mathbf{r}\times\nabla p+\nabla\cdot(\mathbf{r}\times\tau)+\rho\mathbf{r}\times\mathbf{g}. \tag{9}$$

Thus in fluid dynamics of simple fluids the angular momentum conservation law does not supply an equation that is independent of the linear momentum law.

An equation governing macroscopic kinetic energy is found from the inner produce of $\mathbf{v}$ and the momentum equation. It is

$$\rho\frac{D\frac{1}{2}v^2}{Dt}=-\mathbf{v}\cdot\nabla p+\mathbf{v}\cdot(\nabla\cdot\tau)+\rho\mathbf{v}\cdot g. \tag{10}$$

Here, only a portion of the surface work, the velocity times gradients of surface forces (unbalanced forces), accelerates the fluid to increase the kinetic energy. All of the gravity work appears as kinetic energy while heat transfer never directly produces kinetic energy. Subtracting Eq. (10) from the total energy equation, Eq. (8), yields an equation governing the internal energy:

$$\rho\frac{De}{Dt}=-p\nabla\cdot v+\tau:\nabla\mathbf{v}-\nabla\cdot q. \tag{11}$$

The remaining portion of the surface work, "balanced" forces times deformations, increases the random molecular motions and appears as a source of internal energy. *Compression or expansion work,* $p\nabla\cdot$v, is reversible and *viscous dissipation work,* $\tau:\nabla\mathbf{v}$, is irreversible (because τ is symmetric $\tau:\nabla\mathbf{v}=\tau:\mathbf{S}$). Any net heat flux produces internal energy.

3.3 Temperature and Entropy

A very useful form of the thermal energy equation is derived by employing various thermodynamic relations to arrive at a relation for the temperature T,

$$\rho c_p \frac{DT}{Dt} = \beta T \frac{Dp}{Dt} + \boldsymbol{\tau}:\nabla \mathbf{v} - \nabla \cdot q. \qquad (12)$$

It should be noted that the thermodynamic functions for *specific heat at constant pressure, $c_p(p,T)$*, and *thermal expansion coefficient, $\beta(p,T)$*, are unrestricted.

The second law of thermodynamics for the *entropy s* takes the form

$$\rho \frac{Ds}{Dt} = \frac{1}{T} \boldsymbol{\tau}:\nabla \mathbf{v} - \nabla \cdot \frac{\mathbf{q}}{T} - \frac{1}{T^2} \mathbf{q} \cdot \nabla T. \qquad (13)$$

Any viscosity law relating $\boldsymbol{\tau}$ and $\nabla \mathbf{v}$ must have a form that always gives a positive contribution to increase the entropy. The heat-transport terms have been written in a form that displays a reversible effect and an irreversible effect. If the reversible effect is integrated over a volume of interest and Gauss's divergence theorem applied, it becomes a boundary effect of heat flux divided by temperature. Without local viscous dissipation and heat transport, a flow becomes isentropic.

4. GLOBAL CONSERVATION LAWS

Any local law or relation for an arbitrary quantity f that contains a rate of change $\partial f/\partial t$ may be expressed in a global (or integral) form. Consider a finite region of volume V and surface S with outward unit normal $\mathbf{n}$ and an arbitrarily specified surface velocity $\mathbf{w}$. For continuous f, Leibnitz's theorem of calculus gives a relation for the rate of change of the total integrated value of f,

$$\frac{d}{dt} \int f \, dV = \int \frac{\partial f}{\partial t} dV + \int \mathbf{n} \cdot w \, f \, dS. \qquad (14)$$

In order to derive a global law one substitutes the local law for $\partial f/\partial t$; then Gauss's divergence theorem is used to convert as many volume integrals as possible to surface integrals.

4.1 Continuity, Momentum, and Energy

Taking f as the density and employing the continuity equation [Eq. (6)] yields

$$\frac{d}{dt} \int \rho \, dV = - \int \mathbf{n} \cdot (\mathbf{v} - \mathbf{w}) \rho \, dS. \qquad (15)$$

The mass within a region increases because of the mass flux from the relative velocity $\mathbf{n} \cdot (\mathbf{v} - \mathbf{w})$ normal to the moving surface.

The global momentum equation is found by taking f as $\rho \mathbf{v}$ and using Eq. (7):

$$\frac{d}{dt} \int \rho \mathbf{v} \, dV = - \int [\mathbf{n} \cdot (\mathbf{v} - \mathbf{w}) \rho \mathbf{v} + \mathbf{n} p - \mathbf{n} \cdot \boldsymbol{\tau}] dS + \int \rho \mathbf{g} \, dV. \qquad (16)$$

The body force of gravity may be converted to a surface integral, $\rho \mathbf{g} = -\nabla (g \rho h)$, if the flow is incompressible.

The total energy equation, with $E = e + \frac{1}{2} v^2 + gh$, for a region in arbitrary motion is similarly found employing Eq. (8):

$$\frac{d}{dt} \int \rho E \, dV = - \int [\mathbf{n} \cdot (\mathbf{v} - \mathbf{w}) \rho E - \mathbf{n} \cdot \boldsymbol{\tau} \cdot v + \mathbf{n} \cdot v p + \mathbf{n} \cdot \mathbf{q}] dS. \qquad (17)$$

In practical applications, the work of the pressure forces is sometimes represented by two effects as follows:

$$\int \mathbf{n} \cdot v p \, dS = \int [\mathbf{n} \cdot (\mathbf{v} - \mathbf{w}) \rho (p/\rho) + \mathbf{n} \cdot w p] dS. \qquad (18)$$

The first term is called *flow work* and the second the *moving boundary work*. The advantage of this form is that the flow work can be combined with convection of internal energy by introducing the enthalpy $h = e + p/\rho$.

It is also possible to write a global mechanical energy equation. It is

$$\frac{d}{dt} \int \rho \tfrac{1}{2} v^2 dV = - \int [\mathbf{n} \cdot (\mathbf{v} - \mathbf{w}) \rho \tfrac{1}{2} v^2 - \mathbf{n} \cdot \boldsymbol{\tau} \cdot v + \mathbf{n} \cdot v p] dS + \int [\mathbf{n} \cdot g \rho - \boldsymbol{\tau}:\nabla \mathbf{v} + p \nabla \cdot v] dV. \qquad (19)$$

Several practical results derive from this equation [for example, see Eqs. (46) and (89)].

5. INTERFACES

Surfaces where the density is discontinuous characterize not only fluid-solid interfaces, liquid-liquid interfaces, and liquid-gas interfaces, but also shock and combustion waves. In situations with several chemical species it may be necessary to envision that an interface contains absorbed mass; however, pure substances can usually be dealt with assuming that no mass, momentum, or energy is associated with the surface.

5.1 No-Slip Condition

The translational mobility of fluid molecules allows them to interact with neighboring fluid elements. This is the microscopic origin of viscous action, and because of this molecular migration we do not allow discontinuities in tangential velocity at an interface within a fluid. Similarly, at an interface between a fluid and a solid wall, molecules enter the interface and interact with molecules from the wall. After "collision" they return to the bulk fluid with a tangential velocity nearly that of the wall. A kinetic theory model for a gas and a solid wall shows that the tangential gas velocity at the interface differs from the wall velocity by a slip velocity u_s given by

$$\frac{u_s}{U}=\frac{c\lambda}{L}\frac{d(u/U)}{d(n/L)}. \tag{20}$$

Here $u(n)$ is the velocity profile, n is the normal direction, U and L are the characteristic scales of the continuum motion that normalize $u(n)$, c is a constant of order one, and λ is the mean free path. The approximation $u_s=0$ is thus very accurate when the mean free path is small compared to the continuum length, that is, λ/L is small. Indeed, the first approximation in the field of *rarefied gas dynamics* is to use continuum equations with the slip boundary condition above.

The extension of this argument to a fluid-fluid interface produces the result that the tangential component of the velocity is continuous across the interface.

5.2 Jump Conditions

By postulating that mass, momentum, and energy cannot be stored within an interface, it is possible to derive jump conditions that relate variables on either side of a plane interface. Brackets indicate that the quantity is evaluated on either side, and the interface is regarded as stationary. From the mass equation we get

$$[\rho\mathbf{n}\cdot\nu]_{\mathrm{I}}-[\rho\mathbf{n}\cdot\nu]_{\mathrm{II}}=0. \tag{21}$$

Without mass flow across the interface the normal velocity at the interface is zero. The normal momentum relation gives

$$[\rho(\mathbf{n}\cdot\nu)^2-p+\mathbf{n}\cdot(\mathbf{n}\cdot\tau)]_{\mathrm{I}}-[\rho(\mathbf{n}\cdot\nu)^2-p+\mathbf{n}\cdot(\mathbf{n}\cdot\tau)]_{\mathrm{II}}=0. \tag{22}$$

Tangential momentum and the assumption of continuity of the tangential velocity component (no-slip) show that the tangential viscous stress is continuous,

$$[\mathbf{n}\times(\mathbf{n}\cdot\tau)]_{\mathrm{I}}-[\mathbf{n}\times(\mathbf{n}\cdot\tau)]_{\mathrm{II}}=0. \tag{23}$$

Energy conservation results in

$$[\rho\mathbf{n}\cdot\nu(h+\tfrac{1}{2}\nu^2)-\mathbf{n}\cdot q]_{\mathrm{I}}-[\rho\mathbf{n}\cdot\nu(h+\tfrac{1}{2}\nu^2)-\mathbf{n}\cdot q]_{\mathrm{II}}=0. \tag{24}$$

Continuity of the heat flux across the wall is required if there is no mass transfer.

5.3 Surface Tension and Continuum Properties

If a surface is highly curved the simple model above is invalid, and it is necessary to propose a *surface tension* (surface energy). The surface tension coefficient σ relates the pressure change across the surface to the principal radii of curvature, R_1 and R_2:

$$p_{\mathrm{I}}-p_{\mathrm{II}}=\sigma(1/R_1+1/R_2). \tag{25}$$

Although σ is conceptually like a pressure in a two-dimensional world, it is treated as a thermodynamic property of the interface.

6. CONSTITUTIVE EQUATIONS

The microscopic mechanisms to create fluxes of mass, momentum, or energy from a nonuniformity of the appropriate flow property give rise to constitutive relations. Such relationships are not universally valid; however, many chemically simple substances obey linear relations.

6.1 Thermal Conductivity

Fourier's law for heat conduction is linear in the temperature gradient,

$$\mathbf{q} = -\kappa \nabla T. \tag{26}$$

The *thermal conductivity* κ is a thermodynamic property of the material.

6.2 Viscosity

Newton's viscosity law is linear in the rate of expansion and deformation,

$$\tau = \lambda \nabla \cdot v I + 2\mu \mathbf{S}. \tag{27}$$

The coefficients λ (*second viscosity*) and μ (*viscosity*) are thermodynamic properties. The thermodynamic concept of pressure and the mechanical concept of a normal stress are related by Stokes's assumption that the average normal stress is equal to the thermodynamic pressure. This implies that $\lambda = -\frac{2}{3}\mu$. In liquids the viscosity and conductivities decrease with increasing temperature while in gases they increase. Pressure does not have a large effect in either case.

7. NAVIER-STOKES EQUATIONS

This term *Navier-Stokes equations* is applied to the mass, momentum, and thermal energy equations written for a substance obeying Fourier's heat conduction law and Newton's viscosity relation. They are

$$\frac{1}{\rho}\frac{D\rho}{Dt} = -\nabla \cdot v, \tag{28}$$

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p - \tfrac{2}{3}\nabla(\mu \nabla \cdot \mathbf{v}) + 2\nabla \cdot (\mu \mathbf{S}) + \rho \mathbf{g}, \tag{29}$$

$$\rho c_p \frac{DT}{Dt} = \beta T \frac{Dp}{Dt} + \tfrac{2}{3}\mu(\nabla \cdot v)^2 + 2\mu \mathbf{S}{:}\nabla \mathbf{v} + \nabla \cdot (\kappa \nabla T). \tag{30}$$

Another use of the name Navier-Stokes is for the simpler equations that govern an incompressible flow. They will be given below.

8. SCALES AND DIMENSIONAL CONSIDERATIONS

The simplest characterization of a flow occurs when variables are made nondimensional using characteristic scales derived from the specific flow situation of interest. Let the size of the region of interest be characterized by L, the flow speed by U_0, and the fluid reference state by density ρ_0 and temperature T_0 with speed of sound a_0. The proper temperature scale depends on the heat-transfer boundary conditions. In any event, several nondimensional parameters will appear in the equations. The Mach number, Reynolds number, and Froude number refer to dynamics:

$$M = U_0/a_0, \quad Re = \rho U_0 L/\mu_0, \quad Fr = U_0^2/gL. \tag{31}$$

Other nondimensional thermodynamic parameters express the ratio of specific heats ($\gamma = c_{p0}/c_{v0}$, where the specific heat at constant volume is c_v), the isothermal compressibility ($\alpha^* = \alpha_0 \rho_0 c_{p0} T_0$), the thermal expansion coefficient ($\beta^* = \beta_0 T_0$), and the Prandtl number ($Pr = \mu_0 c_{p0}/\kappa_0$). As a first approach to classifying flows it is appropriate to let the thermodynamic parameters be arbitrary and consider different extremes in the dynamic parameters.

9. COMPRESSIBLE FLOWS

Variations in the density must be accounted for in several flow situations. Consider a flow where the fluid undergoes a velocity change U_0 (say from U_0 to complete rest). If the fluid density is ρ_0, the pressure difference needed to cause this velocity change is approximately $\rho_0 U_0^2$. Recognizing that $\Delta p/\Delta\rho = a_0^2$ for a reversible process, we can estimate the percentage of density change as

$$\frac{\Delta\rho}{\rho_0} = \frac{\Delta\rho}{\Delta p}\frac{\Delta p}{\rho_0} = \frac{1}{a_0^2}\frac{\Delta p}{\rho_0} = \frac{1}{a_0^2}\frac{\rho_0 U_0^2}{\rho_0} = \frac{U_0^2}{a_0^2} = M^2. \tag{32}$$

Hence the Mach number is an indicator of compressibility effects from fluid accelerations. To make this point quantitative consider the isentropic (frictionless and without heat conduction) flow of a perfect gas. If the flow is brought to rest at a stagnation point, the pressure change is

$$p_0-p_\infty=\tfrac{1}{2}\rho U_\infty^2[1-\tfrac{1}{4}M^2+O(M^4)]. \qquad (33)$$

This equation shows a 2–3% correction to the incompressible Bernoulli equation for $M \approx 0.3$. The value of $M=0.3$ is often quoted as the limit for incompressible flow; however, the shape of the body can also have an influence. Although the equation above limits the ability to convert inertia to pressure, there is no limit to decreases in pressure by expansion, that is, the conversion of pressure to inertia. The next generation of high-lift wings will have strong expansions of the flow and compressible effects at lower values of M. High-speed compressible flows (see COMPRESSIBLE FLOWS) occur when velocity changes are brought about by strong pressure changes that are accompanied by density changes.

Another type of compressible flow occurs when there is significant energy entering the flow from a wall. The subsequent changes in thermodynamic state cause associated density variations. For example, flow in a natural gas pipeline is compressible even if the initial Mach number is 0.05. This is a "low-speed" compressible flow. "Natural" or "free" convection is another such situation. Here, the characteristic velocity is small and is related to the heat transfer from a hot or cold surface. Acoustics (see ACOUSTICS, LINEAR; ACOUSTICS, NONLINEAR) is another type of compressible flow caused by the rapid normal oscillation of a surface. It is a linear subject for small-amplitude motions.

10. INCOMPRESSIBLE FLOWS

The *incompressible flow* of a general compressible fluid can occur under two major situations. Both are thought of as low–Mach-number limits but with different heat-transfer boundary conditions.

10.1 Adiabatic Walls

When the walls confining the flow are essentially adiabatic, the only mechanism to produce thermal energy is viscous dissipation in regions where velocity gradients exist. Once generated, this energy can be convected by the flow and conducted across temperature gradients. The appropriate temperature scale to measure changes from the reference value is $\mu_0 V_0^2/\kappa_0$. These thermal effects are so weak at low Mach numbers that the flow is nearly isothermal and the density is constant. For $M^2 \to 0$ the appropriate Navier-Stokes equations, Eqs. (28)–(30), simplify to

$$0=\nabla\cdot v, \qquad (34)$$

$$\rho\frac{D\mathbf{v}}{Dt}=-\nabla p+\mu\nabla\cdot\nabla\mathbf{v}+\rho\mathbf{g}, \qquad (35)$$

$$\rho c_p\frac{DT}{Dt}=\beta T\frac{Dp}{Dt}+2\mu\mathbf{S}:\nabla\mathbf{v}+\kappa\nabla^2 T. \qquad (36)$$

Furthermore, as $M^2 \to 0$ the coefficients μ, k, β, and c_p are approximately constant. The continuity and momentum equations are now uncoupled from the energy equation, and the fluid flow can be solved without regard to thermal effects; hence fluid dynamics and heat transfer become separate subjects.

10.2 Isothermal Walls

When the walls containing the flow are purposefully held at a distinctly different temperature than the reference, the thermal energy distribution is dominated by conduction from the walls. Now the proper scale is T_1-T_0, where T_1 is the characteristic wall temperature. In the limit of low Mach number, the continuity and momentum equations, Eqs. (28) and (29), remain the same but the energy equation, Eq. (30), becomes

$$\rho c_p\frac{DT}{Dt}=\nabla\cdot(\kappa\nabla T). \qquad (37)$$

These equations are the "low-speed" compressible equations. The density, specific heat, and transport properties are not constant, and the thermal and mechanical events are coupled. Further simplifications depend upon assumptions about the fluid, such as an incompressible liquid, or flow situation, such as free convection.

Another special case is of major interest and it is an incompressible flow: the case of isothermal walls with a "small" temperature difference, that is $(T_1-T_0)/T_0 \to 0$, and simultaneously a low Mach number. The Navier-Stokes equations [Eqs. (28), (29), and (30)] for this case reduce to

$$0=\nabla\cdot v, \qquad (38)$$

$$\rho\frac{D\mathbf{v}}{Dt}=-\nabla p+\mu\nabla\cdot\nabla\mathbf{v}+\rho\mathbf{g}, \qquad (39)$$

$$\rho c_p \frac{DT}{Dt} = \kappa \nabla^2 T. \tag{40}$$

These equations are the same as those for the adiabatic case except that the temperature equation is simpler. Again the thermodynamic coefficients are constant and the continuity and momentum equations uncoupled from the energy equation. The fluid mechanics of this case and the adiabatic case are the same. The only difference is in the temperature field due to heat-transfer events.

10.3 Characteristics of Incompressible Flows

With appropriate boundary conditions, the continuity and momentum equations yield solutions for the velocity vector and the pressure. The pressure is a mechanical item, as it causes no appreciable change in the thermodynamic state. Indeed, thermodynamics is relevant only in determining values of the coefficients in Eqs. (39) and (40).

Consider the incompressible flow in a region of fixed shape with specified boundary values. In nondimensional variables the flow pattern depends on only two parameters, *Re* and *Fr*. The Reynolds number, $Re = \rho U_0 L/\mu_0$, indicates the inertia effects compared to viscous effects. The Froude number, $Fr = U_0^2/gL$, indicates the importance of inertia and gravity. It is only dynamically significant when the flow is a liquid with a free surface. Then the pressure change across the interface is a boundary condition in the problem.

For a single-phase flow one may introduce h, the distance above a horizontal reference level, as a potential for the gravity force, $\rho \mathbf{g} = \nabla(-\rho g h)$. Let a *modified pressure* be defined by

$$p' \equiv p + \rho g h - p_{\text{ref}}. \tag{41}$$

Now the pressure and gravity forces in the momentum equation, Eq. (35), can be combined as follows:

$$-\nabla p + \rho \mathbf{g} = -\nabla p - \nabla(\rho g h) = \nabla p'. \tag{42}$$

Thus the pressure in a flow without a free surface has a dynamically important part p' and a hydrostatic part with the universal solution $p_{\text{hydro}} = \rho g h - p_{\text{ref}}$. Because pressure is not in a boundary condition, the effect of gravity is to cause a hydrostatic pressure that has no dynamical importance. This also means that the total force on a submerged object consists of a dynamic part (lift and drag) and a buoyancy part. The fact that a fluid is a liquid or a gas is indicated by the value of ρ but nowhere else.

The typical way to express the pressure on a surface is as a *pressure coefficient* that includes the arbitrary reference,

$$C_p \equiv (p - p_{\text{ref}})/\tfrac{1}{2}\rho U_\infty^2. \tag{43}$$

The scale quantity $\frac{1}{2}\rho U_\infty^2$ is called the *dynamic pressure*, and it is the appropriate scale unless the Reynolds number is very low. Similarly the lift or drag force on a body is nondimensionalized by some typical cross-section area times the dynamic pressure $\frac{1}{2}\rho U_\infty^2$.

The equations governing an incompressible flow are invariant under an "unsteady" translational transformation of the coordinate axes: $\mathbf{X} = \mathbf{x} + \int \mathbf{V}(t)\,dt$. The invariance is not complete because the flow, viewed in the transformed coordinates, must be considered to have an additional time-dependent body (gravity) force $\rho d\mathbf{V}/dt$ or, in an alternative viewpoint, a pseudopressure $\pi = p + \rho \mathbf{x} \cdot d\mathbf{V}/dt$ where p is the true pressure in the inertial system.

10.4 Pressure and Vorticity

The pressure field associated with a given flow is governed by an elliptic equation

$$\nabla^2 p = -\rho \nabla \mathbf{v} : \nabla \mathbf{v}. \tag{44}$$

This equation is derived from the inner product of ∇ and Eq. (39). Viscous effects enter indirectly in determining the velocity field.

The vector product of ∇ and Eq. (39) produces an equation governing the vorticity. It is

$$\frac{D\boldsymbol{\omega}}{Dt} = \boldsymbol{\omega} \cdot \nabla \mathbf{v} + \nu \nabla \cdot \nabla \boldsymbol{\omega}. \tag{45}$$

Here the kinematic viscosity $\nu \equiv \mu/\rho$ is employed as a convenient notation. The first two terms in this relation have an analogy with Eq. (2) that describes the lengthening and turning of a material line element $\delta \mathbf{r}$. The analogy is with $\boldsymbol{\omega} \rightarrow \delta \mathbf{r}$. If viscous effects of the last term in Eq. (45) are negligible, then a vortex line, a line parallel to $\boldsymbol{\omega}$ at all points, may be considered as a moving with the fluid particles, and the magnitude of vorticity increases as the line is stretched. The viscous term is a diffusion effect with the same coefficient as the diffusion of momentum. Pressure does not appear because a pressure gradient will always act through the center of mass and cannot engender any solid-body rotation in a particle.

10.5 Mechanical Energy (Engineering Bernoulli Equation)

In many practical situations there is a single fluid stream that enters a device, goes through a process, and then exits. The device might be as simple as a pipe with bends and valves, or as complex as the turbine of a hydroelectric dam. If one considers a uniform flow at both entrance and exit and at least a periodic flow within the device, then the global mechanical energy equation for the device is very simple (for an incompressible flow). It is

$$\left[\frac{p}{\rho}+\tfrac{1}{2}v^2+gh\right]_1-\left[\frac{p}{\rho}+\tfrac{1}{2}v^2+gh\right]_2 =-\frac{dW/dt}{dm/dt}+\frac{\Phi}{dm/dt}. \tag{46}$$

In this equation dW/dt is the work rate of any shaft that crosses the region, dm/dt is the mass flow rate, and Φ is the viscous dissipation integrated over the interior of the region:

$$\Phi\equiv\int\tau\mathbf{:}\nabla\mathbf{v}\;dV=\frac{dm}{dt}\,gh_L. \tag{47}$$

An ideal frictionless flow has $\Phi=0$. The quotient of Φ by the product of the mass flow rate and the acceleration of gravity is called the *head loss* between stations 1 and 2. It has units of length. Sometimes g is included in the definition, that is, $gh_L\rightarrow h_L$ (units of energy per unit mass). The nondimensional form is obtained by dividing by the square of some characteristic velocity, U, and is called the *loss coefficient:*

$$K=gh_L/\tfrac{1}{2}U^2. \tag{48}$$

In pipe flow the loss increases in direct proportion to the length L divided by the diameter D, and this is accounted for by defining a *friction factor* f, so that

$$K_{\text{pipe}}=gh_L/\tfrac{1}{2}U^2=(L/D)f. \tag{49}$$

Loss coefficients are a function of the device geometry, the Reynolds number, and possibly the Froude number.

In many applications the internal flow is at a high Reynolds number and turbulence exists. Turbulence may be thought of as large-scale disorganized velocity fluctuations imposed on a mean flow. Most turbulent energy is in the large-scale fluctuations. However, turbulence flows have processes that reduce the length scales of the turbulent motion to smaller and smaller values until viscosity limits the process. These small-wavelength motions are where the viscous dissipation for the head loss takes place. At very high Reynolds numbers the amount of turbulence produced is independent of the Reynolds number and depends only on the geometry. Likewise the amount of energy proceeding to the small scales becomes independent of the viscosity (Reynolds number). For example, in pipe flow the friction factor at high Reynolds numbers depends only on the ratio of wall roughness height to diameter.

11. SIMPLE LAMINAR FLOWS

A convenient classification of flow situations is internal flows and external flows. In internal flows entrance and exit conditions are specified and walls confine the flow. For external flows a closed body is imagined to be in an infinite fluid that has a uniform velocity at infinity. In many instances we may also isolate a certain part of a flow to discuss a local flow pattern. A brief but thorough review of exact laminar flow solutions may be found in Wang (1989 and 1991).

11.1 Parallel Flows

This situation has one nonzero velocity component that does not vary in the flow direction. The flow is driven by a gradient of the (modified) pressure or by motion of the confining walls. Of course, the confining walls must be parallel. The continuity equation is satisfied identically and the momentum equation, Eq. (35), becomes a linear Poisson equation for $u(y,z)$ with a constant source term,

$$\nabla^2 u = -\frac{1}{\mu}\frac{dp'}{dx}. \tag{50}$$

Since the right-hand side is a constant it becomes the scale for the velocity and the flow is independent of the Reynolds number. As an example the *Poiseuille flow* between stationary parallel plates a distance H apart has the velocity profile

$$u = \frac{H^2}{2\mu}\frac{dp'}{dx}\left[\left(\frac{y}{H}\right) - \left(\frac{y}{H}\right)^2\right]. \tag{51}$$

Solutions for parallel flow in tubes of many cross-section shapes have exact closed-form answers (however, flow in a rectangular tube has only a series-expansion solution).

Couette flow is the name for flow between parallel plates, one stationary and one moving in its own plane at velocity U. This flow is driven by the wall motion, which scales the velocity,

$$u/U = y/H. \tag{52}$$

The linear nature of Eq. (50) means that flows with appropriate boundary conditions, such as the ones above, may be added.

Although these flow solutions are independent of the Reynolds number, they are only observed at low Reynolds numbers. For higher Reynolds numbers they undergo a transition to another flow that has a secondary, nonparallel motion, and/or turbulence.

11.2 Viscous Diffusion

A flow that illustrates the diffusive character of viscous effects is the *Rayleigh problem*. Stokes originally solved this problem; however, Rayleigh used it to estimate the friction drag on a flat plate. Consider a horizontal flat plate with a semi-infinite fluid above it in the y direction. The plate initially at rest is impulsively moved in its own plane, direction x, with a velocity U. This sliding motion generates a net viscous force that is diffused outward to accelerate other fluid particles, Fig. 1. The momentum equation, Eq. (35), for the velocity $u(y,t)$ takes on a parabolic form,

$$\frac{\partial u}{\partial t} \equiv \nu \frac{\partial^2 u}{\partial y^2}. \tag{53}$$

The velocity profile is a similarity solution in terms of the single variable

$$\eta = y/2(\nu t)^{1/2}. \tag{54}$$

All points with combinations of y and t that give the same η have similar velocities. The profile is

$$u = U[1 - \mathrm{erf}(\eta)]. \tag{55}$$

The associated problem where the wall is stationary but the fluid is impulsively moved with velocity U is described by the profile

$$u = U\,\mathrm{erf}(\eta). \tag{56}$$

The important result in either problem is the depth of penetration, δ, of the viscous effects after a time t. It is

$$\delta \sim (\nu t)^{1/2}. \tag{57}$$

The growth of a shear layer (a thin layer with a large velocity gradient) can be estimated using this result. Consider a flow with characteristic width D and flow direction length L. Set t equal to the time it takes to convect the flow through the region; $t = L/U$. By the time the flow reaches the position L, viscous effects will diffuse across the region a depth δ:

$$\frac{\delta}{D} \sim \left(\frac{\nu}{DU}\frac{L}{D}\right)^{1/2} = \left(\frac{1}{Re_D}\frac{L}{D}\right)^{1/2}. \tag{58}$$

This offers another interpretation of the Reynolds number as an indicator of the length scale of viscous diffusion compared to a cross-stream dimension.

11.3 Stagnation Point

When a flow approaches a body and must divide to go around on either side there is an *attachment* or *stagnation point* on the surface where the streamline direction is multivalued, Fig. 2. For high Reynolds numbers the viscous effects are confined to a region near the wall. In some small region near the stagnation point the body can be assumed equivalent to a flat wall (normal direction y, origin at the stagnation point, x and z in the plane of the wall, velocity components u,v,w), and the flow far away, $y \to \infty$, is decelerating in a linear fashion; that is $v \sim -(\alpha+\beta)y$. This flow eventually proceeds along the wall in the x and z directions. As $y \to \infty$, $u \sim \alpha x$ and $w \sim \beta z$ in various proportions according to the shape of the body. For equal flows in x and z the point is an axisymmetric stagnation point. For no flow in the z direction the flow is a plane two-dimensional flow, and the stagnation point is actually a line perpendicular to the flow direction.

The Navier-Stokes equations for these flows can be solved to give a velocity profile that rises from zero at the wall to match smoothly the flow described above. Thus the velocity profiles u and w at any location scale with αx and βz. The nondimensional coordinate normal to the wall is $\eta \equiv (\alpha/\nu)^{1/2}y$. This implies that the thickness of the profile is proportional to $(\nu/\alpha)^{1/2}$. From dimensional considerations one can show that α must have the form $\alpha = CU/L$, where C is a constant determined by the shape of the body, L a length characterizing the size of the body, and U the free-stream velocity. Although the solution satisfies the Navier-Stokes equations, the formulation of the boundary conditions is only realistic for a high Reynolds number UL/ν. Another significant result is that the pressure is constant in the y direction across the viscous layer.

12. WAKES, JETS, AND DRAG

Consider a fixed body with a characteristic dimension d in an infinite fluid. The flow at infinity is a uniform streaming motion in the x direction with a velocity U. For any Reynolds number greater than zero the effect of the body is confined to a region downstream of the body called the *wake*. For definiteness consider a two-dimensional body and a flow

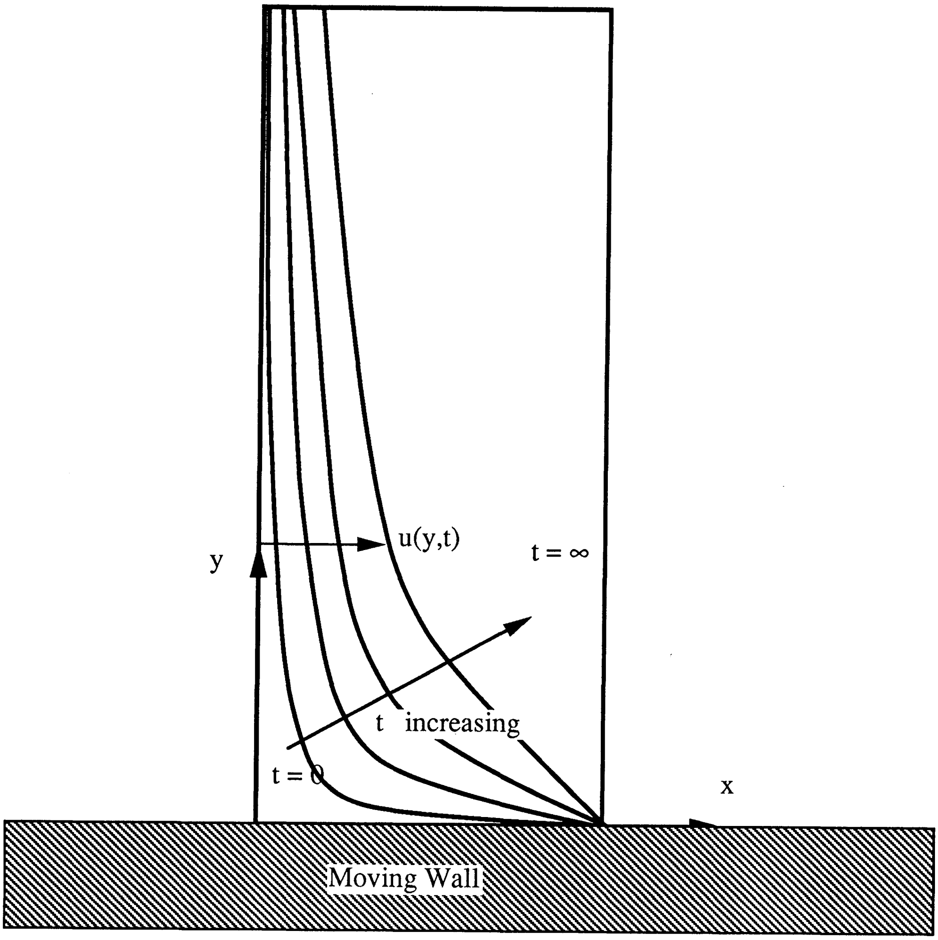

FIG. 1. Viscous diffusion away from a wall that is impulsively set in sliding motion. Acceleration of the fluid is entirely the result of viscous forces.

of a unit depth. A rectangular control region is shown in Fig. 3. It has a uniform flow in at the left with a value U. Because of the body, the flow on the right has a wake velocity profile $u_w(y)$. The upper and lower surfaces are so far removed that the velocity is U; however, in order to conserve mass there is also a small velocity perpendicular to these surfaces. The surfaces are far enough removed so that the pressure is the same on all surfaces. By applying the momentum equation to this region one finds that the drag force is related to an integral property of the wake profile,

$$C_D=\frac{F_D}{\frac{1}{2}\rho U d}=\int_{-\infty}^{\infty}\left[\frac{u_w}{U}-\left(\frac{u_w}{U}\right)^2\right]d\left(\frac{y}{d}\right)=2\frac{\Theta}{d}. \qquad (59)$$

The nondimensional drag coefficient above is the customary form for any bluff body. The drag force F_D is compared to the dynamic pressure $\frac{1}{2}\rho U$ times a cross-section area ld. The dimensional form of the integral, defined as Θ, is called the *momentum thickness*. As one goes downstream the wake decays; $u_w \rightarrow U$ and the thickness becomes larger. This can only happen in such a way that the integral above is the same constant for any downstream position. A survey of results of many drag experiments is given in Hoerner (1965).

In practical situations the wake flow is turbulent; nevertheless, the theory above is still valid with the time-averaged profile used for u_w (see TURBULENT FLOWS). The term *far wake* refers to the downstream region where the wake velocity profiles have established a similarity form. Let $L(x)$ be a characteristic width dimension of the wake and $W(x)$ be the velocity defect on the centerline, that is,

$$W(x)=U-u_w(x,y=0). \qquad (60)$$

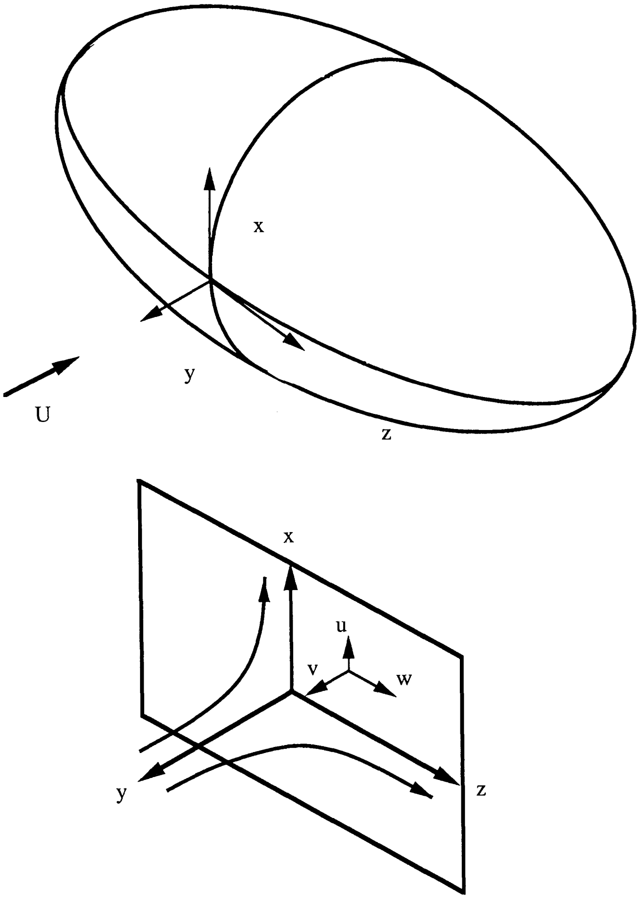

FIG. 2. Stagnation point in a three-dimensional flow. The nose of an ellipsoid has a flow that is an example of a generic stagnation point on a flat wall.

Sufficiently far downstream the exact shape of the body has been "forgotten" and the wake *defect velocity profile* is given by

$$\frac{U-u_w(x,y)}{W(x)}=F(\eta), \tag{61}$$

where

$$\eta=y/L(x).$$

In the far wake the second term in the momentum thickness definition becomes negligible and one can deduce that the growth of the wake is $L\sim x^{1/2}$ and the decay of the centerline velocity defect is $W\sim x^{-1/2}$. A detailed analysis of the momentum equation including assumptions about the turbulence is required to determine $F(\eta)$. Experiments show that the plane two-dimensional wake $u_w(x,y)$ behaves as

$$\frac{W}{U}=1.58\left(\frac{x-x_0}{\Theta}\right)^{-1/2},$$
$$\frac{L}{\Theta}=0.252\left(\frac{x-x_0}{\Theta}\right)^{1/2}. \tag{62}$$

Here x_0 is an effective origin to account for details of the flow near the body. A similar analysis for an axisymmetric wake $u_w(r,z)$ shows that the decay equations are

$$\frac{W}{U}\sim\left(\frac{z-z_0}{\Theta}\right)^{-2/3},$$
$$\frac{L}{\Theta}\sim\left(\frac{z-z_0}{\Theta}\right)^{1/3}. \tag{63}$$

Precise coefficients for these decay equations are hard to obtain. Part of the reason is that the axisymmetric wake does not sustain turbulence in its latter stages of decay.

Jets issuing into an infinite reservoir have many of the same characteristics as wakes. They are unstable at very low Reynolds numbers and commonly turbulent. Instead of a drag force, the jet is a source of positive momentum in a stagnant reservoir. The momentum crossing any downstream plane is constant,

$$U^2D=W^2L\int_{-\infty}^{\infty}\left(\frac{u_j}{W}\right)^2 d\left(\frac{y}{L}\right). \tag{64}$$

Here U and D are constants characterizing the velocity and width of the jet, $W=u_j(x,y=0)$ is the centerline jet velocity, and $L(x)$ is the local jet width. Again the exact similarity profile of the jet, $u_j/W=F(\eta)$ with $\eta=y/L$, depends on the details of the turbulence.

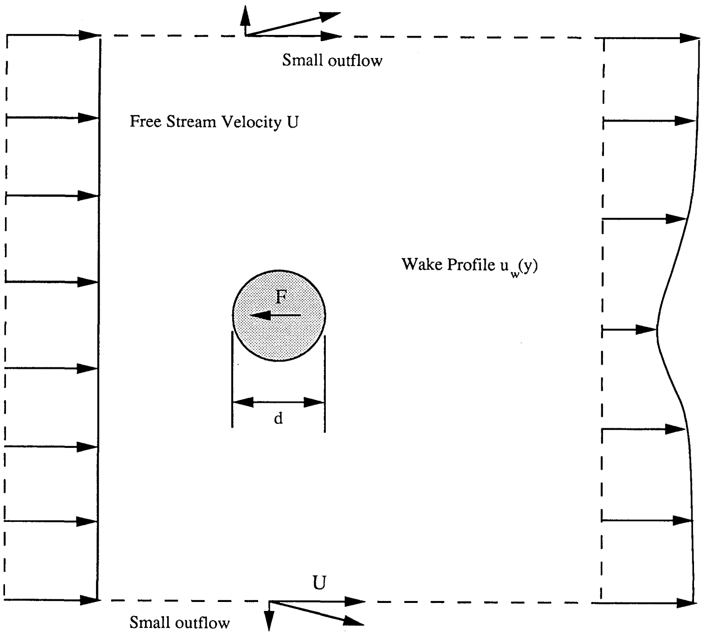

FIG. 3. Wake of a body in an infinite fluid. A control volume analysis shows that the drag of the body is related to the momentum defect of the wake velocity profile.

The development laws for jet width and centerline velocity for plane two-dimensional jets are

$$\frac{W}{U}=2.7\left(\frac{x-x_0}{D}\right)^{-1/2},$$
$$\frac{L}{D}=0.078\left(\frac{x-x_0}{D}\right). \qquad (65)$$

The corresponding relations for axisymmetric jets are

$$\frac{W}{U}=6.4\left(\frac{x-x_0}{D}\right)^{-1},$$
$$\frac{L}{D}=0.067\left(\frac{x-x_0}{D}\right). \qquad (66)$$

In both cases the linear growth of the jet width implies an increase in the mass flow across downstream stations by entrainment of reservoir fluid.

13. SWIRLING FLOWS

The term *vortex* does not have a rigorous definition. It is applied to any flow pattern with spiral or circular streamlines. A measure of vortex strength is the *circulation.* Circulation is defined as the tangential component of velocity integrated around a specified closed loop, a line integral.

$$\Gamma=\int_C \mathbf{t}\cdot v\, ds. \qquad (67)$$

Stokes's theorem allows conversion of the line integral into an integral over any surface with C as its edge. By noting that $\omega=\nabla\times\mathbf{v}$, we get

$$\Gamma=\int_C \mathbf{n}\cdot\omega\, dA. \qquad (68)$$

A flow with circulation must have vorticity somewhere within the circuit C.

13.1 Various Vortex Profiles

If the vorticity is concentrated into a Dirac δ function along the z axis we get a pure circular flow called an *ideal vortex.* The swirling flow velocity in cylindrical coordinates is

$$v_\theta=\Gamma/2\pi r. \qquad (69)$$

This is also known as a *potential vortex* because it has $\omega=0$ (the necessary and sufficient condition for a velocity potential to exist) everywhere except the origin. The profile satisfies the Navier-Stokes equations exactly, except for the singularity at the origin.

The *Rankine vortex* has uniform vorticity in a core that exist out to a distance r_0. This gives a solid-body rotation in the core, $r<r_0$:

$$v_\theta=(\Gamma_0/2\pi r_0)(r/r_0). \qquad (70)$$

Outside the core the vorticity is zero and the ideal profile above exists. This vortex model has a discontinuity in slope (or shear stress) at the core radius.

A vorticity distribution that is Gaussian in the radius will not be steady but will diffuse outward because of viscosity. The vortex associated with this distribution is called a *Lamb* or *Oseen* vortex. The velocity profile at a certain time t is

$$v_\theta=\frac{\Gamma}{2\pi r}\left[1-\exp\left(-\frac{r^2}{4\nu t}\right)\right]. \qquad (71)$$

The governing equation in cylindrical coordinates is

$$\frac{\partial(rv_\theta)}{\partial t}=\nu\left(\frac{\partial^2(rv_\theta)}{\partial r^2}-\frac{1}{r}\frac{\partial(rv_\theta)}{\partial r}\right). \qquad (72)$$

This vortex can be viewed as the decay of an ideal vortex and Eq. (71) is an exact solution to the Navier-Stokes equations. The circulation at infinity, or total vorticity, is constant. The Oseen vortex contains an infinite amount of angular momentum and kinetic energy.

A vortex that has a finite amount of angular momentum is the profile discovered by G. I. Taylor. If the differential equation above is differentiated with respect to t the form governing $\partial v_\theta/\partial t$ is the same as that governing v_θ. The profile found by differentiating the Oseen profile is

$$v_\theta=\frac{Hr}{8\pi\nu t^2}\exp\left(-\frac{r^2}{4\nu t}\right). \qquad (73)$$

Here H is the strength constant. There are an infinite number of vortex solutions like the *Taylor vortex,* each with a sharper profile and a faster time decay. In fact, these vortex solutions form a complete set of basis functions of Eq. (72).

When a vortex is "pulled" or stretched along its axis the vorticity is intensified. Hence, one may reach an equilibrium between intensification and radial diffusion to obtain a steady-state profile. This is known as *Burgers's vortex.* The straining is given by radial and axial profiles

$$v_r = -ar, \quad v_z = 2az. \tag{74}$$

The swirling profile is a steady Oseen profile:

$$v_\theta = \frac{\Gamma}{2\pi r}\left[1 - \exp\left(-\frac{ar^2}{2\nu}\right)\right]. \tag{75}$$

The parameter a defines the straining.

An important illustration that the longitudinal and radial flows in a vortex can be quite complex is *Sullivan's vortex.* At $r \to \infty$ the flow is like Burgers's vortex. Near the axis, however the flow has two cells as shown in Fig. 4. The velocities are

$$v_r = -ar + \frac{6\nu}{r}\left[1 - \exp\left(-\frac{ar^2}{2\nu}\right)\right],$$

$$v_z = 2az\left[1 - 3\exp\left(-\frac{ar^2}{2\nu}\right)\right], \tag{76}$$

$$v_\theta = \frac{\Gamma}{2\pi r} H\left(-\frac{ar^2}{2\nu}\right),$$

where the function $H(\zeta)$ is defined by

$$H(\zeta) = \frac{1}{37.905}\int_0^\zeta \exp\left(-z + 3\int_0^z [1 - \exp(-s)]s^{-1}ds\right)dz. \tag{77}$$

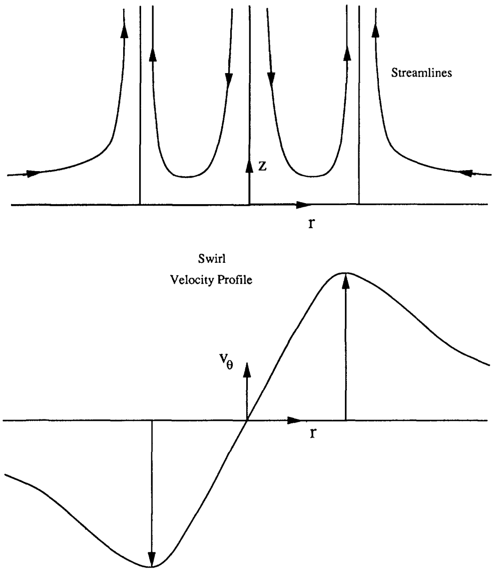

FIG. 4. Sullivan's vortex. Velocity profile and cross-section view of streamlines show a complex pattern with flow going upward in one part of the vortex and downward in another part.

13.2 von Kármán Viscous Pump

The interaction of a swirling flow and a solid wall occurs in several situations. In one of the most general problems, a solid wall (disk) in the x-y plane is imagined to rotate about the z axis with a specified angular velocity. A second parallel disk at $z = z_0$ has another specified angular velocity. One of the simplest cases is a rotating disk in a semi-infinite fluid, the *von Kármán viscous pump.* Here, the second disk is stationary and z_0 is at infinity. Another interesting case is when the disk at infinity rotates and the disk at the origin is at rest, that is the flow of a fluid with a solid-body rotation above a stationary wall. This is known as the *Bödewadt problem.*

In both of these problems the proper scaling for the z directions is

$$\zeta = z(\Omega/\nu)^{1/2}. \tag{78}$$

The velocity of swirl has the form

$$v_\theta = r\Omega G(\zeta). \tag{79}$$

In the von Kármán problem G goes monotonically from $G = 1$ at $\zeta = 0$ (the rotating wall) to $G = 0$ at $\zeta = \infty$. Actually, the fluid motion is confined to a region near the moving wall; $G(\zeta = 4)$ is nearly zero. Viscous forces have diffused from the rotating disk to accelerate the fluid near the disk. Note that the magnitudes of the velocities are proportional to $r\Omega$ and the depth of rotating fluid proportional to $(\nu/\Omega)^{1/2}$. For high rotation speeds the layer is very thin.

The first effect is that the rotating disk accelerates nearby particles by viscous forces. Since the fluid has no pressure gradient to keep the particles in a circular path they are flung outward along the disk. The radial velocity is given by

$$v_r = r\Omega F(\zeta), \tag{80}$$

At the rotating disk $F(\zeta = 0) = 0$ and at infinity $F(\zeta = \infty) = 0$; however, a peak occurs at about $\zeta = 1$. This outward flow near the disk must be replaced by a flow from infinity toward the disk, hence the term *viscous pump*. The inward flow is scaled by

$$v_z = -(\nu\Omega)^{1/2} H(\zeta). \tag{81}$$

Since the flow must turn when it approaches the disk, $H(\zeta=0)=0$, and the constant flow from infinity toward the disk is determined from the solution as $H(\zeta=\infty)=0.886$.

The Bödewadt problem is similar except that the disk, and therefore the flow, at infinity is rotating as a solid body while the disk at $z=0$ is stationary. At infinity there must be a pressure gradient in the radial direction that turns the particles in a circular pattern. At the stationary disk (wall) the viscous forces destroy this motion in a thin layer near the wall. Now, the equilibrium of the centrifugal motion and the pressure gradient is upset. The pressure gradient forces the particles toward the center as they slow down. This flow is accompanied by a uniform outflow along the z axis.

To a great extent these problems are complementary. The absence of a pressure gradient in the von Kármán problem yields a spiral outward flow along the rotating disk; the presence of a pressure gradient yields a spiral inward flow along the stationary disk when the rotating fluid is slowed in the Bödewadt problem.

13.3 Vortex Breakdown

Intense vortices undergo a transition called vortex *breakdown* or vortex *bursting*. Viewed in a coordinate frame where the breakdown is stationary, the flow has a large axial velocity which is usually jetlike in the core. A typical empirical axial profile is

$$v_z = V\left[1 + Q\exp\left(-\frac{ar^2}{2\nu}\right)\right]. \tag{82}$$

Here Q and a are parameters. The swirl profile is gives by the steady Oseen or Burger vortex discussed above. The transition begins as flow on the vortex axis slows down and the vortex expands. Two major types of breakdown are observed. Figures 5 and 6 from Faler and Leibovich (1977) give examples. Both types have a stagnation point on the axis and a region of reverse flow. If a dye filament is introduced in the vortex core the *bubble-type breakdown* will show a large bubble of collected dye in a separated region with reverse flow. There is a slow exchange of fluid in the bubble with the surrounding flow. Dye going around the bubble will form a tail that spirals into a region of turbulent flow. In the *spiral-type breakdown* the dye filament has a kink at the stagnation point and spirals out into a turbulent flow. The final flow in either

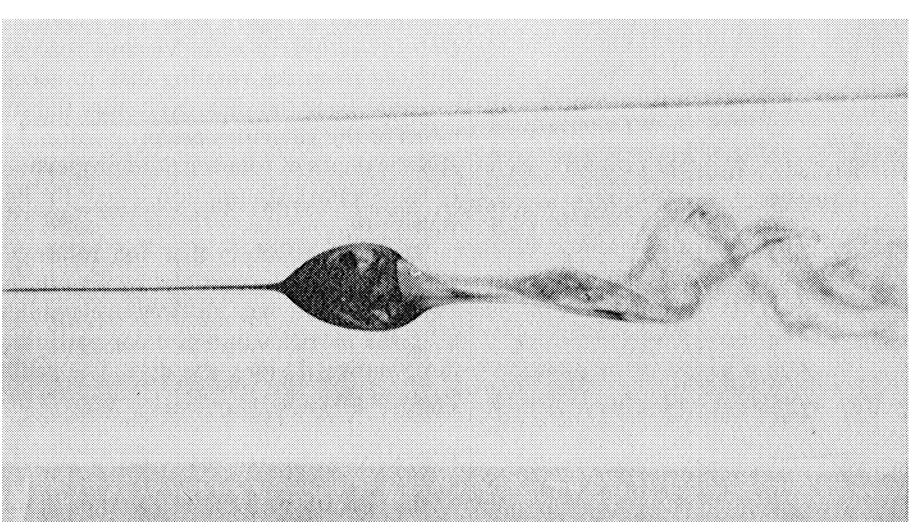

FIG. 5. Bubble-type vortex breakdown. The recirculation bubble is simultaneously filled and emptied from the rea . (From Faler and Leibovich, 1977).

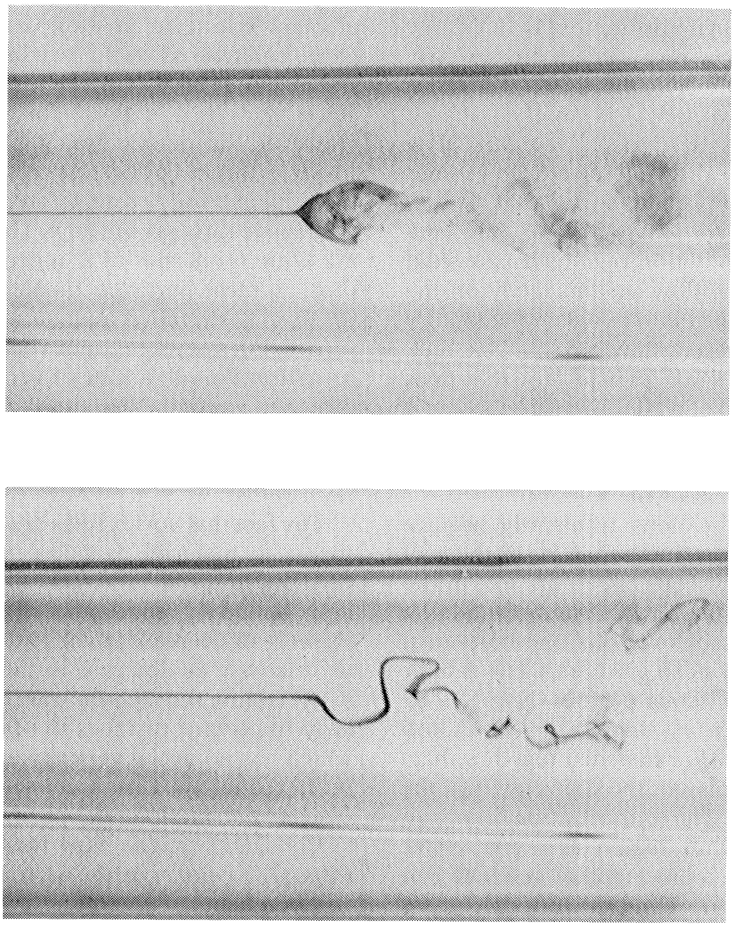

FIG. 6. Spiral-type vortex breakdown. The common mode that occurs on aircraft delta wings. The kink always breaks down into turbulence after a turn or two. (From Faler and Leibovich, 1977.)

case will be a turbulent vortex with about twice the radius of the original vortex.

An axisymmetric theory of an inviscid flow shows that there are two distinct velocity profiles, conjugate flow states, such that each fluid particle has the same angular momentum and the same total pressure. Thus the initial and final states are connected by jump conditions analogous to a shock wave or a hydraulic jump. It is further found that vortices can support axisymmetric traveling waves. The vortex is called supercritical if waves can only propagate downstream and subcritical if waves can propagate upstream. One proposition is that vortex breakdown occurs when disturbance waves from downstream collect at a location where they can no longer move against the flow. The fact that vortex breakdown is a finite-amplitude flow structure makes this an oversimplification; however, it is observed experimentally that the upstream vortex flow is supercritical and the downstream flow subcritical. Review articles on vortex breakdown are Escudier (1988) and Leibovich (1984).

14. HIGH-REYNOLDS-NUMBER FLOWS

The viscosity of common liquids and gases is small, and it does not take a very high velocity to yield a high Reynolds number. Consider a characteristic flow dimension of 10 cm and a velocity of 1 m/s; then for air (ν=0.150 cm^2/s) the Reynolds number is

$UL/\nu=6670$. Water in this sense is even less viscous than air ($\nu=0.010$); for water the corresponding Reynolds number is 10^5. Large Reynolds numbers mean, according to Sec. 10.3, that the diffusion distance for viscous shear stress (or vorticity) is small compared to the characteristic dimension of the flow field. Because the diffusion distance becomes small, the first approximation is that the viscous effects (or vorticity gradients) are confined to vanishingly thin regions on the solid boundaries of the flow. In this situation the flow may be divided into two complementary regions with different flow physics. The bulk of the flow field is an *inviscid flow* that does not satisfy the no-slip condition. The inviscid flow slips past the wall on the thin viscous region. The magnitude of the slip velocity over the walls is a result of the solution.

Practical applications frequently require knowledge of the wall shear stress or the wall heat flux. These viscous effects are lost in the inviscid approximation. To understand the events in the viscous regions one must deal directly with the steep gradients. The proper physics in the viscous regions is given by *boundary-layer theory.* Boundary-layer theory and inviscid flow are matched together, having as the common part the slip velocity of the inviscid solution. The concentration of certain physics into a thin region as a parameter becomes large is a prototype of singular perturbation problems. Thus, the term boundary layer is applied to other events of a similar physical structure.

14.1 Inviscid Flows

At high Reynolds numbers, the first approximation is that an inviscid flow covers the entire domain. If the governing equations are nondimensionalized with a characteristic velocity U, length L, and fluid density ρ and the Reynolds number is set equal to infinity, all terms originally preceded by the viscosity coefficient drop out of the equations. Euphemistically one says that the flow is that of an inviscid fluid.

The inviscid vorticity equation is

$$\frac{D\boldsymbol{\omega}}{Dt}=\boldsymbol{\omega}\cdot\nabla\mathbf{v}. \tag{83}$$

From this equation some important facts about vorticity may be deduced. The similar structure of Eq. (83) governing $\boldsymbol{\omega}$ and Eq. (2) governing the length vector of a material line element $\delta\mathbf{r}$ leads to an intuitive understanding of the behavior of vorticity in inviscid flows. A vortex line is an instantaneous concept in the sense that it is defined for a given time. However, for inviscid flow it is permissible to imagine that a vortex line is attached to the material and follows along on the particles as they move through the flow. The vorticity has the same properties as a material line drawn through these particles. Vorticity increases if the line is stretched and turns if the line is turned. Furthermore, since vorticity obeys the condition $\nabla\cdot\boldsymbol{\omega}=\mathbf{0}$, a tube of vortex lines has a constant strength, the strength being measured by the circulation or the integral of the vorticity across any cross section of the tube, Eq. (67).

The fact that vortex lines are attached, so to speak, to material particles means that the vorticity is specified as part of the incoming flow boundary conditions. The subsequent increase or decrease in vorticity is the same as the increase or decrease in the length of the material line through the particles. A particularly important result is the fact that a flow which has no initial vorticity will continue to be irrotational. This special class is called *ideal* or *potential flows.*

Consider a steady flow with a vortex line through a certain set of particles. These particles also have streamlines, which are also particle paths, and together with the vortex line they form a surface called the *Lamb surface.* The normal to the surface will be perpendicular to both $\boldsymbol{\omega}$ and $\mathbf{v}$, that is, in the direction $\mathbf{v}\times\boldsymbol{\omega}$. On a Lamb surface it is possible to integrate the momentum equation to find the famous *Bernoulli equation,*

$$p/\rho+gh+\tfrac{1}{2}v^2=\text{const.} \tag{84}$$

The value of the constant may be different for each Lamb surface. If the flow is irrotational, Lamb surfaces can no longer be identified and the same constant applies to the whole flow.

The momentum equation normal to the streamlines cannot be explicitly integrated; however, it is informative. At any point a streamline has a radius of curvature R, whose direction defines a coordinate n normal to the streamline. The inviscid momentum equation for steady flow may be written as

$$\frac{d}{dn}\left[\frac{p}{\rho}+gh\right]=-\frac{v^2}{R}. \tag{85}$$

The bracketed term is actually the modified pressure p'/ρ. Any change in this pressure across streamlines is balanced by the centrifugal force v^2/R. In particular, if the streamline is straight, $R\to\infty$, there is no change in the pressure in the normal direction. For example, a jet flowing into a large reservoir has the same pressure in the core of the jet exit as that of the reservoir.

Ideal flows are dominated by the shape of the boundaries. To see why this is true first note that in an ideal flow the particles do not rotate,

$$\omega=\nabla\times\mathbf{v}=\mathbf{0}. \tag{86}$$

This is the necessary and sufficient mathematical condition for the existence of a *velocity potential* ϕ that obeys

$$\mathbf{v}=\nabla\phi. \tag{87}$$

The incompressible continuity equation demands that particles do not expand and furnishes a relation that governs ϕ,

$$\nabla\cdot v=\nabla^2\phi=0. \tag{88}$$

Thus the solution for the velocity and streamlines is governed by an elliptic equation. Specifying the boundary shape and the normal component of velocity across the boundary (which for a solid wall is zero) completely determines the flow on the interior. The entire flow is sensitive to a change in the boundary; in particular, there is always an upstream influence. These flows are dominated by geometry. Once the streamlines and velocities are set by the geometry and kinematics (no rotation or expansion), the pressure force required to produce these motions may be found from the Bernoulli equation. It is only at this stage that a fluid property, the density, enters as a scaling factor for the level of the pressure, that is, p/ρ.

14.1.1 Internal Flows. The ideal flow into a channel contraction is shown in Fig. 7. The geometry forces the streamlines to curve and crowd together as they enter the smaller section. Inviscid flow slips over a wall; hence, any interior streamline might be considered as a wall containing a flow. One might also imagine that the flow is one half of a symmetric contraction.

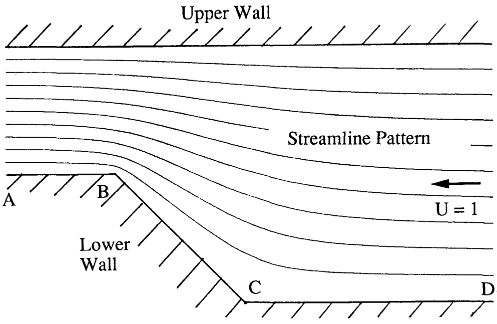

FIG. 7. Ideal flow into a contraction. Streamlines for equal increments of volume flow. Wider distance between streamlines indicates a slower velocity, and a smaller distance a faster velocity.

Streamlines have been drawn in equal increments, that is the volume flow rate AV is constant (A is the cross-sectional area between streamlines and V the average velocity). This means that where the streamlines are far apart the velocity is low and vice versa. By Bernoulli's equation the pressure at any location decreases if the velocity is high and increases if the velocity is low. The centers of curvature are first above the streamlines and then below the streamlines. Correspondingly the pressure gradient across streamlines changes sign in these different regions.

First, consider the flow along the upper flat wall. The streamtube smoothly contracts to a smaller area. Correspondingly in Fig. 8 the velocity monotonically increases to a higher value. The pressure will also show a monotonic decrease to the final value in the small channel. The situation is quite different for the bottom wall. As the flow approaches the concave corner, the stream tube broadens. Theory shows that there is always a stagnation point at a concave corner. Thus the pressure here is the maximum value, the stagnation pressure. The high pressure not only slows the flow approaching the corner but it gives a normal pressure gradient across the streamlines required by the radius of curvature. The rising pressure as the flow enters the corner (even one with a smooth contour) is a practical concern, because it is a possible place for the boundary layer to separate (see Boundary Layers, Sec. 14.2). As the flow proceeds up the sloping wall and approaches the convex corner the streamlines converge. The velocity at a

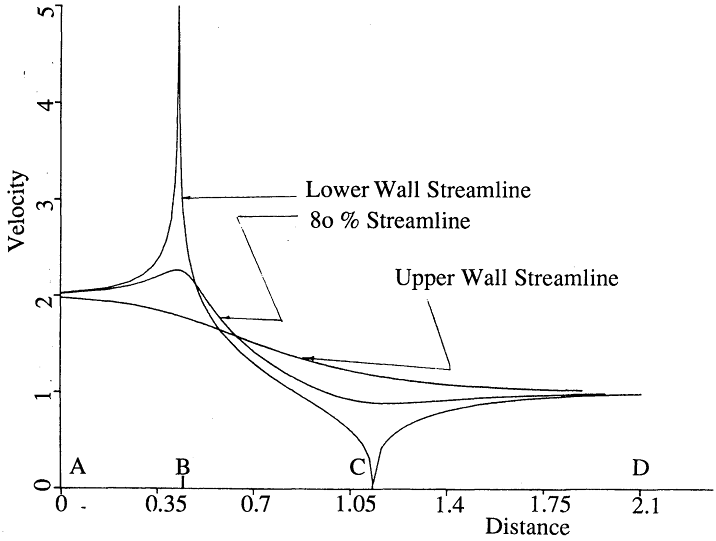

FIG. 8. Ideal flow into a contraction. Velocity as a function of distance along the streamlines of Fig. 7. A slower velocity indicates a higher pressure and vice versa. For streamlines in the lower half of the contraction the pressure first rises, then decreases to a very low value, and subsequently rises again to the final value.

convex corner is theoretically infinite. The corresponding pressure is unreasonably negative. Downstream of the corner, the flow encounters another adverse pressure gradient and again the likelihood of separation.

Mathematically one can show that the flow in the lower half of the channel first slows down approaching the concave corner, and then accelerates to overshoot the final velocity near the convex corner. On the other hand, the flow in the upper half of the channel monotonically accelerates to the higher value. It has no regions of adverse pressure gradients.

14.1.2 External Flows. A solid body is frequently so far removed from other objects that it can be considered to be in an infinite fluid. First, consider the nose region of a blunt but smoothly rounded body, either two dimensional or axisymmetric. The oncoming flow slows down and stops at the stagnation point. Here the static pressure is now equal to the free-stream stagnation or total pressure (free-stream static plus free-stream dynamic pressure). The pressure on the surface then drops as the flow accelerates away to either side. In the process the velocity always becomes greater than that of the approaching free stream, and the pressure is correspondingly lower than the free-stream pressure.

Downstream from the point where the maximum surface velocity occurs, the flow slows down and the associated pressure rises. If one looks at the object head on, there is a high-pressure region surrounding the stagnation point (or stagnation line in the case of a two-dimensional object) followed by a low-pressure region that continues out to the edge of the object. A somewhat surprising fact is that net integrated drag force on the frontal area is zero regardless of the shape of the nose.

After the flow reaches its maximum velocity the pressure increases and an adverse pressure gradient exists. Thus on the shoulders of an object there is a possibility of boundary-layer separation. This is called leading-edge separation in the case of wings. If it does occur it is usually a very thin region that soon reattaches to the body. In that case it does not materially affect the drag. On bodies with sharp corners, a square-fronted object, for example, the flow separates in a large region along the sides. Now the low-pressure region is lost (the proper object for an ideal flow calculation is the body plus an accounting for the separated wake region), and a substantial nose drag is encountered.

The design of wings or blades to produce a large normal force, lift force, is the subject of aerodynamics (*q.v.*). The exact shape of a wing results from an effort to control separation and decrease drag.

Many effects of ideal flow can be understood with reference to the energy of the flow. In order to have a finite kinetic energy we consider a body that is moving through a fluid that is at rest at infinity. Let the body have a unidirectional velocity $U(t)$. Consider a region having one surface at infinity, containing the fluid on the inside, and a second surface at the wall of the body. The global mechanical energy, Eq. (19), is especially simple for inviscid, incompressible flow. It is

$$\frac{d}{dt}\int_{\text{flow}} \rho\tfrac{1}{2}v^2 dV = -\int_{\text{body}} \mathbf{n}\cdot vp\, dS = UF_D. \qquad (89)$$

This equation shows that the work done by the moving body, UF_D, must appear as a increase in the global kinetic energy of the fluid.

For a steadily moving closed body *without a lift force,* the ideal flow in the wake is a potential flow that returns to a still state in a short distance behind the body. The rate of increase in the energy of the flow field is zero and so the drag is also zero, $C_D=0$. In many cases this is unrealistic because flow separates from the body. The turbulent separated flow produces a wake that has a finite amount of kinetic energy. In this case we interpret the drag force work as that required to increase the length of the turbulent wake. This is the energy viewpoint that is complementary to the momentum analysis of Sec. 12. The idea that a body moving through a fluid can leave a permanent mark at infinity also applies to ship waves. The waves propagate to infinity with undiminished energy. Hence, by the equation above there is a wave drag that is equal to the rate at which energy is supplied to the wave system. A similar event happens in the flow over a lifting body. The lift force can only be generated by a net circulation. Therefore the vortex lines associated with this circulation must ultimately, for a three-dimensional body, trail off in a singular surface in the wake. These vortex lines produce a flow of finite energy in the plane perpendicular to the body motion; see Fig. 9. Thus the drag, called *induced drag* or *drag due to lift,* is related to the increase in the length of the wake. For a more extensive discussion see AERODYNAMICS.

If a body is accelerated, the energy of the flow surrounding it increases, and an extra pressure force at the body surface is needed to accomplish this. In the case of a potential flow all velocities scale with U and the average extent of the flow is a constant fraction K of the body volume V. The drag force that the acceleration must overcome is

$$UF_D = \frac{d}{dt}\int \rho\tfrac{1}{2}v^2 dV = \frac{d}{dt}(\rho\tfrac{1}{2}U^2 K\mathrm{V})$$
$$= K\rho\mathrm{V}U\frac{dU}{dt}. \qquad (90)$$

The force is equivalent to a certain mass of fluid, $K\rho\mathrm{V}$, added to the inertia of the body, hence the term *added mass.* The added-mass constant for a sphere is $K=\frac{1}{2}$. The theory still holds for surfaces also. A disk moving normal to its plane has an equivalent $K\rho\mathrm{V}=\rho 8r_0^3/3$. If the fluid is a liquid, the added-mass forces can be large because ρ is large. In gases they are negligible unless the motion is rapid, for

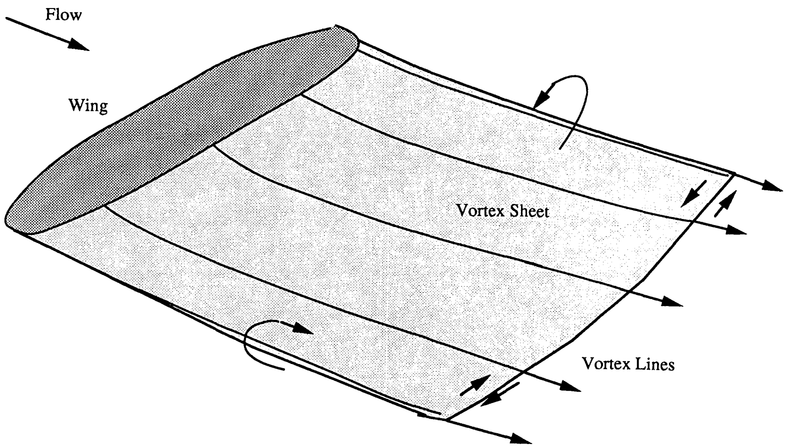

FIG. 9. Ideal potential-flow vortex sheet behind a finite wing. This sheet is a singular surface in the solution of the Laplace equation. Spanwise velocity is discontinuous across the sheet even though the longitudinal velocity is continuous. A finite vortex may exist at the edges of the sheet.

example, a loud-speaker cone, or the surface is large, such as the opening of a parachute.

14.2 Boundary Layers

Inviscid flow theory fails where the fluid slips over the walls. It also fails where one stream slips over another at a higher speed (this would be a sheet of vorticity). These apparent discontinuities in velocity are smoothed out by viscosity in thin regions called *boundary layers.* They exist at high Reynolds numbers because the diffusion length scale for viscous effects is much smaller that the characteristic dimension of the flow field.

Elementary boundary-layer theory is developed for plane bodies with surfaces having a smoothly varying radius of curvature, R. A set of coordinates is laid out with the x axis along the surface and y normal to the surface (Fig. 10). If R is large compared to the thickness of the boundary layer, the coordinates may be considered as a Cartesian system, that is, no curvature terms appear in the equations. Flow in a steady two-dimensional boundary layer, with velocity components $u(x,y)$ and $v(x,y)$, is governed by the following equations:

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0, \tag{91}$$

$$\frac{\partial p}{\partial y}=0 \Rightarrow p=p(x \text{ only}), \tag{92}$$

$$u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}=-\frac{1}{\rho}\frac{dp}{dx}+\nu\frac{\partial^2 u}{\partial y^2}. \tag{93}$$

The first equation is the continuity equation and the second is the y-direction momentum equation. Equation (92) reduces to a statement that the pressure is constant across the boundary layer. This means that the known pressure of the inviscid flow is impressed on the boundary layer. The last equation is the x-direction momentum equation. One viscous term, $\nu\partial^2 u/\partial x^2$, has dropped out of the equation as negligible. The boundary-layer equations are parabolic in mathematical character. The terms $u\partial u/\partial x$ and $\nu\partial^2 u/\partial y^2$ dominate the x and y behavior, respectively.

Appropriate boundary conditions are the no-slip condition at the wall, the condition that inviscid flow cannot satisfy,

$$u(x,0)=0, \quad v(x,0)=0, \tag{94}$$

and initial u velocity profile within the layer,

$$u(x_0,y)=u_i(y). \tag{95}$$

The final boundary condition is that the u velocity (at large y) match the inviscid velocity (at the wall). Specifically,

$$u(x,y\to\infty)\equiv u_e(x)=u_{\text{inviscid}}(x,y=0). \tag{96}$$

The velocity at infinity in the boundary layer $u_e(x)$ matches the (slip) velocity of the inviscid flow on the wall. The velocity $u_e(x)$ is called the *external flow*, also sometimes called the free stream since it occurs as $y\to\infty$. No initial nor matching conditions on the vertical velocity v can be prescribed without overdetermining the problem. The matching condi-

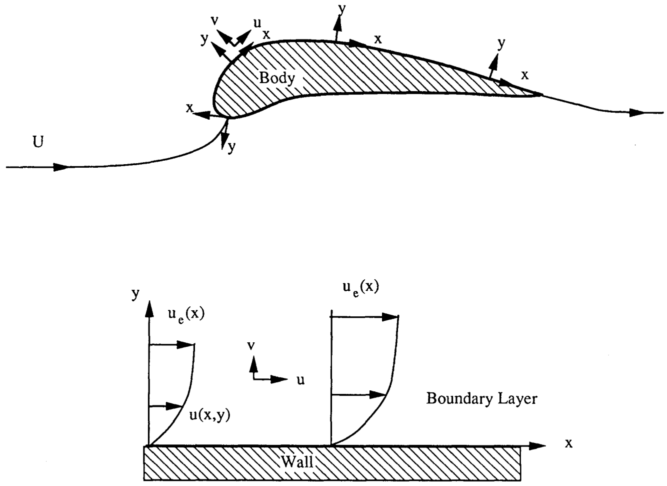

FIG. 10. Boundary-layer coordinates. Coordinates are tangent to the surface and normal to the surface. The boundary layer is so thin and the curvature of the surface so small that the coordinates are essentially Cartesian.

tion also allows the pressure to be given in terms of u_e. Evaluating Eq. (93) as $y \to \infty$ yields

$$u_e \frac{du_e}{dx} = -\frac{1}{\rho}\frac{dp}{dx}. \tag{97}$$

This is a differential form of the Bernoulli equation.

The simplest boundary-layer flow is the flow over a flat plate with zero pressure gradient; $u_e = u_0$ and $u_i = u_0$. It is known as the *Blasius flow.* This is actually a member of a class of solutions called *Falkner-Skan flows.* These are *similarity* solutions in the sense that there are trajectories in the x-y plane with similar velocities. That is,

$$\frac{u(x,y)}{u_e(x)} = f'(\eta), \tag{98}$$

where

$$\eta = y/\delta(x). \tag{99}$$

The notation to call the velocity f' is because f has a physical interpretation. Specifically $f = \text{const}$ is a streamline. The boundary-layer equations admit similarity solutions if u_e and δ vary as power functions

$$u_e = u_0(x/L)^m, \tag{100}$$

$$\delta = [\nu x/u_e(x)]^{1/2}. \tag{101}$$

The solution $m=1$ is the plane stagnation point discussed in Sec. 11.3. Solutions $0 < m < 1$ are associated with inviscid flows over a plane two-dimensional wedge of included angle $\Theta_0 = 2\pi m/(m+1)$. The angle is zero for $m=0$ and Blasius's solution is obtained. All of the flows above are accelerating for $m > 0$. Unique solutions for decelerating flows exist only for the range $-0.0904 \leqslant m < 0$; see Fig. 11. The $m = -0.0904$ solution has zero shear stress and is on the verge of separating for all x.

The similarity solutions are also used as initial profiles for bodies that begin with the appropriate local geometry. Any body with a blunt leading edge begins with the stagnation-point boundary layer, a body beginning with a sharp edge of finite angle begins with a wedge flow boundary layer, and a body beginning with a sharp cusp has the Blasius flow as the starting solution.

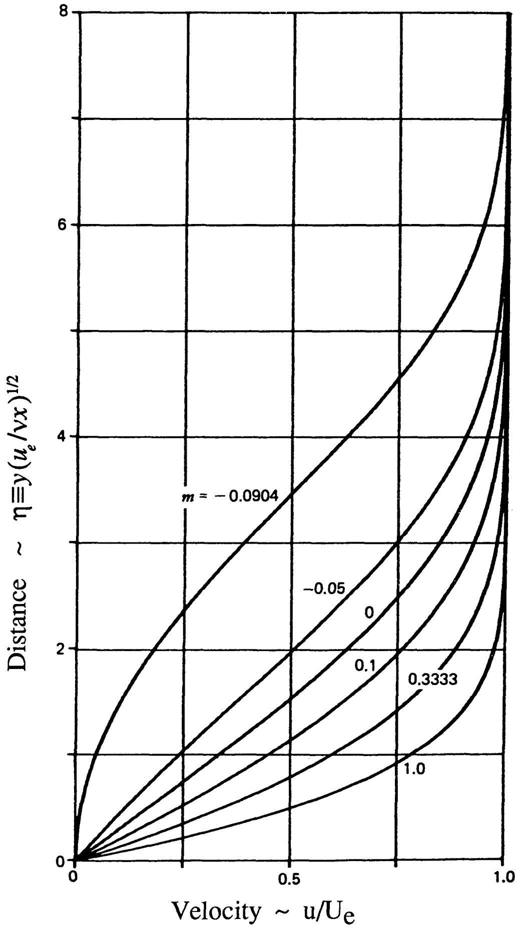

FIG. 11. Velocity profiles in Falkner-Skan boundary layers. The parameter m indicates the external velocity by $u_e(x) = ax^m$. Positive m indicates an accelerating flow with a favorable pressure gradient. Adverse gradients exist only up to $m = -0.0904$, where the flow is on the verge of separating.

14.2.1 Physical Characteristics.

Boundary layers have the same pressure across the layer at any x location. This pressure is imposed by the inviscid flow and largely determines the development of the layer. Without any pressure gradient, the Blasius solution, the boundary-layer thickness grows as $\delta \sim x^{1/2}$ and the wall shear stress decreases as $\tau \sim x^{-1/2}$. An accelerating flow, $dp/dx < 0$, is called a *favorable pressure gradient.* It tends to thin the boundary layer, increase the shear stress, and broaden the velocity profile. An *adverse pressure gradient,* $dp/dx > 0$, tends to thicken the layer rapidly and decrease the wall shear stress. Since the same pressure force acts on all particles in the layer, those next to the wall with the least momentum are slowed most rapidly. It takes only a slight application of adverse pressure to turn the particles next to the wall around and cause them to flow upstream. When this happens *separation* is said to occur. A thin separation bubble that reattaches quickly can be calculated with boundary-layer equations.

However, if the separation region is large, then the assumption that the boundary-layer theory is thin is violated and the calculation is stopped. A large separated region modifies the inviscid flow upstream. Hence a proper boundary-layer calculation needs to have the modified external velocity as its boundary condition. If the actual pressure distribution is used in the boundary-layer calculation, then the prediction of the separation point is reasonably accurate.

The parabolic nature of the boundary-layer equations means that effects are carried downstream (the timelike direction), but that there is no upstream influence. A change in the external velocity $u_e(x)$ after some point in the flow will not be felt upstream of that point. The dominant convective term $u(\partial u/\partial x)$ gives the timelike behavior. In an adverse pressure gradient, when particles near the wall are turned around u becomes negative and the direction of signal characteristics changes. Thus information is carried backward by the reverse flow near the wall in the region of separated flow. In very thin separation bubbles the reverse convection can be ignored; however, in large separation regions it cannot.

14.2.2 Three-Dimensional Effects.

Boundary layers on axisymmetric bodies are only slightly more complicated than two-dimensional layers. The only new physical feature is the divergence or convergence of the streamlines as they move to places of higher or lower radius. There is a transformation, Mangler's transformation, that maps the axisymmetric problem back into an equivalent two-dimensional boundary layer. Divergence thins the layer and increases the shear stress while convergence thickens the layer and decreases the stress. Pressure gradients do not change sign in the transformation. An adverse gradient is still adverse in the equivalent two-dimensional problem.

A boundary layer on a general cylindrical object placed at a sweep angle with respect to the free stream is three dimensional in the sense that all three velocity components are variables. However, the flow in a plane perpendicular to the leading edge is exactly like a two-dimensional boundary layer. This is known as the sweep independence principle. Once this flow is known the spanwise flow parallel to the cylinder axis can be calculated.

Truly three-dimensional boundary layers can have much more complicated behavior. Consider a set of inviscid streamlines that are curving over a surface boundary layer. The inviscid flow curvature is produced by a transverse pressure gradient (the pressure gradient in the flow direction slows or speeds the velocity):

$$\frac{d}{ds}\left(\frac{p}{\rho}\right) = -\frac{V^2}{R}\,. \qquad (102)$$

This gradient acts undiminished through the boundary layer, and, in particular, it acts on the particles deep within the layer that have only a small velocity. It causes, through an essentially inviscid mechanism, a much smaller radius of curvature. Thus a general rule is that fluid within the boundary follows more highly curved streamlines than does the external flow. The particle paths within the boundary layer tend to separate. At any position the particles through a boundary-layer profile have come from a variety of upstream locations.

Likewise the particles at this location will spread to different regions as they go further along. This transverse spreading is another distinct action that happens in a three-dimensional boundary layer. Since particle paths are subcharacteristics of the boundary-layer equations, transverse spreading must be accounted for in formulating boundary conditions and solving problems.

Secondary flow is the flow in the direction perpendicular to the external streamline and parallel to the wall. It is a jetlike profile, zero at the wall and zero again at $y \to \infty$. This means that the net viscous force in the outer part of the jet is in the direction of the jet. Therefore it can add to the pressure force that originally produced the jet and generate velocities that are higher in magnitude those in the inviscid flow. It is not uncommon to find velocities in the upper parts of boundary layers that are significantly higher than those in the external inviscid flow.

15. LOW-REYNOLDS-NUMBER FLOWS

When the Reynolds number of a flow is very low, the inertia effects are negligible compared to viscous and pressure effects. These flows are also known as *Stokes flows* or *creeping flows;* however, "low–Reynolds-number flows" is the most descriptive name.

At moderate or high Reynolds numbers the proper scales are ρ, U, and L [except for the normal coordinate in boundary-layer theory where $(\nu/U)^{1/2}$ is needed]. For low Reynolds numbers the density (inertia) is irrelevant and the appropriate scales are μ, U, and L. When these scales are used, the momentum equation in dimensionless variables is

$$Re\,\frac{D\mathbf{v}^*}{Dt}=-\nabla p^{**}+\nabla\cdot\nabla\mathbf{v}^*. \tag{103}$$

In the low–Reynolds-number limit the inertia term drops out and the pressure and viscous forces must balance everywhere in the flow,

$$\mathbf{0}=-\nabla p^{**}+\nabla\cdot\nabla\mathbf{v}^*. \tag{104}$$

An equivalent form in terms of the stress tensor is

$$\mathbf{0}=-\nabla p^{**}+\nabla\cdot\boldsymbol{\tau}^*. \tag{105}$$

The appropriate form of the vorticity equation is

$$\begin{aligned}\mathbf{0}&=\nabla\cdot\nabla\boldsymbol{\omega},\\ \mathbf{0}&=\nabla\cdot\nabla(\nabla\times\mathbf{v}).\end{aligned} \tag{106}$$

This equation states that diffusion is the only mechanism to govern vorticity in low-*Re* flows. It is important to notice that all low-*Re* equations are linear and independent of time.

As the viscous forces become stronger and stronger, the pressure rises to counteract them. For this reason the proper nondimensional pressure is

$$p^{**}=\frac{p-p_{\text{ref}}}{\mu U/L}. \tag{107}$$

Note that the low–Reynolds-number pressure scale compared to the high–Reynolds-number pressure, the dynamic pressure, scale is the inverse Reynolds number:

$$\frac{\mu U/L}{\frac{1}{2}\rho U^2}=\frac{1}{2\,Re}. \tag{108}$$

In low–Reynolds-number flows the pressures are quite large compared to the dynamic pressure.

Any flow property in a low-*Re* flow is independent of the fluid density. This means that the lift, drag, and pressure coefficients that were previously defined using the dynamic pressure are actually inappropriate. Nevertheless, in practice the high–Reynolds-number forms are retained, and as a result they always have a Re^{-1} dependence as *Re* approaches zero. For example, as $Re\to 0$ the drag coefficient for a sphere is

$$C_D=\frac{F}{\frac{1}{2}\rho U^2\pi r_0^2}=\frac{24}{Re}. \tag{109}$$

The accuracy of this equation deteriorates if *Re* is greater than 0.5. (Aside: intuitively we would not expect a theory for $\epsilon\to\infty$ to be good unless $\epsilon>$ a few hundred, say 100. A completely equivalent theory in terms of a new parameter $1/\epsilon\equiv\eta\to 0$ would mean $\eta=1/\epsilon<0.01$ or so.)

The fact that linear equations govern low-*Re* flows leads to many theoretical consequences. Consider a problem with $\mathbf{v}$ as a solution. The reverse flow, that is $\mathbf{v}\to-\mathbf{v}$, is also a solution. Furthermore, the stress and pressure change sign; $\boldsymbol{\tau}\to-\boldsymbol{\tau}$ and $p-p_{\text{ref}}\to-(p-p_{\text{ref}})$. Hence, one may argue that a symmetric object must have symmetric streamlines and an antisymmetric pressure distribution. Several conclusions stem from these facts. The requirement for symmetric streamlines means that external flow over an object cannot have a wake. It also requires the flow over a rectangle on a wall to separate both in front of and behind the rectangle; see Fig. 12.

The ability of Stokes equations to produce flow into a corner has been investigated by Dean and Montagnon (1949) and Moffatt (1964). In plane flow smooth solutions are

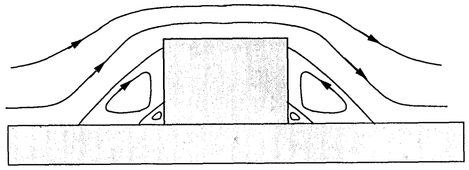

FIG. 12. Low-Reynolds-number flow over a block. Streamlines must be symmetric and so separation takes place on both sides of the block. Low-Reynolds-number flow cannot smoothly turn a 90° corner and this leads to separation. The separation vortex is actually an infinite sequence of vortices of smaller and smaller size.

not possible if the corner angle is less than 146.3°. For smaller angles a vortex must occur in the corner. Hence the pattern of separation in front of and behind the rectangular block is expected. Actually the vortex itself generates a smaller vortex nearer the corner. Theoretically there is an infinite sequence of smaller and smaller vortices (called Moffatt vortices) that are nested in the corner.

15.1 Internal Flows—Lubrication Theory

Internal flows in porous media and in lubrication situations have channels that are very narrow compared to their length. Consider a channel with rigid walls and a slowly varying cross section and curvature. Flow in such a channel is locally like a viscous parallel (Poiseuille) flow driven by a pressure gradient (see flows of Sec. 10.1). The total pressure drop is the integrated value of the local values. When one wall moves and the other wall is stationary, a situation common to bearings, the local velocity profile is a linear combination of a Couette profile and a Poiseuille profile. The local pressure gradient is established by the local channel width and the requirement of a constant flow rate.

The essential hydrodynamic action in lubrication is illustrated by flow in a converging passage with one wall moving. The flow in a slider block, Fig. 13, typifies the physics. The moving wall drags fluid into the passage by viscous forces. Pressure builds up in the center and tends to retard the flow in the front half and aid the flow out the second half. The force that can be supported is indicated by the maximum pressure. It is related to the other parameters of the problem by

$$p_{\max}-p_0=\frac{3\mu UL}{4h_0^2}\,\frac{h_0-h_1}{h_0}\,. \qquad (110)$$

This equation is an approximation for small $(h_0-h_1)/h_0$. In a journal bearing the rotating shaft is eccentric to the journal. This creates a converging passage where high pressures are generated that support the shaft. The fluid is returned to the other side in the diverging section. It has very low pressures and frequently cavitation occurs.

15.2 External Flows

The streaming flow over a solid body at low Reynolds number turns out to be a singular perturbation problem. Stokes's equation, Eq. (105), neglects convective terms like $u\partial u/\partial x$, which must become significant at some large distance from the body. Thus the singularity in the theory is at infinity. In three-dimensional flow it is possible to solve Stokes's equations near the body and to have the solutions match to U_∞ far away. In a certain sense the first-order outer flow is the constant

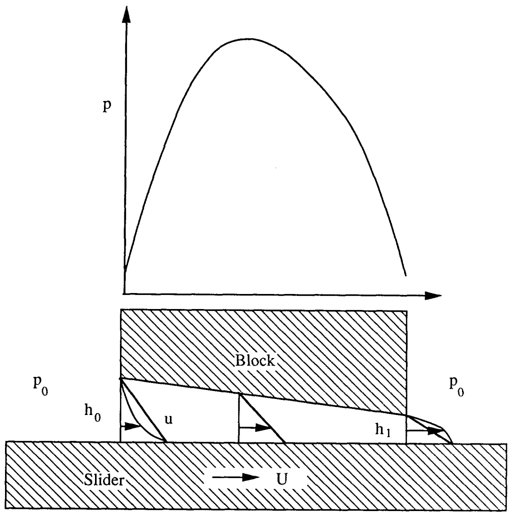

FIG. 13. Slider-block lubrication flow. Viscous forces drag the fluid into the narrowing channel. A pressure gradient is established to retard or accelerate the flow and maintain a constant flow rate. The velocity profiles are a linear Couette component plus the Poiseuille component from the pressure gradient.

U_∞. Thus in three-dimensional problems the singular behavior is not even noticed. For any three-dimensional object it is possible to get a good solution and a drag coefficient. In two dimensions the situation is quite different. Stokes's equation has no solutions that will tend to U_∞, and the far field must be solved and matched to the near-field Stokes flow. An alternative approach is to linearize the problem about U_∞ as formulated by Oseen. He approximated the convective term as $U_\infty \partial u/\partial x$ and could find solutions that cover both regions. The drag on a circular cylinder from an Oseen solution is

$$C_D = \frac{8\pi}{Re[0.5 - \Gamma + \ln(8/Re)]}. \qquad (111)$$

Here Re is based on the diameter and Γ is the Euler constant. From a practical standpoint it is very difficult to produce a low–Reynolds-number flow without end or sidewall effects.

16. STABILITY AND TURBULENCE

The flows discussed above are not necessarily unique solutions. Sometimes solutions are known to exist only for restricted values of the Reynolds number. The question of stability and nonuniqueness is addressed in the article FLUID DYNAMICS, NONEQUILIBRIUM. Many times the flow that exists is a time-dependent flow with a mean profile and fluctuations of 10%–20% called turbulence. For this subject the reader should consult the article TURBULENT FLOWS.

GLOSSARY

Conservation Laws, Local: Differential equations in space and time that govern the properties of matter at each and every point in space.

Conservation Laws, Global: Integral equations that relate the average properties of a region to the events at the surface of the region.

Constitutive Equations: Relations for the molecular fluxes of mass, momentum, or energy in terms of thermodynamic properties and the state of motion of the fluid.

Interfaces: Surfaces where the density is discontinuous because of a change of material or shock or combustion wave.

Jump Conditions: Relations that govern discontinuities of fluid properties at interfaces.

Stability: The growth or decay of a small perturbation that is imagined to exist within the flow. Contrast with "mathematical stability": stability against small changes in boundary conditions.

Turbulence: Flows that have an unsteady fluctuation in the local velocity. The fluctuations must be sustained and have a continuous spectrum.

Viscous Dissipation: The portion of the work of viscous stresses that heats the fluid to increase its internal energy.

Vorticity: Solid-like rotation of a fluid particle.

INTRODUCTION

Fluid matter, under applied stresses, flows and dissipates energy through viscous friction within the fluid and at bounding walls. Thermodynamically, this is already a nonequilibrium system needing external fluxes of energy, momentum, or mass to sustain the fluid motion. However, if the stresses are small enough, the state of the fluid is dominated by dissipative processes and remains close to the equilibrium conditions of the fluid at rest. The velocity field has the same symmetry as the externally imposed conditions. This state of fluid motion is called the thermodynamic branch or the primary flow.

Experience shows that a point is reached where the primary flow is not stable, even though it is in dynamic equilibrium with energy input balancing energy dissipation and

applied stresses balancing viscous drag. At the point of instability, internal fluctuations or small external disturbances are selectively amplified and the fluid motion bifurcates (branches) to a new type of motion with different symmetry. As the stresses are increased from zero, the fluid flow may undergo a sequence of such symmetry-breaking bifurcations, or it may suddenly make a transition directly to turbulence. A smooth change in an externally imposed control parameter—for example, mass flux—can be used to bring fluid flows to the point of instability. However, in some flows there is also a spatial evolution from a simple uniform structure to turbulence as the fluid passes downstream from the source. Thus there is a wide range of possible responses of fluid flows to increasing applied stresses.

The hydrodynamic instability of the basic flow, the resulting secondary flows, and the process of transition to turbulence are the subjects of this article. This is an extremely broad field, since instability is the rule rather than the exception in fluid dynamics. It is also a highly interdisciplinary field, involving mathematicians, physicists, engineers, and any other applied scientists working with processes involving fluid motion.

There are many ways in which transitional flows are important to science and technology. First, an important new scientific viewpoint comes from the observation that nonequilibrium systems may spontaneously order themselves into cooperative motion with well-defined patterns and length scales. This process is referred to as self-organization, and the resulting patterns are called dissipative structures. These structures can be a key element of technological devices; an example from optics is the spontaneous amplification and saturation of a single mode in a laser cavity. Perhaps there are hydrodynamic analogs that will also be put to practical use. An important and unifying idea is the slaving principle: certain critical modes arise from fluctuations and entrain all the remaining modes. As a result, the original continuum equations of motion may be reduced in many problems to a finite set of nonlinear ordinary differential equations. The study of such equations—dynamical systems—has been under intense development in recent decades.

Understanding hydrodynamic instabilities also helps clarify the origins and mechanics of turbulence. In many turbulent flows, large-scale structures resemble the secondary flows that arose during the instabilities leading to the turbulent state. Also, turbulence may sustain itself through processes very similar to instabilities, such as through inertial effects at local inflection points within the turbulent velocity field or through instability of a region of vorticity to stretching and reorientation. Finally, turbulent flows are governed by the same deterministic equations that describe transitional flows; thus there may be some relation between the occurrence of extreme disorder in turbulent flows and the observation of chaotic dynamics in some of the simpler flows arising from instability.

Technological applications often seek either to induce or to delay instabilities and the onset of turbulence. In heat-transfer or mixing processes, secondary flows and turbulence are desirable because they improve transport. Similarly, the onset of turbulence in airfoil boundary layers may prevent boundary-layer separation that could adversely affect the airfoil lift. On the other hand, if both separation and turbulent boundary layers could be prevented, the airfoil would have improved lift-to-drag characteristics; hence there has been considerable research into the design of laminar airfoils in which transition is suppressed by geometry, suction, etc. In other applications (such as ventilation) it is also desirable to maintain steady uniform flows because of the higher energy costs associated with the more dissipative turbulent flows; such flows are also likely to cause harmful vibrations. Still other applications seek a compromise whereby secondary flows are created to increase transport but further transition is arrested in order to minimize energy consumption. Finally, flows on the verge of transition might be useful as amplifiers of weak disturbances.

An essential feature of nonequilibrium flows is the nonlinearity of the equations of motion. An important consequence of nonlinearity is the nonuniqueness of states of motion satisfying the equations and boundary conditions. Some, but not all, such states may be stable; which one of a multiplicity of stable solutions is selected depends on the history by which the flow state was prepared. This is in contrast to linear problems, which respond to imposed conditions in a unique way. It is now also known that a system of only three coupled nonlinear ordinary differential equations can produce motion that is chaotic; that is, the motion is so sensitive to initial conditions that predictability decays exponentially with time.

The study of nonequilibrium systems advances through close interaction of precise experiments (often under computer control), mathematical analysis, and large-scale numerical simulations. While many important theoretical models have been developed to understand transitional flows, experiments identify both the successes and limitations of these models in describing real processes. Often the bridge between experiments and the mathematical models is made using accurate numerical simulations. Simulations, in turn, serve as exploratory tools when either theory or experiment is intractable. Unfortunately, many problems in transitional flows involve ranges of space and time scales that are still beyond the capabilities of computers. Over all, the subject remains full of unanswered questions, and the theory is undergoing rapid growth. Thus it is helpful to approach this subject with a broad overview of the basic instability mechanisms and of the observational facts.

In the following, we start with a mathematical primer in order to create a point of view for examining the variety of instability phenomena. This point of view is tentative; for example, we are still far from a complete understanding of transition in shear flows and in wakes. The next part of the article then discusses several important and physically distinct types of instabilities, including a description of the geometries and relevant parameters, an outline of the basic theory, and a summary of experimental observations. Notation conforms to the usage found in the literature and may vary somewhat from one type of flow to another. The article continues with a discussion of the application of the theory of chaotic dynamical systems to nonequilibrium flows. It concludes with a guide to further reading. Instabilities in compressible, magnetohydrodynamic, and non-Newtonian fluids have been excluded (see COMPRESSIBLE FLOWS; MAGNETOHYDRODYNAMICS). Also, the important subjects of experimental and numerical methods are beyond the scope of this article, although some references are given in the guide to further reading.

1. MATHEMATICAL TOOLS

The starting point for analysis of nonequilibrium flows is the set of mass, momentum (Navier-Stokes), and energy conservation equations for an incompressible fluid. The fluid is assumed to be a pure fluid in local thermodynamic equilibrium obeying Newton's law relating viscous stress to rate of strain and Fourier's law of heat conduction. For the origin of these equations and the generalization to a wider class of fluids (for example, compressible fluids), see FLUID DYNAMICS, EQUILIBRIUM.

The independent variables are position

$$\mathbf{r}=(x_1,x_2,x_3)=(x,y,z) \text{ with Cartesian}$$

$$\text{unit vectors } \hat{\mathbf{x}},\hat{\mathbf{y}},\hat{\mathbf{z}}$$

$$=(r,\theta,z) \text{ with cylindrical polar}$$

$$\text{unit vectors } \hat{\mathbf{r}},\hat{\boldsymbol{\theta}},\hat{\mathbf{z}},$$

and time t. The fields are velocity

$$\mathbf{u}=(u_1,u_2,u_3)=(u,v,w),$$

vorticity

$$\omega\equiv\nabla\times\mathbf{u},$$

pressure p, temperature T, density ρ, concentration c. The thermodynamic coefficients for various fluid properties are kinematic viscosity ν ($\mathrm{m^2\,s^{-1}}$), specific heat c_p ($\mathrm{J\,kg^{-1}\,K^{-1}}$) (at constant pressure), thermal conductivity k_{th} ($\mathrm{W\,m^{-1}\,K^{-1}}$), thermal diffusivity $\kappa\equiv k_{\mathrm{th}}/\rho c_p$ ($\mathrm{m^2\,s^{-1}}$), diffusion coefficient κ_c ($\mathrm{m^2\,s^{-1}}$), surface tension γ ($\mathrm{N\,m^{-1}}$), and coefficient of expansion

$$\alpha\equiv-\frac{1}{\rho}\left(\frac{\partial\rho}{\partial T}\right)_p .$$

A body force per unit mass $-g\hat{\mathbf{z}}$ acts due to a gravitational field with local acceleration g in the downward vertical direction $-\hat{\mathbf{z}}$. With these definitions (but omitting concentration-dependent terms), the equations are

$$\nabla\cdot\mathbf{u}=0, \tag{1a}$$

$$\frac{\partial\mathbf{u}}{\partial t}+(\mathbf{u}\cdot\nabla)\mathbf{u}=-\frac{1}{\rho}\nabla p+\nu\nabla^2\mathbf{u}-g\hat{\mathbf{z}}, \tag{1b}$$

$$\frac{\partial T}{\partial t}+(\mathbf{u}\cdot\nabla)T=\kappa\nabla^2T+\boldsymbol{\tau}':\nabla\mathbf{u}+\frac{\alpha}{\rho c_p}\left(\frac{\partial p}{\partial t}+(\mathbf{u}\cdot\nabla)p\right), \tag{1c}$$

$$\rho=\rho(T), \tag{1d}$$

$$\Delta p=\gamma\nabla\cdot\hat{\mathbf{n}}, \tag{1e}$$

where $\tau'_{ij}\equiv\nu(\partial u_i/\partial x_j+\partial u_j/\partial x_i)$ is the viscous part of the stress tensor for a Newtonian fluid and Δp is the jump in pressure entering a fluid whose interface has outward normal $\hat{\mathbf{n}}$. The nonlinearity of these equations is evident in the advective terms $(\mathbf{u}\cdot\nabla)\mathbf{u}$, $(\mathbf{u}\cdot\nabla)T$, and $(\mathbf{u}\cdot\nabla)p$ and the dissipative term (often ignored) $\boldsymbol{\tau}':\nabla\mathbf{u}$. Further nonlinearity may arise from the boundary conditions, typically in the case of deformable surfaces. Indeed, the problem is not completely posed until initial conditions and boundary conditions are set; these will be discussed in Sec. 2 below for each particular type of instability.

1.1 Characteristic Scales and Nondimensional Form of the Equations

It is very useful, though sometimes tricky, to identify the intrinsic scales of the problem. There is typically a length scale d over which the gradients are originally imposed (e.g., the gap between two parallel plates held at different temperatures in a thermal convection experiment, or the boundary-layer thickness). The other length scales of the system may be referred to this length scale; for example, experiments are confined to a dimension L in a direction where the theory idealizes an infinite extent. The dimensionless length $\Gamma\equiv L/d$ is called the aspect ratio for that direction. Systems with large aspect ratio are almost translationally invariant in the long direction and allow (approximately) a separation of spatial variables. Small–aspect-ratio systems usually preclude a separation of the spatial variables; however, they may be dynamically simpler in the sense that they permit only a small finite number of active modes.

One of the most important dimensionless constants applied to the study of transition flows is the Reynolds number Re. Assuming a characteristic velocity of magnitude U (for example, the free-stream velocity in boundary layer flow or the center-line velocity in flow through ducts), we have

$$Re\equiv Ud/\nu. \tag{2}$$

This is often interpreted as the ratio of "inertial forces" to "viscous forces." An alternative interpretation is that $Re=\tau_a/\tau_\nu$. Here τ_a is the advective time scale U/d, the time for a fluid element with characteristic speed U to transport momentum across the characteristic length d. The viscous time scale $\tau_\nu\equiv d^2/\nu$ measures the time scale for momentum to diffuse across the same length d.

New space and time scales may enter the problem after flow transition occurs. This applies especially to secondary-flow patterns, in which there is a length $2\pi/k$ associated with a mode with wave vector k (usually this scale is set by d) and a correlation length ξ that describes the distance over which the organized motion remains correlated. There is also a time scale, often quite long, for disruptions of a pattern to diffuse through the system. In flows that evolve spatially into fully turbulent motion, there are empirical space and time scales associated with the streamwise development; however, these scales await a systematic theoretical description.

Typically, the first step of analysis is to convert the governing equations to nondimensional form by expressing dependent and independent variables in terms of the intrinsic scales. Results may then be compared from experiments with similar geometries but different sizes and fluids. Also, the relative importance of terms may be inferred; this must be done with caution, however, since solutions can have singular dependence on small parameters over subdomains of the flow. An example is boundary layers, in which there are large gradients and viscous terms remain important even when the viscosity is very small.

To illustrate a nondimensional form of the Navier-Stokes equation, let $\mathbf{r}'=\mathbf{r}/d$, $t'=t/\tau_a=tU/d$, $\mathbf{u}'=\mathbf{u}/U$, and $p'=p/\rho U^2$. Then

$$\frac{\partial \mathbf{u}'}{\partial t'}+(\mathbf{u}\cdot\nabla)\mathbf{u}'=-\nabla p'+\frac{1}{Re}\nabla^2\mathbf{u}'-\frac{1}{Fr^2}\hat{\mathbf{z}}. \tag{3}$$

Here the additional dimensionless parameter $Fr\equiv U/(gd)^{1/2}$ (Froude number) measures the relative importance of inertial and gravitational terms and is important in free-surface problems. Note that since g is fixed and the range of kinematic viscosities ν for common working fluids is limited, it is usually not possible to match both Reynolds number and Froude number in comparing the motion of real ships to that of ship models. Such a match might be achieved, however, in some modeling experiments by using liquid helium.

There is an ambiguity in the choice of time scale: one might have chosen $t''=t/\tau_\nu=t\nu/d^2=(1/Re)t'$. Indeed, sometimes this is more appropriate since the growth and spreading of disturbances near the first instability is characterized by a viscous time scale. The choice of scales is seldom unique; furthermore, many problems (for example, boundary-layer problems) require a separation into spatial regions or time domains governed by completely different scales.

Other dimensionless parameters will arise in the specific instability problems discussed in Sec. 2 below.

1.2 Analytical Approaches

This section is rather formal and the reader may wish to look briefly first at particular examples of instabilities in Sec. 2. The following material is, however, an important primer for much of the current research literature on instability phenomena.

1.2.1 Energy Methods and Global Stability. A general argument shows that the solution corresponding to the thermodynamic branch is unique when the external stresses are sufficiently small. In this case, if a fluid system is started from an arbitrary initial state consistent with the governing equations (for example, the initial velocity field is divergence-free), then there will be a transient motion that ultimately settles into the unique primary flow. Similar arguments, based on energy considerations or on various integral forms of the governing equations, can even set bounds on the applied stresses beneath which the primary flow remains stable. Little is assumed about the nature of the stresses, so that the theory shows when the system is globally stable to all perturbations. Sometimes these limits correspond to the observed stability limits, but often they are too conservative: the flow may remain stable well beyond the established limits. Nonetheless, these techniques yield valuable insights into the physical processes involved in flow stability; see Joseph (1976a,b, 1985) for further discussion.

1.2.2 Operator Form of the Disturbance Field Equations. Consider the total velocity and pressure fields as the sum of the base fields $(\mathbf{U},P)$ and disturbance fields $(\mathbf{u},p)$. The base fields* separately satisfy the equations of motion and boundary conditions. In the following, we assume fixed boundaries (see Secs. 2.1–2.3 for problems with moving boundaries); also, we ignore thermal effects (see Sec. 2.4). The resulting equations for the disturbances are

$$\nabla\cdot\mathbf{u}=0, \tag{4a}$$

$$\frac{\partial \mathbf{u}}{\partial t}+(\mathbf{U}\cdot\nabla)\mathbf{u}+(\mathbf{u}\cdot\nabla)\mathbf{U}+(\mathbf{u}\cdot\nabla)\mathbf{u}$$
$$=-\nabla p+\frac{1}{Re}\nabla^2\mathbf{u}, \tag{4b}$$

with homogeneous conditions on the boundary δV,

$$\mathbf{u}|_{\delta V}=\mathbf{0},\quad p|_{\delta V}=0. \tag{4c}$$

This system may be rewritten in operator form as

$$\mathscr{L}\Psi+\mathscr{N}(\Psi,\Psi)=\mathscr{M}\frac{\partial\Psi}{\partial t}, \tag{5a}$$

where

$$\Psi\equiv\begin{pmatrix}u_x\\u_y\\u_z\\p\end{pmatrix}, \tag{5b}$$

---

*The base field need not be the primary flow (thermodynamic branch). We could be linearizing about a secondary flow to find *its* stability properties.

$$\mathscr{L}\equiv\begin{pmatrix} \frac{1}{Re}\nabla^2-\mathbf{U}\cdot\nabla-\frac{\partial U_x}{\partial x} & -\frac{\partial U_x}{\partial y} & -\frac{\partial U_x}{\partial z} & -\frac{\partial}{\partial x} \\ -\frac{\partial U_y}{\partial x} & \frac{1}{Re}\nabla^2-\mathbf{U}\cdot\nabla-\frac{\partial U_y}{\partial y} & -\frac{\partial U_y}{\partial z} & -\frac{\partial}{\partial y} \\ \frac{\partial U_z}{\partial x} & \frac{\partial U_z}{\partial y} & \frac{1}{Re}\nabla^2-\mathbf{U}\cdot\nabla-\frac{\partial U_z}{\partial z} & -\frac{\partial}{\partial z} \\ \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} & 0 \end{pmatrix}. \qquad (6a)$$

$$\mathscr{M}\equiv\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \qquad (6b)$$

and the nonlinear term is

$$\mathscr{N}(\Psi^{(1)},\Psi^{(2)})=-\begin{pmatrix} \mathbf{u}^{(1)}\cdot\nabla u_x^{(2)} \\ \mathbf{u}^{(1)}\cdot\nabla u_y^{(2)} \\ \mathbf{u}^{(1)}\cdot\nabla u_z^{(2)} \\ 0 \end{pmatrix}. \qquad (6c)$$

Note further that $\mathscr{N}$ is a bilinear operator:

$$\begin{aligned}&\mathscr{N}(\Psi^{(1)}+\Psi^{(2)},\Psi^{(3)}+\Psi^{(4)})\\ &\quad=\mathscr{N}(\Psi^{(1)},\Psi^{(3)})+\mathscr{N}(\Psi^{(1)},\Psi^{(4)})\\ &\qquad+\mathscr{N}(\Psi^{(2)},\Psi^{(3)})+\mathscr{N}(\Psi^{(2)},\Psi^{(4)}), \qquad (7a)\end{aligned}$$

$$\mathscr{N}(a\Psi^{(1)},b\Psi^{(2)})=ab\mathscr{N}(\Psi^{(1)},\psi^{(2)}). \qquad (7b)$$

(Nonlinear terms arising from the kinematical conditions of free-surface problems do not have this property.)

1.2.3 Linear Stability. An important first step in analyzing the system equation (5a) is to neglect the nonlinear term $\mathscr{N}(\Psi,\Psi)$ and solve the linear problem

$$\mathscr{L}\Psi=\mathscr{M}\frac{\partial\Psi}{\partial t}, \qquad (8a)$$

subject to the same boundary conditions

$$\mathbf{u}|_{\delta V}=\mathbf{0},\quad p|_{\delta V}=0. \qquad (8b)$$

Typically, systems are idealized as unbounded in one or two directions, say x and y. For example, fluid channels are presumed infinitely long and infinitely wide (but they have finite depth). There are two choices in completing the statement of the problem:

1. Temporal instability: the linear system is considered an initial-value problem with a specified initial disturbance $\Psi(x,y,z,t=0)$. The initial disturbance and subsequent solution are constrained to be bounded functions of the spatial variables, but the solution may, in the event of instability, become unbounded in time.*
2. Spatial instability: there is a prescribed harmonic forcing at some surface, say $x=0$: $\Psi(x=0,y,z,t)=\Psi(y,z)e^{i\omega_0 t}$. (Some specification of the spatial derivatives of Ψ at $x=0$ is also necessary.) The solution is presumed to also be harmonic in time but may become unbounded in space, say as $x\to\infty$.

According to the method of normal modes, one ignores particular initial or forcing conditions and looks for a complete set of linearly independent solutions to the problem posed by Eq. (8) and its boundary conditions. Arbitrary disturbances can then be represented by series expansions in the normal modes (see Sec. 1.2.4). If any of these normal modes is found to grow exponentially in time or space (depending on how the problem is posed), the base flow is deemed to be unstable.

If the base flow $\mathbf{U}$ is steady, then the operator $\mathscr{L}$ (which contains $\mathbf{U}$) is time independent, and so we can expect a separation of the normal-mode solutions into the form

$$\Psi(x,y,z,t)=\Psi_n(x,y,z)\exp(s_n t), \qquad (9)$$

where Ψ_n then satisfies the generalized eigenvalue equation

$$\mathscr{L}\Psi_n=s_n\mathscr{M}\Psi_n. \qquad (10)$$

---

*In inviscid flow theory, the possibility has arisen for there to be divergence, in finite time, of the velocity in some local region of space.

The index n shows that there are many modes consistent with the boundary conditions, as in the analogous example of vibrations of a stretched string. In most problems studied so far, the base flow only depends on one coordinate, say z, so that the operator $\mathscr{L}$ is also independent of x and y. In this case we may further expect the normal-mode solutions to be of the form

$$\Psi_n(x,y,z)=\Psi_{nk_xk_y}(z)\exp(ik_xx+ik_yy). \tag{11a}$$

In systems with cylindrical symmetry, $\mathscr{L}$ is independent of z and θ and the solutions must be strictly periodic in θ. We then expect solutions of form

$$\Psi_n(r,\theta,z)=\Psi_{nmk_z}(r)\exp(ik_zz+im\theta). \tag{11b}$$

Clearly, there are many practical problems (for example, swept wings, complex turbine geometries, etc) that are intrinsically three dimensional, so that the above separations are not possible. These are much less tractable for analysis and numerical methods must be employed; however, it is often best to first consider two-dimensional limiting cases.

Thus the linear stability problem often reduces to the form

$$\mathscr{L}(k_x,k_y,z;Re)\Psi_{nk_xk_y}=s_n(k_x,k_y;Re)\mathscr{M}\Psi_{nk_xk_y}, \tag{12}$$

where the dependence of the linear operator on (k_x,k_y,z,Re) has been made explicit and the k_y,k_y dependence of the eigenvalues $s=s_n(k_x,k_y;Re)$ constitutes a dispersion relation. Note that we may think of the index n as describing different "bands" of dispersion relations $s=s_n(k_x,k_y;Re)$, because there are infinitely many solutions $\Psi_{nk_xk_y}(z)$ even when $(k_x,k_y;Re)$ are fixed.

If the problem is posed as a temporal instability problem, the wave numbers k_x and k_y must be real so that the solution remains a bounded function of the spatial variables. However, the eigenvalue s may be taken to be complex:

$$s_n(k_x,k_y;Re)=\sigma_n(k_x,k_y;Re)+i\omega_n(k_x,k_y;Re). \tag{13}$$

If as the Reynolds number Re is increased, $\sigma_n(k_x,k_y;Re)$ passes from a negative value to a positive value, we have instability to a temporally growing mode, that is, a mode whose magnitude grows as $\exp(\sigma_nt)$. The value of Re where this crossover occurs is given by the marginal stability condition:

$$\sigma_n(k_x,k_y;Re)=0. \tag{14}$$

This implicitly defines a relationship $Re=f_n(k_x,k_y)$, and the minimum Re over all choices of n,k_x,k_y establishes a critical Reynolds number Re_c and critical wave numbers k_{xc},k_{yc}. Usually, the index n is ordered so that $n=1$ corresponds to the least stable band. Often, the symmetry is such that only the magnitude $k\equiv(k_x^2+k_y^2)^{1/2}$ is important; in other cases [especially parallel shear flows with a base flow $U(y)$ in the x direction], it can be shown that instability occurs soonest for two-dimensional modes so that we can let $k_y=0$ and define $k\equiv k_x$. Assuming $n=1$ for the most unstable band, the marginal stability condition then reduces to a marginal curve $Re=f(k)$ whose minimum defines the critical values (k_c,Re_c)—see Fig. 1(a). Evaluating the imaginary part of s at these critical values gives a critical frequency $\omega_c\equiv\omega_1(Re_c,k_c)$. If this frequency $\omega_c=0$, the instability has historically been called an exchange of stabilities: one steady flow is replaced by another steady flow. If instead $\omega_c\neq0$, this is usually called a Hopf bifurcation: a steady flow changes to a time-periodic flow.

When the problem is posed as a spatial stability problem, the eigenvalue s is con-

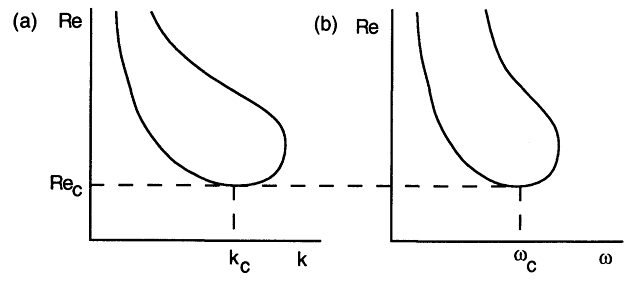

FIG. 1. Marginal stability curves (a) for temporal instability (b) for spatial instability.

strained to be purely imaginary and equal to the driving frequency:

$$s_n(k_x,k_y;Re)=i\omega_0. \tag{15}$$

This implicitly defines a functional dependence of a wave number, now complex, on the other parameters:

$$k_x(\omega_0,Re,k_y)=k_{xr}(\omega_0,Re,k_y)+ik_{xi}(\omega_0,Re,k_y). \tag{16}$$

The wave number k_y is usually set equal to zero or to some real value: the time-harmonic forcing at $x=0$ is either uniform or spatially periodic in the y direction. If, as the Reynolds number is increased, the imaginary part $k_{xi}(\omega_0,Re)$ goes from positive to negative, then we have instability to a spatially growing mode whose magnitude grows as $\exp(k_{xi}x)$. The marginal stability condition is now written as

$$k_{xi}(\omega_0,Re,k_y)=0. \tag{17}$$

Assuming that $k_y=0$, this gives a marginal curve

$$Re=Re(\omega_0), \tag{18}$$

whose minimum defines the critical values (ω_c,Re_c): see Fig. 1(b). The real part of the critical wave number is then determined by $k_c\equiv k_{xr}(\omega_c,Re_c)$.

Usually the temporal stability problem is much simpler, since the linear problem, Eq. (12), has a much more complicated dependence on k than on s. It is important to note that, regardless of whether the problem is posed as one of temporal instability or spatial instability, there is a unique critical Reynolds number Re_c where linear stability theory predicts transition to occur. However, above the critical Re_c one may be interested in knowing how the temporal and spatial growth rates are related. An approximate relation is given by Gaster's transformation (Gaster, 1962):

$$k_i\approx-\sigma/v_{gc}, \tag{19a}$$

where v_{gc} is the group velocity of the critical eigenmode:

$$v_{gc}\equiv\frac{\partial\omega}{\partial k}\quad\text{evaluated at } Re_c,k_c. \tag{19b}$$

It is an intriguing aspect of study of hydrodynamic instabilities that for some flows (for example, flow between rotating cylinders) the first transition occurs very close to the predicted critical Reynolds number, but in other flows (for example, boundary-layer instability) linear stability theory overestimates the threshold for transition. The latter situation is understood to result from the susceptibility of the flow to finite, rather than infinitesimal, disturbances; however, the process of transition in this case remains incompletely understood.

1.2.4 Evolution of Arbitrary Disturbances. Of course, a real experiment cannot just launch a single normal mode into the flow to see if it grows. Thus the normal-mode approach must be related to the practical situation of more general initial disturbances or more general forcing conditions. Suppose the domain is bounded in the transverse coordinate z, as in channel flow or in thermal convection in horizontal layers. (In other problems, like pipe flow or flow between cylinders, replace z with r). Then the spectrum of eigenvalues $s_n(k_x,k_y;Re)$ for given k_x and k_y is discrete and the corresponding set of eigenfunctions is complete. An arbitrary disturbance then evolves as a superposition of normal modes:

$$\Psi(x,y,z,t)=\int_{-\infty}^{\infty}dk_x\int_{-\infty}^{\infty}dk_y\sum_{n=1}^{\infty}A_n(k_x,k_y)\times\Psi_{nk_xk_y}(z)e^{i(k_xx+k_yy)}e^{s_n(k_x,k_y;Re)t}, \tag{20}$$

where the mode amplitudes $A_n(k_x,k_y)$ are determined by the initial condition $\Psi(x,y,z,t=0)$.

For flows with at least one boundary at infinity, such as boundary layers and free shear layers, the spectrum will contain, for fixed k_x and k_y, a *finite* number of discrete eigenvalues $s_n(k_xk_y;Re)$, and the corresponding set of eigenfunctions cannot be complete. There are various ways of dealing with this situation, such as by solving the linearized equations with Fourier-Laplace transforms (Huerre and Monkewitz, 1990) or by admitting a wider class of basis functions subject to the generalized boundary conditions that disturbances $\mathbf{u},p$ remain bounded (rather than vanish) as $z\to\infty$ (Grosch and Salwen, 1978; Salwen and Grosch, 1981).

1.2.5 Convective versus Absolute Instabilities. What happens, within the scope of the linearized theory, to a local initial disturbance as it propagates in space and time? This question leads to an important distinction between types of instabilities. Neglecting nonlinear effects, a local disturbance will generate a wave packet that travels with the group velocity of the fastest-growing mode. If the disturbance travels away from the origin fast enough that the flow at the origin returns to the unperturbed state, even though the disturbance itself continues to grow as it moves [Fig. 2(a)], then the flow is said to undergo a convective instability. If the growth and spreading are sufficiently rapid that the flow at the origin is permanently affected, even though the center of the disturbance moves off in the direction of the group velocity [Fig. 2(b)], then the flow is said to undergo an absolute instability.

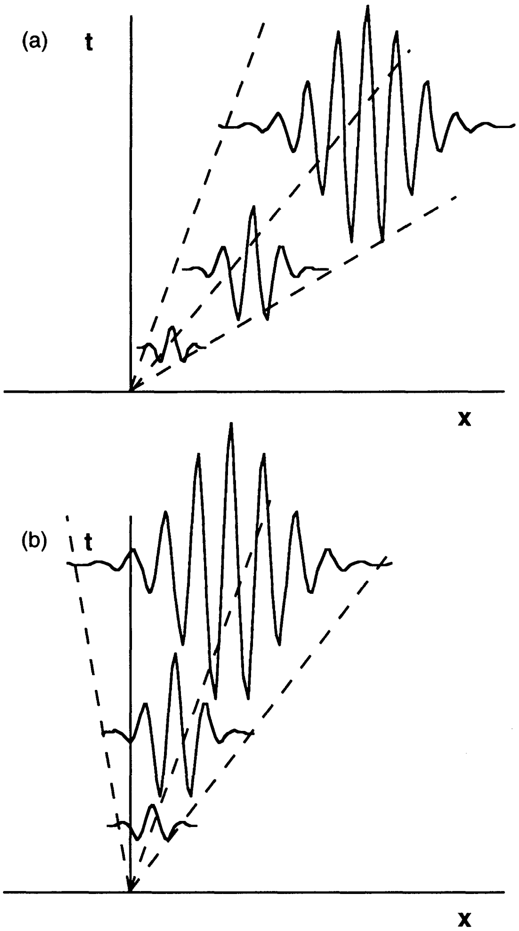

FIG. 2. Space–time diagram showing propagation of a local disturbance in (a) convectively unstable flow; (b) absolutely unstable flow.

Many open flows, in which there is a steady unidirectional mass flow through the system, are likely to be convectively unstable. If the length of the experimental system is too short, the instability might be overlooked because disturbances are washed out of the system before they are detected. On the other hand, even if the disturbances are detected, the resulting secondary flow will be erratic in phase and amplitude because it is driven by random fluctuations upstream of the detector. Power spectra of the velocity fluctuations will show broad peaks even though the linear-stability theory indicates a well-defined frequency at onset of the instability. In contrast, the secondary mode in an absolutely unstable flow becomes coherent (assuming no further instabilities) and exhibits a well-defined frequency (sharp peaks in a power spectrum). Note that one way to overcome the randomness in a convectively unstable flow is to force the flow with a controlled disturbance stronger than any fluctuations or noise in the system.

While convective instabilities are associated with open flows, they can occur in closed systems that produce traveling-wave modes with nonzero group velocity. Examples are binary-fluid convection and flow between counterrotating cylinders. If some means of feedback is provided—even in an open flow, for example, by having the flow impinge on a downstream obstacle such that pressure disturbances are radiated back upstream—the entire flow domain can still become filled with a coherent secondary flow. This is sometimes referred to as a global instability. Feedback provided by the end walls of convectively unstable closed systems can produce very interesting large length- and time-scale dynamics. An example is the "blinking state" in binary-fluid convection, where the waves slowly switch back and forth in time from left-going to right-going.

1.2.6 Temporal or Spatial Modulation: Floquet Theory. In some cases the base flow may be periodic in space and/or time. This may be due either to a physical modulation of stresses that drive the flow (Davis, 1976) or to the fact that a well-established secondary flow is considered as the base flow and we wish to consider *its* stability relative to further changes in the flow patterns.

If the base flow is time periodic with period T, then the Floquet theory of linear differential equations with periodic coefficients (Iooss and Joseph, 1990) leads to a modified eigenfunction of the form

$$\Psi=\Psi_n(t)\exp(s_n t), \tag{21a}$$

where

$$\Psi_n(t+T)=\Psi_n(t), \tag{21b}$$

and s_n, called the Floquet exponent, has an imaginary part within the bounds

$$-\pi/T\leqslant\omega_n<\pi/T. \tag{21c}$$

If the base flow is *spatially* periodic in the x direction with period Λ (but presumed homogeneous in the y direction), then the eigenfunction is modified to

$$\Psi_n=\Psi_{nk_xk_y}(x,z)\exp(ik_x x+ik_y y) \tag{22a}$$

with a spatially periodic part

$$\Psi_{nk_xk_y}(x+\Lambda,z)=\Psi_{nk_xk_y}(x,z), \tag{22b}$$

and the real part of the spatial Floquet exponent is within the bounds

$$-\pi/\Lambda\leqslant k_{xr}<\pi/\Lambda. \tag{22c}$$

(By analogy with solid-state physics, we call this range the "first Brillouin zone" and the Floquet theory for the form of Ψ_n given above is also known as Bloch's theorem.)

A special case of Floquet theory, applied to the parametric instability of surface waves, is discussed in Sec. 2.1.3.

1.2.7 Weakly Nonlinear Theory and Amplitude Equations. The linear-stability calculations, though difficult enough, do not determine the form of the flow after transition occurs. Disturbances cannot continue to grow exponentially; because of the nonlinearity of the equations, the base flow will be altered and higher harmonics of the disturbing mode will be produced through self-interaction. Perhaps this will lead to a saturation of the growing mode into a state that resembles the critical eigenfunction. If this new saturated secondary flow is itself stable and grows continuously from zero amplitude as the Reynolds number is increased, we say there is a supercritical bifurcation, and perturbation theory may be used to find approximations to the secondary flow.

The theory requires identification of a small parameter, typically $\epsilon\equiv(Re-Re_c)/Re_c$. We seek an equation for the complex amplitude $A(t;\epsilon)$, presumed small, of the eigenmode $\Psi_{1k_xk_y}(z)\exp(ik_x x+ik_y y-i\omega_c t)$ that has marginally destabilized the base flow at $Re=Re_c$. Landau (1944), with his usual heuristic brilliance, proposed an equation of the form

$$\frac{dA}{dt}=\sigma_0(1+ic_0)\epsilon A-(g_r+ig_i)|A|^2A, \tag{23}$$

the Landau equation. (Landau's formulation has been adapted to the notation of this article; also, many authors use τ_0^{-1} in place of σ_0.)

Several comments are in order. First, the linearized equation

$$\frac{dA}{dt}=\sigma_0(1+ic_0)\epsilon A \tag{24}$$

has eigenvalue $\sigma_0(1+ic_0)\epsilon$, which is just the first-order term in an expansion of the eigenvalue s in the parameter ϵ:

$$s=i\omega_c+\sigma_0(1+ic_0)\epsilon+O(\epsilon^2). \tag{25}$$

Considering this as a Taylor-series expansion, we identify

$$\sigma_0(1+ic_0)=\frac{\partial s}{\partial\epsilon}=Re_c\frac{\partial s}{\partial Re}\bigg|_{Re=Re_c}. \tag{26}$$

A second and very important comment is that this is the only form of the equation up to cubic order in A that is consistent with translational invariance in x and y. In another coordinate frame with coordinates $(x',y')=(x-x_0,y-y_0)$, the amplitude is $A'=A\exp(ik_x x_0+ik_y y_0)$. The physics must be the same, and so the same amplitude equation must be obtained for A'. Thus any phase shifts in A must cancel from the amplitude equation, as they do for the Landau form. We say that the amplitude equation is equivariant under translations in the (x,y) plane.

Finally, the complex Landau constant $g=g_r+ig_i$ describes the nonlinear saturation of the amplitude and the finite-amplitude corrections to the frequency ω. Before showing this, we note that computation of the Landau constant depends on the particular flow and requires a detailed perturbation analysis. The numerical value of g depends on the normalization chosen for the eigenfunction Ψ; unfortunately, authors sometimes overlook the important requirement to state this normalization when quoting a value for g.

In order to solve the Landau equation, write $A=\rho e^{i\phi}$. Then two equations result:

$$\frac{d\rho}{dt}=\sigma_0\epsilon\rho-g_r\rho^3, \tag{27a}$$

$$\frac{d\phi}{dt}=\sigma_0 c_0\epsilon-g_i\rho^2. \tag{27b}$$

Looking for solutions with ρ steady in time, we get, for $g_r>0$,

$\epsilon<0$: $\rho=0$, $\phi=\sigma_0 c_0\epsilon t$, stable;

$\epsilon>0$: $\rho=0$, $\phi=\sigma_0 c_0\epsilon t$, unstable,

$\rho=(\sigma_0\epsilon/g_r)^{1/2}$, $\phi=\sigma_0(c_0-g_i/g_r)\epsilon t$, stable;

for $g_r<0$,

$\epsilon<0$: $\rho=0$, $\phi=\sigma_0 c_0\epsilon t$, stable,

$\rho=(-\sigma_0\epsilon/g_r)^{1/2}$, $\phi=\sigma_0(c_0-g_i/g_r)\epsilon t$, unstable;

$\epsilon>0$: $\rho=0$, $\phi=\sigma_0 c_0\epsilon t$, unstable.

Note that Eq. (27a) for the magnitude ρ is decoupled from the phase equation. However, Eq. (27b) for the phase ϕ retains a dependence on ρ through the nonlinear term $-g_i\rho^2$. The solutions for ϕ may be interpreted as corrections to the frequency: $\omega=\omega_c+d\phi/dt$. Thus for $\epsilon>0$ in the supercritical case ($g_r>0$), the frequency is altered by a linear correction $\sigma_0 c_0\epsilon$ and a leading-order nonlinear correction $-g_i\rho^2=-\sigma_0(g_i/g_r)\epsilon$. The solutions for ρ and their stability are shown in the bifurcation diagrams of Fig. 3. Note the characteristic $\epsilon^{1/2}$ dependence of the bifurcating solutions. We see that the sign of the real part of the Landau constant is crucial. For positive g_r there is a stable supercritical mode bifurcating from the base state. For negative g_r, there is subcritical bifurcation to a solution that is unstable, and higher-order terms in the amplitude equation are needed to resolve what happened for $\epsilon>0$.

In fact, an exact time-dependent solution may be found for Eq. (27a) given an initial nonzero disturbance ρ_0:

$$\rho^2=\frac{\sigma_0\epsilon}{g_r}\,\frac{1}{1+(\sigma_0\epsilon/g_r\rho_0^2-1)e^{-2\sigma_0\epsilon t}}. \tag{29}$$

FIG. 3. Bifurcation diagrams for (a) supercritical bifurcation, (b) subcritical bifurcation, (c) subcritical bifurcation combined with turning point, resulting from a fifth-order term in the amplitude equation.

There have been beautiful experiments in several systems showing how the time-dependent growth ($\epsilon>0$) or decay ($\epsilon<0$) conforms to this equation. As an example from wake flow, see Provansal *et al.* (1987). Furthermore, the $\epsilon^{1/2}$ growth predicted by the Landau equation has been shown in precise experiments for several systems, including thermal convection and Taylor-Couette flow between rotating cylinders. For critical discussion of some of these experiments, see Ahlers (1989).

An amplitude equation with a fifth-order term $(h_r+ih_i)|A|^4A$ with $g_r<0$ but $h_r>0$ gives the bifurcation diagram in Fig. 3(c). The overlap of two stable solutions for $-g_r^2/4\sigma_0 h_r<\epsilon<0$ is experimentally observed as hysteresis: a carefully done experiment will observe the base flow while increasing ϵ up to $\epsilon=0$ but, upon decreasing ϵ, not recover the base flow until the lower limit $\epsilon=-g_r^2/4\sigma_0 h_r$. Even when the base flow is stable in the overlap range, a finite disturbance of sufficient size can produce the secondary-flow solution instead. Thus it may be very difficult to approach the linear-stability threshold $\epsilon=0$ in experiments involving subcritical bifurcations. This problem is exacerbated by the possibility that the upper-branch secondary flow, typically a two-dimensional flow, may be unstable to a wider class of perturbations (for example, three-dimensional disturbances). Thus one never sees a saturated secondary mode: only, perhaps, a transient that resembles it. Typically (in shear flows) there is a cascade of instabilities to turbulence, a situation sometimes referred to as snap-through transition to turbulence.

The systematic derivation of Landau's equation for specific flow problems was first accomplished for convection by Malkus and Veronis (1958), for channel flow by Stuart (1958, 1960) and Watson (1960), and for Taylor-Couette flow between rotating cylinders by Davey (1962). An important method for obtaining amplitude equations is the technique of center-manifold reduction (see Iooss and Adelmeyer, 1992; Haken, 1983; Richtmeyer, 1981). After the amplitude equations are obtained up to some order of approximation by such a reduction process, it may be necessary to convert them to normal form: a nonlinear change of variables eliminates as many nonlinear terms as possible (see Guckenheimer and Holmes, 1983). A variety of different flow problems may be reduced to the same normal form, which can often be predicted simply with such general considerations as the dimensionality of the problem (the number of interacting marginally stable modes) and the governing symmetries. Thus there is a universality among widely different physical systems in the sense that they are described by the same equation. In order to get the numerical values of the *coefficients* of the normal form, however, one must carry out the reduction process in detail for each particular fluid flow.

The existence of modes with a continuous band of wave vectors (k_x,k_y) centered around the critical wave vector $(k_c,0)$ is accounted for by allowing the amplitude to vary slowly in space and time. This leads to an extension of the Landau equation called an envelope equation (Newell, 1974, 1989). For steady-state transitions ($\omega=0$), as in thermal convection (see below), the envelope equation is

$$\frac{dA}{dt}=\sigma_0\epsilon A+\sigma_0\xi_0^2\left(\frac{\partial}{\partial x}-\frac{i}{2k_c}\frac{\partial^2}{\partial y^2}\right)^2 A-g|A|^2A, \tag{30}$$

where $\sigma_0\equiv\partial\sigma/\partial\epsilon$ and $\sigma_0\xi_0^2\equiv\partial^2\sigma/\partial k^2$ (evaluated at $\epsilon=0$ and $k=k_c$).

If there is a transition to oscillatory modes in quasi one-dimensional systems with reflection symmetry, one obtains either traveling waves or standing waves (depending on the nonlinear parameters); this leads to a coupled pair of complex Ginzburg-Landau equations:

$$\begin{aligned}\frac{dA}{dt}&=\sigma_0(1+ic_0)\epsilon A+v_g\frac{\partial A}{\partial x}\\&\quad+\sigma_0\xi_0^2(1+ic_1)\frac{\partial^2 A}{\partial x^2}-(g_r+ig_i)|A|^2A\\&\quad-(h_r+ih_i)|B|^2A,\end{aligned} \tag{31a}$$

$$\begin{aligned}\frac{dB}{dt}&=\sigma_0(1+ic_0)\epsilon B-v_g\frac{\partial B}{\partial x}\\&\quad+\sigma_0\xi_0^2(1+ic_1)\frac{\partial^2 B}{\partial x^2}-(g_r+ig_i)|B|^2B\\&\quad-(h_r+ih_i)|A|^2B.\end{aligned} \tag{31b}$$

Recalling that $s\equiv\sigma+i\omega$, the linear parameters are defined by derivatives evaluated at $\epsilon=0$ and $k=k_c$:

$$\sigma_0(1+ic_0)\equiv\frac{\partial s}{\partial\epsilon}$$

and

$$\sigma_0\xi_0^2(1+ic_1)\equiv\frac{\partial^2\sigma}{\partial k^2}.$$

Also, $v_g\equiv\partial\omega/\partial k$ is the group velocity, which must be small for the above equations to be a valid approximation. These equations can lead to some surprising dynamics that have been confirmed in experiment, including (for appropriate boundary conditions) spontaneous reversal of traveling-wave direction or to localized states. This discussion falls under the general topic of nonlinear pattern formation, the subject of reviews by Cross and Hohenberg (1993) and Newell *et al.* (1993).

1.2.8 Bifurcation Theory. Linear-stability theory predicts when a particular solution is unstable to a class of disturbances. The flow that results may or may not be described in terms of small perturbations away from the original flow, with dynamics described by amplitude equations. However, a more general question concerns the overall "universe" of possible solutions given a particular level of imposed stresses. Recall that for small stresses, there is a unique solution. As the stresses are increased, say in response to some control parameter μ, new solutions become possible. The classification of such solutions, their stability, and their relation to each other is the subject of bifurcation theory. Usually the theory is organized according to the systematic variation of one or more control parameters $(\mu_1,\mu_2,\ldots,\mu_m)$. We refer to the space of all possible values of these parameters as an m-dimensional parameter space with elements $\mu \equiv (\mu_1,\mu_2,\ldots,\mu_m)$.

Often, the first experiments with a fluid dynamical system will map the domains occupied in parameter space by various observed flows. Such a map is often called a phase diagram,* by analogy to thermodynamic response of substances to changes in temperature and pressure. As the parameters $\mu_1,\mu_2,\ldots,\mu_m$ are explored, the observed flows are not necessarily all possible solutions; they are just some of the stable ones. Furthermore, the observed flows may depend on the history of preparation. Often special efforts must be made to produce a flow that is a solution but is not usually obtained under normal experimental procedures. For example, control parameters may be quickly jumped to new values. There will be a strong transient, after which the final state may be quite different from that obtained by slow variation of the parameters to the same final values. Bifurcation theory serves as a guide to this search process.

For some flows (for example, boundary layers and free shear layers), the parameters evolve downstream and are thus not completely under the experimenter's control. In this case, bifurcation theory may be of more limited use but can still serve as a conceptual guide to understanding the transition process. Furthermore, the use of bifurcation theory is much simpler for small finite-sized systems or for systems hypothetically constrained to periodic boundary conditions. For such systems, there is a denumerable set of solutions, whereas infinite, translationally invariant systems possess continuous families of solutions. Moreover, a precise description of real experiments rests on a proper accounting of the finite size and of inevitable perturbations to assumed symmetries (Benjamin, 1978a,b).

A more modest goal than finding all possible fluid-flow solutions for a given μ is to find only those solutions that lie in a neighborhood in parameter space of the critical value μ_c where a particular solution becomes unstable. Under such circumstances, we say that the original solution "bifurcates" to the new solutions. Such bifurcation phenomena are most easily understood by first considering a single control parameter μ. Three complementary views of bifurcations are obtained by examining the response to changes in μ of

1. the spectrum of eigenvalues s of the normal modes of the problem linearized about the original solution;
2. some measure X that distinguishes different flow states from one another—for example, a component of the flow velocity at a particular point in space;
3. the dynamics in an abstract phase space whose coordinates are the amplitudes of relevant degrees of freedom of the system.

Discussion of phase-space dynamics is postponed to Sec. 3.

Consider a solution steady in time. We know that instability occurs when the eigenvalue s of some perturbation crosses the imaginary axis. If the eigenvalue remains real as it crosses [Fig. 4(a)], we speak of a steady-state bifurcation. If the eigenvalue is complex, then it crosses the imaginary axis at two complex-

FIG. 5. One-parameter bifurcations of steady solutions, with simplified versions of normal-form equations. Solid curves are stable solutions and dotted curves are unstable solutions. (a) Saddle node; (b) transcritical; (c) supercritical pitchfork; (d) subcritical pitchfork; (e) supercritical Hopf.

conjugate points $\pm i\omega_c$ [Fig. 4(b)] and we speak of a Hopf bifurcation.*

Next consider the variation of the measure X with μ. Plots of the curves $X(\mu)$ for all the possible solutions near μ_c are called bifurcation diagrams. The types of single-parameter ("codimension one") bifurcations from steady-state solutions are shown in Fig. 5 (Crawford, 1991). The measures X may be considered to be solutions of normal-form equations of the type

$$\frac{dX}{dt} = f(X,\mu), \tag{32}$$

where the appropriate $f(X,\mu)$ are shown in the figure. For the steady-state bifurcations, X may be considered real; for the Hopf bifurcation, the measure X for the bifurcating solution is complex with both an amplitude and a phase.

The pitchfork bifurcations in Fig. 5 assumed the symmetry that solutions with both X and $-X$ exist. Imperfections in the system will break this symmetry, changing these bifurcations into a composition of transcritical and saddle-node bifurcations as in Fig. 6(a). Furthermore, the idealized base state may be slightly wrong, again because of imperfections, and an inhomogeneous term must be put into the normal forms. The $X=0$ solutions of the transcritical and pitchfork bifurcations no longer solve the perturbed normal form and, as shown in Figs. 6(b) and 6(c), there is no true bifurcation of the base state into a qualitatively different solution, just a smooth deformation. This is called an imperfect bifurcation, and the generalization of the normal-form equations to account for perturbations is called an unfolding of the bifurcation. Note that there may be a nearby solution of different form, but it is no longer connected at some μ_c to the base state. Only the saddle-node bifurcation survives as generic, which means that it is not altered qualitatively by general perturbations of the normal form.

Suppose two parameters can be varied. Special cases of the bifurcations produced by varying, say, μ_1 can be obtained by tuning the other parameter, μ_2. These are called codimension-two bifurcations and include, for example,

---

*A complication arises in interpreting the bifurcation to traveling waves in systems with a preferred direction of flow, say channel flow. At any fixed value of μ, the traveling wave can appear as a stationary solution by transformation to a reference frame moving with the phase velocity of the traveling wave. However, the amplitude equation or "normal form" describing the bifurcation will be different from the normal form for a steady-state bifurcation because it will contain coefficients that cause the frequency of the wave to vary with amplitude [such as g_i in Eqs. (23) and (31)].

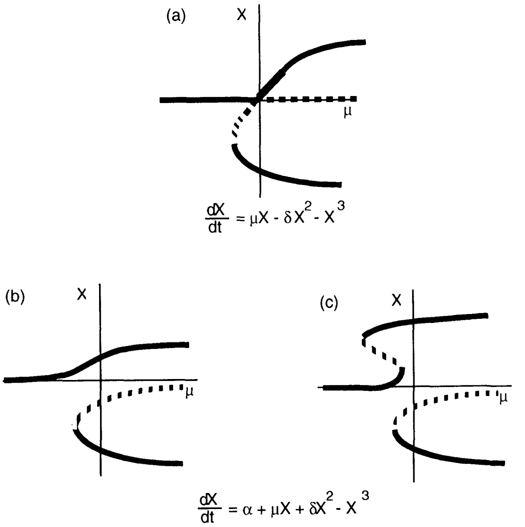

FIG. 6. The effect of system imperfections on a pitchfork bifurcation. (a) Reflection symmetry is no longer valid, and so a small term δX^2 is added to the normal form. (b), (c) Two cases resulting from a more general perturbation that causes the basic state $X=0$ to deform smoothly rather than reach a bifurcation: a small term α is added to the normal form.

1. switching of a bifurcation from supercritical to subcritical;
2. simultaneous bifurcation (bicriticality) of two independent modes that are not degenerate as a result of symmetry;
3. collision of two real eigenvalues to produce a complex-conjugate pair just when the eigenvalues cross the imaginary axis so that the frequency grows from zero (soft-mode instability).

Symmetry plays a crucial role in many fluid-dynamics bifurcation problems; the theory of bifurcations with symmetry has been under active development in recent years. For recent reviews, see Golubitsky *et al.* (1988) and Crawford and Knobloch (1991).

2. INSTABILITIES

The range of possible instabilities in fluid problems is enormous, and so we concentrate here on a few fundamentally different physical processes.

2.1 Waves and Instabilities at Flat Fluid Interfaces

Consider a flat interface $z=0$ between a fluid layer of density ρ_1 and a second one of density ρ_2 lying above the first (Fig. 7). The bottom layer terminates at $z=-h_1$ and the top layer terminates at $z=h_2$. There is an interfacial tension γ between the two fluids, and a body force $-\rho_i g\hat{\mathbf{z}}$ acts on each fluid (here and below, $i=1$ or 2). The base state is fluids at rest: $\mathbf{U}_1=\mathbf{0}$ and $\mathbf{U}_2=\mathbf{0}$. As shown in Fig. 7, let the fluid layer be deformed to a surface $z=\zeta(x,y,t)$, with consequent velocity fields $\mathbf{u}_1$ and $\mathbf{u}_2$. Our objective is to see how this deformation and these velocity fields evolve in time.

This is one case where the inviscid approximation works well. Furthermore, since the flow starts out irrotational ($\nabla\times\mathbf{u}_i=0$), we express the velocity fields in terms of potentials: $\mathbf{u}_i=\nabla\phi_i$. Incompressibility leads to Laplace's equation:

$$\nabla^2\phi_i=0, \tag{33}$$

with boundary conditions

$$u_z=\frac{\partial\phi_i}{\partial z}=0 \text{ at } z=\mp h_i \text{ for finite-width layers,} \tag{34}$$

or

$$\lim_{|z|\to\infty}\phi_i=0 \quad \text{for semi-infinite layers.} \tag{34b}$$

Given ϕ, the pressure p_i of each fluid is determined from Bernoulli's equation for unsteady motions:

$$\frac{\partial\phi_i}{\partial t}+\frac{1}{2}(\nabla\phi_i)^2+gz+\frac{p_i}{\rho_i}=C_i(t), \tag{35}$$

where $C_i(t)$ is an arbitrary function of time and can be absorbed into ϕ_i.

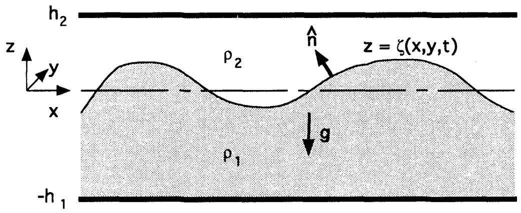

FIG. 7. Deformed interface $z=\zeta(x,y,t)$ between two fluids; gravity $\mathbf{g}$ acts downwards. The unit vector $\hat{\mathbf{n}}$ is normal to the surface.

Two linear conditions at the interface must also be satisfied. First, the pressure jump across the interface whose unit normal vector is $\hat{\mathbf{n}}$ is given by

$$p_2 - p_1 = -\gamma \nabla \cdot \hat{\mathbf{n}} \tag{36a}$$

$$= -\gamma \nabla \cdot \frac{(-\zeta_x, -\zeta_y, 1)}{[1+(\zeta_x)^2+(\zeta_y)^2]^{1/2}}, \tag{36b}$$

where the subscripts denote partial derivatives and all terms are evaluated at $\mathbf{r}=(x,y,\zeta(x,y,t))$. Combined with Bernoulli's equation above, the condition becomes

$$\rho_2\left(\frac{\partial \phi_2}{\partial t}+\frac{1}{2}(\nabla\phi_2)^2+g\zeta\right)-\rho_1\left(\frac{\partial \phi_1}{\partial t}+\frac{1}{2}(\nabla\phi_1)^2+g\zeta\right)$$

$$= -\gamma \nabla \cdot \frac{(-\zeta_x, -\zeta_y, 1)}{[1+(\zeta_x)^2+(\zeta_y)^2]^{1/2}}. \tag{37}$$

Second, the interface must follow the fluid motions. A scalar field $F(x,y,z) \equiv z-\zeta(x,y,t)$ has the constant value 0 on the interface, and so

$$\left(\frac{\partial}{\partial t}+\mathbf{u}_i \cdot \nabla\right)[z-\zeta(x,y,t)]=0, \tag{38}$$

which implies that the potentials satisfy

$$\frac{\partial \phi_i}{\partial z}=\frac{\partial \zeta}{\partial t}+\frac{\partial \phi_i}{\partial x}\frac{\partial \zeta}{\partial x}+\frac{\partial \phi_i}{\partial y}\frac{\partial \zeta}{\partial y}. \tag{39}$$

Again, all terms are evaluated at $\mathbf{r}=(x, y,\zeta(x,y,t))$.

Linearization keeps terms only to first order in the perturbations ϕ_1, ϕ_2, and ζ (and their derivatives). Furthermore, derivatives evaluated at the interface are approximated by derivatives evaluated at $z=0$. We expect solutions of the form

$$\Psi=\begin{pmatrix}\phi_1\\ \phi_2\\ \zeta\end{pmatrix}$$

$$=\begin{pmatrix}\hat{\phi}_1(z)\\ \hat{\phi}_2(z)\\ \zeta_0\end{pmatrix}\exp(ik_x x+ik_y y)\exp(st)+\text{c.c.} \tag{40}$$

(c.c. stands for "complex conjugate"). Insertion into the linearized problem yields the dispersion relation [here $k \equiv (k_x^2+k_y^2)^{1/2}$]

$$s^2=\frac{(\rho_2-\rho_1)gk-\gamma k^3}{\rho_1 \coth kh_1+\rho_2 \coth kh_2} \quad \text{for finite layers;} \tag{41a}$$

$$s^2=\frac{(\rho_2-\rho_1)gk-\gamma k^3}{\rho_1+\rho_2} \quad \text{for semi-infinite layers.} \tag{41b}$$

If $\rho_2 < \rho_1$ (light fluid over heavy fluid), $s=i\omega$ is purely imaginary, and so the modes are neutrally stable traveling waves:

$$\zeta(x,y,t)=\zeta_0 \exp[i(k_x x+k_y y-\omega t)]. \tag{42}$$

When the densities of both fluids are significant, the modes are called internal waves. For the case $\rho_2=0$, $\rho_1 \equiv \rho$, and semi-infinite layers, we recover the linear dispersion relation for "water" waves,

$$\omega^2=gk-(\gamma/\rho)k^3, \quad \text{capillary gravity waves.} \tag{43}$$

The two limiting cases are

$$\omega \approx \begin{cases}(gk)^{1/2}, & \text{long wavelength: gravity waves}\\ (\gamma k^3/\rho)^{1/2}, & \text{short wavelength: capillary waves.}\end{cases} \tag{44}$$

Both terms in the dispersion relation have equal size when

$$\lambda \equiv 2\pi/k$$

$$=2\pi(\gamma/\rho g)^{1/2}$$

$$\approx 1.7 \text{ cm (for pure water).} \tag{45}$$

$(\gamma/\rho g)^{1/2}$ is called the capillary length. A full treatment of this problem, including damping due to viscosity, is found in Chandrasekhar (1961).

2.1.1 Heavy Fluid Above Light Fluid: Rayleigh-Taylor Instability. Perhaps one of the most intuitive instabilities is that of a heavy fluid lying on top of a light fluid. Anyone who paints a ceiling thinks of this situation. A flat layer of heavy fluid can certainly be supported by the hydrostatic pressure of a lighter fluid, but any deformation of the interface quickly grows so that the fluids overturn (unless the heavy layer is thin enough to be supported, as it divides into droplets, by adhesion to the ceiling). The classic analysis of this problem is due to Lord Rayleigh.

A small perturbation grows if the eigenvalue s of the mode given in Eq. (40) has a positive real part. If the fluid is initially at rest but has an initial deformation $\zeta(x,y;t=0) =\zeta_0 \cos kx$, the interface will evolve in the linear approximation as $\zeta(t)=\zeta_0 \cos kx \cosh st$. From Eq. (41), growth will occur if $\rho_2>\rho_1$ and $k<k_{\text{cutoff}}=[(\rho_2-\rho_1)g/\gamma]^{1/2}$. Without surface tension all wave numbers are unstable. Thus the effect of surface tension is to place a small-wavelength cutoff: only modes with wavelengths longer than $2\pi/k_{\text{cutoff}}$ will grow. For pure water above air, this wavelength is again 1.7 cm. The cutoff wavelength is simply demonstrated by showing that water will remain in an inverted container if the opening is covered by a wire mesh. There is also a wave number of maximum growth rate. For semi-infinite layers $k_{\max}=k_{\text{cutoff}}/\sqrt{3}$.

Taylor (1950) recognized that this instability would also take place if the system had a uniform acceleration **a** in the direction towards the more dense layer, that is, if the light fluid pushes the heavy fluid. If there is both a uniform body force per unit mass **g** and a uniform acceleration **a**, one obtains an equivalent system by transforming to a noninertial frame at rest relative to the accelerating fluids and assuming a body force per unit mass $\mathbf{g}'=\mathbf{g}-\mathbf{a}$. Thus the surface of liquid in an upright container will be unstable if it is accelerated downwards faster than free fall.

An important application of this idea occurs in the study of inertial-confinement fusion (see FUSION, INERTIAL CONFINEMENT). A spherical pellet of deuterium is rapidly compressed by an radial inward thrust (ablative acceleration) of vapor produced by an intense laser pulse heating the pellet exterior. As the less dense vapor accelerates into the more dense interior of the pellet, an instability develops that disrupts the desired uniform compression. Another important application comes from plasma fusion: curved magnetic fields can act like an effective gravitational force. Inverted situations can arise so that confined plasmas are subject to Rayleigh-Taylor instabilities (see Infeld and Rowlands, 1990).

Considering again a planar geometry, the nonlinear behavior of the unstable interface is quite complex. The dense fluid may form falling spikes while the lighter fluid rises as bubbles with rounded fronts. The deforming interface is subject to shear instabilities, and there is a complicated process of breakup, coalescence, and mixing. A review of this process and its study may be found in Sharp (1984). Recently, well-controlled experiments (Fermigier *et al.*, 1992) have applied an amplitude-equation formalism to explain the weakly nonlinear pattern formation in unstable thin layers.

2.1.2 Shocks at Fluid Interfaces: Richtmeyer-Meshkov Instability. Treating a shock as an instantaneous acceleration, one expects instabilities in shock waves passing through a fluid interface (Richtmeyer, 1960; Meshkov, 1969). In fact, instability occurs regardless of the direction of the shock. Strong mixing is induced by the instability. An astrophysical application is the study of supernova explosions. Shock-tube experiments by R. F. Benjamin are compared to numerical simulations in Cloutman and Wehner (1992).

2.1.3 Parametrically Excited Surface Waves. In 1831 Michael Faraday observed pronounced deformations of the surface of liquid in a dish that oscillated up and down. Furthermore, the frequency of the surface patterns appeared to be *half* that of the driving frequency. This was an early record of the phenomenon of parametric instability, which has since been found and exploited in a wide variety of systems (mechanical, electrical, optical, etc.).

Benjamin and Ursell (1954) found that the linearized analysis of Faraday's experiment with a vibrating layer of fluid leads to Mathieu's equation [Eq. (50) below]. Let the undisturbed surface lie at $z=0$ and assume that the vertical position of the bottom of the dish vibrates in time as $z_0(t)=-h+\epsilon \cos\Omega t$. As with Taylor's analysis of accelerating fluid layers, we can transform to a noninertial frame by replacing gravity g with an effective gravity $g+\epsilon\Omega^2 \cos\Omega t$. The nomenclature "parametric instability" arises because the forcing of this system arises through one of the *parameters* (gravity). The surface is described in the noninertial frame by

$$z=\zeta(x,y,t)=\zeta_0(t)S_{lm}(x,y). \tag{46}$$

The indices l and m are integers and arise as follows. For rectangular containers of dimensions a and b,

$$\begin{aligned}S_{lm}(x,y)&=\cos(k_x x)\cos(k_y y)\\&=\cos(l\pi x/a)\cos(l\pi x/b),\end{aligned} \tag{47a}$$

where the second part of the equation shows that the wave number $k^2 \equiv (k_x^2 + k_y^2)^{1/2}$ must be quantized according to $k^2 = k_{lm}^2 = (l\pi/a)^2 + (m\pi/b)^2$ in order to satisfy the boundary condition that at each wall the surface is flat in the direction normal to the wall (a kinematic consequence of the condition that the normal component of the velocity must vanish). For cylindrical containers of radius r_0

$$S_{lm}(r,\theta) = J_l(k_{lm}r)\cos(l\theta+\phi), \tag{47b}$$

where the same boundary condition requires that k_{lm} is the mth zero of the derivative $J_l'(k_{lm}r_0)$.

The amplitude $\zeta_0(t)$ satisfies the equation

$$\frac{d^2\zeta_0}{dt^2} + \beta\frac{d\zeta_0}{dt} + (\omega_{lm}^2 + \epsilon\Omega^2 k_{lm}\tanh k_{lm}h\ \cos\Omega t)\zeta_0 = 0, \tag{48}$$

where β is the phenomenological damping coefficient and, from Eq. (41a),

$$\omega_{lm}^2 = k_{lm}(g+\gamma k_{lm}^2/\rho)\tanh k_{lm}h. \tag{49}$$

Defining $\tilde{\zeta}_0 \equiv e^{\beta t}\zeta_0$ and $\tau \equiv \Omega t/2$ we have Mathieu's equation:

$$\frac{d^2\tilde{\zeta}_0}{d\tau^2} + (p - 2q\cos 2\tau)\tilde{\zeta}_0 = 0, \tag{50}$$

where

$$p \equiv 4(\omega_{lm}^2 - \beta^2)/\Omega^2, \tag{51a}$$

$$q \equiv 2\epsilon k_{lm}\tanh k_{lm}h. \tag{51b}$$

Mathieu's equation has the remarkable property (McLachlan, 1947) that for a given level of forcing q there are bands $b_n(q) < p < a_n(q)$ ($n = 0,1,2,3,\ldots$ with $b_0 = -\infty$) within which a solution $\tilde{\zeta}_0$ diverges exponentially with time and has the Floquet form

$$\tilde{\zeta}_0 = e^{(\mu+i\pi)\Omega t/2}\phi_n(t) \quad \text{for } n \text{ odd:}$$

$$\text{subharmonic relative to } \cos\Omega t$$

$$[\text{Floquet exponent } (\mu+i\pi)\Omega/2], \tag{52a}$$

$$\tilde{\zeta}_0 = e^{\mu\Omega t/2}\phi_n(t) \quad \text{for } n \text{ even:}$$

$$\text{harmonic relative to } \cos\Omega t$$

$$(\text{Floquet exponent } \mu\Omega/2), \tag{52b}$$

with $\phi_n(t+2\pi/\Omega) = \phi_n(t)$ and $\mu(p,q) > 0$ (real). Thus the actual surface deformation is given by

$$\zeta_0(t) = e^{(\mu\Omega/2-\beta)t}e^{i\pi\Omega t/2}\phi_n(t)$$

$$\text{or} \tag{53}$$

$$\zeta_0(t) = e^{(\mu\Omega/2-\beta)t}\phi_n(t)$$

and is unstable provided the frequency ratio $4(\omega_{lm}^2 - \beta^2)/\Omega^2$ lies inside one of the unstable bands and $\mu(p,q) > 2\beta/\Omega$. This requires a threshold value of the forcing amplitude ϵ that will depend on frequency (recall that q is proportional to ϵ); note that in the limit of zero damping ($\beta = 0$) there are resonant frequencies $\omega_{lm} = n\Omega/2$ at which there is an unstable solution for vanishingly small forcing $\epsilon = 0$. In a real system with small damping, a small modulation signal adjusted to resonance can cause a large response (assuming that nonlinearities saturate the unstable solution), and we have a parametric amplifier.

If the Faraday experiment is done in relatively small containers, the mode frequencies will be distinct so that only one mode might become parametrically unstable for carefully selected amplitude ϵ and frequency Ω. However, as ϵ is increased, bands of instability for different modes overlap and there is competition. Since the full equations are nonlinear and since symmetry-caused degeneracy ensures that three or more modes interact when bands overlap, one has the ingredients for chaotic dynamics. This is exactly what has been observed by Ciliberto and Gollub (1985). In their experiment, a cylinder of radius $r_0 = 6.35$ cm held a water layer of depth $h \approx 1$ cm. The (4,3) mode was excited for a frequency $\Omega/2\pi = 15.77$ Hz at a drive amplitude $\epsilon \approx 37$ μm (quite small). Nearby, at 16.21 Hz, a (7,2) mode could be excited with nearly the same drive amplitude. At a small range of intermediate frequencies and drive amplitudes greater than 100 μm, the bands overlapped and chaotic dynamics was found. For such systems, the nonlinear perturbation analysis, though difficult, is tractable thanks to the clearly separated modes. Thus considerable progress has been made in a first-principles quantitative understanding of the chaotic dynamics of this fluid system. Recent reviews may be found in Miles and Henderson (1990) and Gollub (1991).

2.1.4 Surface Waves.

Consider a small-amplitude surface wave as the base state:

$$\Psi_1 = A_1\Psi_{10}e^{i(\mathbf{k}_1\cdot\mathbf{r}-\omega_1 t)}. \tag{54a}$$

What is its stability? An important mechanism for instability is through resonant wave interactions with other wave modes. The simplest such interaction is the resonant triad, arising from the nonlinear mixing of two waves,

$$\begin{aligned}\Psi_2&=A_2\Psi_{20}e^{i(\mathbf{k}_2\cdot\mathbf{r}-\omega_2 t)}\\ \Psi_3&=A_3\Psi_{30}e^{i(\mathbf{k}_3\cdot\mathbf{r}-\omega_3 t)},\end{aligned}\tag{54b}$$

to form a wave varying like

$$\exp\{i[(\mathbf{k}_2+\mathbf{k}_3)\cdot\mathbf{r}-(\omega_2+\omega_3)t]\}.$$

This will be seen by the original wave $(\mathbf{k}_1,\omega_1)$ as a forcing term that is resonant if

$$\mathbf{k}_1=\mathbf{k}_2+\mathbf{k}_3,\tag{55a}$$

$$\omega_1(\mathbf{k}_1)=\omega_2(\mathbf{k}_2)+\omega_3(\mathbf{k}_3).\tag{55b}$$

This is a stringent condition on the dispersion relations and may not be satisfied for any choice of $\mathbf{k}_1,\mathbf{k}_2,\mathbf{k}_3$. Indeed, for gravity waves $\omega=(gk)^{1/2}$ the resonant conditions cannot be satisfied at this order, and a higher-order four-wave resonance must be sought instead (Phillips, 1974). For gravity capillary waves, however, the resonant-triad conditions can be met, and the consequences have been explored in some beautiful experiments by Henderson and Hammack (1987). For reviews of wave interactions, with discussion of amplitude equations, see Phillips (1974), Craik (1985), and Hammack and Henderson (1993).

2.2 Capillary Phenomena

In the above examples, surface tension played a stabilizing role, as was the case when it caused a cutoff of short-wavelength modes in the Rayleigh-Taylor instability. In base states that start out with curved surfaces, however, surface tension may be destabilizing. If we ignore damping, this may be understood by energy considerations: a base state will be unstable if a new surface of lower energy can be found. This is indeed the case, for example, in the breakup of a cylindrical liquid column into drops (Fig. 8).

The analysis of surface deformations is similar to that for surface waves, except that we now have a cylindrical interface defined by $r=a+\zeta(z,\theta)$. For perturbations $\zeta(z)=\zeta_0\, e^{i(kz+m\theta)+st}$, a linear analysis gives

$$s^2=\frac{\gamma}{\rho a^3}\frac{kaI_n'(ka)}{I_n(ka)}(1-k^2a^2-m^2),\tag{56}$$

where $I_n(ka)$ is a modified Bessel function of order n. Only the term $1-k^2a^2-m^2$ determines the sign of s^2 and we see, then, that s is real and instability occurs if $m=0$ (axisymmetric disturbances) and $k<1/a$. In other words, the column is unstable for all wavelengths $\lambda>2\pi a$, the circumference of the column. The fastest growing mode occurs for $ka=0.6970$, or $\lambda=1.435(2\pi a)$, with a growth rate $s=0.3433(\gamma/\rho a^3)^{1/2}\approx(0.12\ \mathrm{s})^{-1}$ for a water column with radius $a=0.5$ cm and surface tension $\gamma=73$ dyn/cm. In experiments, the column is produced as a jet exiting from a nozzle with velocity U. Forcing the column with a speaker oscillating at frequency ω_0 rad/s gives a well defined wave number $k=U/\omega_0$. The growth rate may be inferred by fitting an exponential envelope to the jet profile; good agreement is found (Donnelly and Glaberson, 1966) on comparing the initial growth with the inviscid theory. See Drazin and Reid (1981) and Chandrasekhar (1961) for further discussion. For experimental investigation of the nonlinear regime, see Goedde and Yuen (1970).

Capillarity is also important for studying the shapes of rotating and oscillating liquid drops. Indeed, the problem of equilibrium shapes and their stability for rotating fluid masses held together either by gravity or by

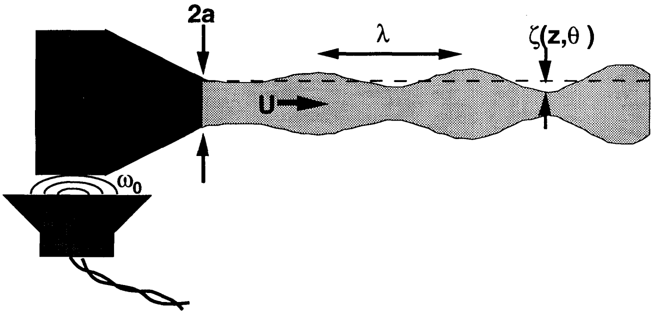

FIG. 8. Liquid column or "jet" emanating from a nozzle. The column is deformed by a disturbance of wavelength $\lambda=2\pi U/\omega_0$, where ω_0 is the angular frequency of a loudspeaker exciting the nozzle. The disturbance grows if $\lambda>2\pi a$, the circumference of the column.

surface tension is a classic one (Chandrasekhar, 1969). In 1834 Jacobi found a family of ellipsoidal figures of equilibrium that broke the axisymmetry of the rotating spheroids derived by Maclaurin a century earlier. In 1885, Poincaré also found a pear-shaped family of solutions and coined the term "bifurcation" to describe the branching of the solution families. A resurgence of interest in the problem for the case where the drops are held together by surface tension has occurred thanks to the ability to conduct extended experiments in zero gravity. This has also lead to extensive studies of the modes of oscillation of liquid drops. These studies are motivated, in part, by the development of zero-gravity materials processing technology. For a review, see Wang (1988).

2.3 Propagating Fronts

An important class of nonequilibrium phenomena concerns the shape of a propagating front separating one medium from another. Examples of this situation include

1. propagation of one fluid into another, where the two fluids have different viscosities (viscous fingering); this arises, for example, in secondary oil recovery when water is used to drive oil through the porous beds towards extraction wells;
2. advance of a region undergoing the chemical reactions of combustion into an unignited phase (flame fronts); this is of obvious importance for the efficiency of combustion processes;
3. expansion of a domain undergoing crystallization (directional solidification); the resulting structures may strongly influence the metallurgical properties of commercial alloys;
4. the motion of an interface of a fluid that is wetting a solid substrate; this concerns technological problems of coating, draining, and drying.

The phenomenology of these problems is very rich, often producing intricate structures as a result of fingering instabilities. The front deforms into fingers that penetrate the second medium; these fingers may themselves experience fingering instabilities, etc. However, in some circumstances (see below) the front shape is ultimately governed by a selection process that can be quite subtle.

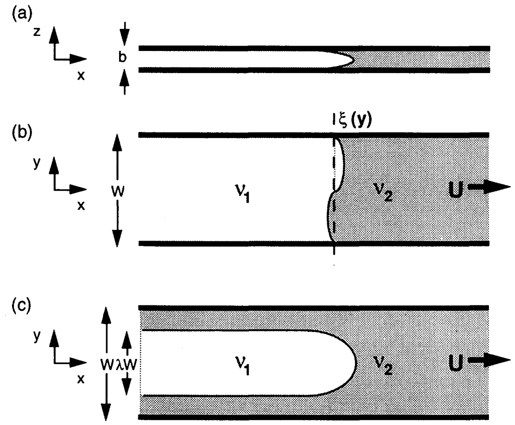

FIG. 9. Hele-Shaw cell. (a) Cross section of narrow direction; (b) cross section of wide direction, showing hypothetical interface undergoing deformation $x-Ut=\xi(y)$; (c) a viscous finger.

One problem that has received considerable attention is the Saffman-Taylor problem concerning the shape of the interface between a less viscous fluid (for example, air) pushing a more viscous fluid (for example, oil or glycerine) through a very narrow channel called a Hele-Shaw cell (Fig. 9). Because the gap b between the top and bottom walls of the cell is so small, the flow is two dimensional and is dominated by viscosity, obeying Darcy's law that the velocity—defined here to be an average across the narrow gap—is proportional to the pressure gradient:

$$\mathbf{u}_i=-(b^2/12\mu_i)\nabla p_i, \qquad (57)$$

where $i=1$ or 2 distinguishes the two fluids and μ_i is the dynamic viscosity. Gravity is neglected on the assumption that the cell is horizontal. Incompressibility then implies that the pressure will satisfy Laplace's equation in each fluid:

$$\nabla^2 p_i=0. \qquad (58)$$

The base flow is simply the case where both fluids and the interface move with velocity $\mathbf{U}=U_0\hat{\mathbf{x}}$. Observing from a frame of reference moving with the undisturbed interface, we want to known what happens if there is a deformation

$$x=\xi(y)=\xi_0\cos(ky)e^{\sigma t}. \qquad (59)$$

We omit discussion of the kinematic and pressure-jump conditions at the interface (which has interfacial tension γ), noting that in simplest form* they are similar to those given in Sec. 2.1. Linearized analysis gives the result

$$\sigma=[(\mu_2-\mu_1)U-(\gamma b^2/12)k^2]k/(\mu_1+\mu_2). \qquad (60)$$

This implies that $\sigma>0$ and instability occurs for wave numbers

$$k^2<[12(\mu_2-\mu_1)/\gamma b^2]U. \qquad (61)$$

If the flow is confined by side walls a distance W apart (where free-slip boundary conditions are usually assumed as a good approximation), the wave numbers k are restricted to values $k=2\pi n/W$. Taking $n=1$ for the smallest wave number and defining the dimensionless parameter

$$d_0\equiv\frac{b^2}{W^2}\frac{\gamma}{(\mu_2-\mu_1)U}, \qquad (62)$$

we see that instability occurs if the velocity is large enough that $d_0<3/\pi^2$.

The nonlinear problem turns out to be one of very great subtlety. This is because surface tension is a singular perturbation, so that solutions for small surface tension do not asymptotically approach those for zero tension. A one-parameter family of steady-state solutions was found for zero surface tension by Saffman and Taylor (1958):

$$\frac{\xi(y)}{W}=\frac{1-\lambda}{\pi}\ln\cos\frac{\pi y}{\lambda W}, \qquad (63)$$

where the parameter λ is the width of the finger relative to the width of the cell [as $y\rightarrow\pm\lambda W/2$, $\xi(y)\rightarrow-\infty$]. However, there is no indication which value of λ will be chosen by an experiment. Furthermore, Eq. (61) may be interpreted to say that as surface tension vanishes, even very-short-wavelength perturbations destabilize a front. Relative to such short-wavelength perturbations, the Saffman-Taylor front looks locally flat and ought to be subject to the same instability. Experiments show, however, that viscous fingers are stable and that a width parameter λ is uniquely determined by the velocity. Considerable progress has been made recently in understanding the intricacies of this problem; see Saffman (1986) and Bensimon *et al.* (1986).

2.4. Thermal- or Buoyancy-Driven Instabilities

We know intuitively that fluid layers that are warmer at the bottom will have a tendency to overturn. Gradients in concentration of a solute can have a similar effect. The overturning is driven by buoyancy with respect to some body force, usually gravity; the overturning is resisted by viscosity and diffusion. If a sufficient source of heat or solute is steadily applied, the overturning can be sustained. The transport of heat or solute will be greatly enhanced over the rate that would occur through diffusion alone. This enhanced means of transport is called convection; if the fluid motion responsible for the convection occurs spontaneously, this is called free convection. If the motion is imposed (for example, by external pumps) then this is forced convection, a case not necessarily associated with instabilities. There are also cases of mixed convection in which externally imposed motion is influenced by buoyancy forces. The more general concept of transport arising through fluid motion is also termed advection, with the term "convection" usually restricted to heat transport or buoyancy-related solute transport.

The situation producing free convection can be generalized to cases in which gradients are imposed horizontally; for example, one side of a vertical chamber may be kept warmer than the other. Such cases are of immense practical importance but, even though the basic mechanism for instability is the same, the analysis is substantially different from the case of vertically imposed gradients. Finally, rotation may be imposed on a differentially heated annulus, producing models important to geophysical and astrophysical studies.

Early quantitative experiments on convection in horizontal fluid layers were reported by Bénard in 1900. Heating the layers from below, he often obtained arrays of nearly hexagonal cells of overturning fluid. In 1916, Rayleigh published his theory for buoyancy-

---

*As discussed in Bensimon *et al.* (1986), there are more appropriate pressure-drop conditions that include the effect of the velocity of the interface as it slips along the bounding plates.

induced instability in fluid layers heated from below. Ironically, it was realized much later (Block, 1956; Pearson, 1958) that Bénard's experiments corresponded to what is now known as Marangoni convection, in which the source of instability is temperature variation of the surface tension of the fluid. However, the original idea of fluid layers heated from below (still referred to as Bénard convection) has led to some of the most refined and precise experiments in fluid mechanics.

Figure 10 shows the basic configuration of experiments with horizontal fluid layers. (For a general review of the physics of convection, see Normand *et al.*, 1977.) In the ideal case, the layers have infinite horizontal extent while the top and bottom plates have infinite thermal conductivity (and thus completely uniform temperature). In practice, materials are chosen so that the top and bottom plates have much larger conductivity than the fluid, while the side walls are chosen to be good insulators. It should be noted that transparent top plates are often used in order for the fluid motion to be visible, while the bottom plate is often made of polished metal that serves as a mirror in the shadowgraph method for visualizing fluid-density differences. Heat is usually supplied by heaters embedded in the bottom plate, with servo control to establish either constant temperature difference or constant heat flux. The top-plate temperature may be regulated by carefully directed fluid currents from a temperature-controlled bath. The whole system is isolated from room-temperature fluctuations by an insulating container.

A rectangular container with horizontal dimension L_x and L_y and gap d between the plates has aspect ratios L_x/d and L_y/d; a cylindrical container of diameter D has an aspect ratio D/d. Experiments are often designed with either large aspect ratio (say greater than 30) or small aspect ratio (1–3). Sometimes one aspect ratio (say in the y direction) is intentionally made smaller than the other in order to establish a preferred alignment of the convective rolls, rendering the horizontal variation of the observed patterns nearly one dimensional. The large–aspect-ratio systems conform better to the ideal of infinite horizontal extent; however, after instability occurs the situation can be very complex because the (near) isotropy and translational invariance of the system produce a quasicontinuum of interacting modes. The small–aspect-ratio systems pose a substantially different stability problem, but one that may be solvable by numerical methods. In this case, a small number of modes can dominate the behavior of the system, and the dynamics is, in principle, reducible to a system of ordinary differential equations. An interesting variation on the design of convection apparatus has been the construction of annular containers.

Consider an infinite incompressible fluid layer whose top ($z=d/2$) and bottom ($z=-d/2$) layers are held at temperatures T_t and T_b, respectively. For small enough temperature differences, heat is simply conducted through the fluid, which remains motionless. This base state is

$$\mathbf{U}=\mathbf{0} \quad \text{(fluid is at rest)}, \tag{64a}$$

$$T=T_b+\frac{T_t-T_b}{d}\left(z+\frac{d}{2}\right) \quad \text{(linear temperature profile)}, \tag{64b}$$

$$\rho=\rho_b[1-\alpha(T-T_b)] \quad \left(\text{neglecting } \frac{d\alpha}{dT}\right), \tag{64c}$$

$$P=P_b-\int_0^z \rho(z)g\,dz. \tag{64d}$$

Here $\alpha\equiv-(1/\rho)(\partial\rho/\partial T)$ is the thermal expansion coefficient of the fluid.

If the bottom plate is cooler than the top, the system is stably stratified and fluid remains at rest. If the temperature gradient is reversed by heating the fluid layer from below, instability sets in when the thermally induced buoyancy is strong enough to overcome the dissipative effects of viscosity ν and thermal diffusivity κ. Imagine a small parcel of fluid of size a that is slightly warmer (by an

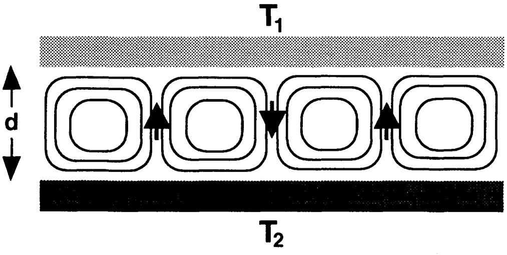

FIG. 10. Convective cells forming in fluid heated from below. When temperature T_2 is sufficiently larger than temperature T_1, fluid rises and falls in cellular patterns.

amount θ) than the surrounding fluid. The buoyancy force is $\rho_b\alpha\theta a^3 g$; the parcel accelerates until the buoyancy force is opposed by a viscous drag approximately equal to $\rho\nu u a$ (compare to Stokes's formula, $6\pi\rho\nu u a$, for the drag on a sphere of radius a moving with velocity u). This gives $u \sim g\alpha\theta a^2/\nu$. Thus the time for the parcel to move a distance comparable to its size is $\tau \sim a/u \sim \nu/g\alpha\theta a$. However, heat diffuses out of the parcel with a time scale $\tau_\theta \sim a^2/\kappa$. This time must be longer than the time scale of motion of the parcel; otherwise the cause of the buoyancy (the temperature difference) is removed. Thus we require $\tau < \tau_\theta$, meaning $\nu/g\alpha\theta a < a^2\kappa$ or $\alpha g\theta a^3/\nu\kappa > 1$. Now the characteristic scale for θ is $T_b - T_t$, while the characteristic scale for the size of the parcel is d. Thus we expect instability to occur when the Rayleigh number

$$Ra \equiv \alpha g(T_2 - T_1)d^3/\nu\kappa \tag{65}$$

exceeds some critical value Ra_c. The numerical value of Ra_c must be obtained from the detailed stability analysis using the equations of motion and appropriate boundary conditions.

Let the deviation from the base state be given by velocity $\mathbf{u}(u,v,w)$, temperature θ, and pressure p. In the Oberbeck-Boussinesq approximation the temperature variation is coupled to the dynamics only through the buoyancy force per unit volume $\rho_b\alpha\theta g$; otherwise, the density and other material properties of the fluid are assumed constant. These can be well approximated in the laboratory provided the temperature differences remain moderate (in practice, of order several kelvins). The physical quantities can be scaled by d (distance), $\tau_\theta \equiv d^2/\kappa$ (time), κ/d (velocity), and $\kappa\nu/\alpha g d^3$ (temperature). With the scalings the full nonlinear equations (Boussinesq equations) for the disturbance fields are

$$\nabla\cdot\mathbf{u} = 0, \tag{66a}$$

$$\frac{1}{Pr}\left(\frac{\partial\mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla)\mathbf{u} + \nabla p\right) = \nabla^2\mathbf{u} + \theta\hat{\mathbf{z}}, \tag{66b}$$

$$\frac{\partial\theta}{\partial t} + (\mathbf{u}\cdot\nabla)\theta = \nabla^2\theta + Ra\, w. \tag{66c}$$

The Prandtl number $Pr \equiv \nu/\kappa$, a quantity solely based on the fluid physical properties, expresses the relative importance of the two nonlinear terms $(\mathbf{u}\cdot\nabla)\mathbf{u}$ versus $(\mathbf{u}\cdot\nabla)\theta$, and thus may be expected to strongly affect the nonlinear behavior. The term $Ra\, w$ comes from the advective transport of thermal energy in the base-state profile by the z component w of the disturbance velocity. There are two types of boundary conditions at $z = \pm\frac{1}{2}$ (note that z now refers to the dimensionless vertical coordinate): free (stress-free), $\theta = \partial u/\partial z = \partial v/\partial z = w = 0$, appropriate (approximately) if the convecting fluid is bounded by another fluid of much lower viscosity and the interface is assumed to remain flat; and rigid (no slip), $\theta = u = v = w = 0$, appropriate if the convecting fluid is bounded by rigid walls.

The linearized problem is obtained by neglecting the advective terms $(\mathbf{u}\cdot\nabla)\mathbf{u}$ and $(\mathbf{u}\cdot\nabla)\theta$. Assuming a system of infinite horizontal extent, solutions may be expected of the following form:

$$(u,v,w,\theta,p) = (\hat{u}(z),\hat{v}(z),\hat{w}(z),\hat{\theta}(z),\hat{p}(z)) \times \exp[st + i(k_x x + k_y y)]. \tag{67}$$

Some manipulation yields equations coupling $\hat{w}$ and $\hat{\theta}$:

$$Pr[(D^2 - k^2)^2\hat{w} - k^2\hat{\theta}] = s(D^2 - k^2)\hat{w}, \tag{68a}$$

$$(D^2 - k^2)\hat{\theta} + Ra\hat{w} = s\hat{\theta}, \tag{68b}$$

where $D \equiv d/dz$. Two types of boundary conditions at $z = \pm\frac{1}{2}$ are

$$\hat{\theta} = \hat{w} = D^2\hat{w} = 0 \quad \text{(stress-free or "free")}, \tag{69a}$$

$$\hat{\theta} = \hat{w} = D\hat{w} = 0 \quad \text{(no slip or "rigid")}. \tag{69b}$$

The eigenvalue s for this problem, with either type of boundary conditions, is real, and so the secondary flow that results from instability is a steady flow. Although the case of stress-free boundary conditions at both walls is unrealistic, it has the advantage that closed-form solutions for the fields and dispersion relation $s = s(k,Ra,Pr)$ can be obtained. They are

$$(\hat{w},\hat{\theta}) = (W_n,\Theta_n)\sin(n\pi z), \tag{70}$$

$$s^2 + (1+Pr)(k^2 + n^2\pi^2)s + Pr\frac{(k^2+n^2\pi^2)^3 - k^2 Ra}{k^2 + n^2\pi^2} = 0. \tag{71}$$

The condition $s = 0$ gives a family of marginal stability curves indexed by the integer n:

$$Ra(k,n) = (n^2\pi^2 + k^2)^3/k^2. \qquad (72)$$

The minimum Rayleigh number is obtained for $n = 1$; minimization must also be done over k. The resulting critical Rayleigh number Ra_c and critical wave number k_c are summarized in Table 1 for all three possible pairs of boundary conditions. These critical values do not depend on Prandtl number. We note that the stability problem with rigid boundaries requires numerical solution of a transcendental equation to obtain the marginal curve $Ra(k)$.

A nonlinear analysis must determine if the resulting eigenmodes saturate into a stable secondary flow. Furthermore, for an infinite system, there is no preferred direction for the wave vector **k**. Thus it is necessary to investigate the nonlinear selection of a stable pattern out of all possible combinations of modes with wave numbers of the same magnitude but different directions. Most study has been given to three possible cases:

1. two wave numbers, $\pm k_c\hat{\mathbf{x}}$ (parallel rolls);
2. four wave numbers, $\pm k_c\hat{\mathbf{x}} \pm k_c\hat{\mathbf{y}}$ (cross rolls);
3. six wave numbers, $\pm k_c\hat{\mathbf{x}}$ and $\pm\frac{1}{2}k_c\hat{\mathbf{x}} \pm \frac{1}{2}\sqrt{3}k_c\hat{\mathbf{y}}$ (hexagons).

Perturbation theory establishes a nonlinear state for each of these types and then examines its instability to perturbations of the form of the other two types. For fluids that satisfy the Oberbeck-Boussinesq approximations, parallel rolls are the only stable choice for Rayleigh numbers just above threshold. These rolls have an amplitude that satisfies a form of the Landau equation discussed in Sec. 1.2.7 with real coefficients:

$$\frac{dA}{dt} = \sigma_0\epsilon A - g|A|^2 A. \qquad (73)$$

Here $\epsilon \equiv (Ra - Ra_c)/Ra_c$ and g is a real Landau constant. One measure of the roll amplitude accessible to experiment is the ratio of the heat transfer with convection to the heat transfer in the conducting state. This is called the Nusselt number. Precise experiments show that $Nu \propto \epsilon^{1/2}$, in accordance with the $\epsilon^{1/2}$ growth of the amplitude A predicted by the Landau equation.

As the Rayleigh number is raised above the critical value Ra_c, the convection rolls may select a wave number k from a continuous finite range of wave numbers bounded by the marginal stability curve. Thus nonlinear theory must also address, for each wave number k, the question of stability of rolls with that wave number to arbitrary disturbances when Ra exceeds the marginal stability value $Ra_m(k)$. Rolls with wave numbers close to the marginal stability boundary turn out to be unstable to large–length-scale modulations (Eckhaus instability) that end up replacing the roll pattern with a parallel set of rolls with a stable wavelength. Alternatively, a cross-roll instability changes wavelength by replacing the unstable rolls with a perpendicular set of rolls. A final mechanism for wave-number adjustment is through local reorientation of the rolls in what is called the zigzag instability. For the rolls that fall within the wave-number band stable to these perturbations, however, there will eventually be a secondary instability to a qualitatively different type of flow when the Rayleigh number is increased to a large enough value. The "zoo" of possibilities includes "bimodal instability," which produces oscillations traveling along the roll boundaries, and "skew-varicose" deformation of the rolls. The Prandtl number Pr becomes very important in determining the instability mode for finite-amplitude rolls because, as remarked above, Pr measures the relative importance of the nonlinear terms $(\mathbf{u}\cdot\nabla)\mathbf{u}$ and $(\mathbf{u}\cdot\nabla)\theta$. The result of this analysis is a stability balloon (in this case called the Busse balloon) in a parameter space whose coordinates are (k,Pr,Ra). For coordinates outside this balloon, steady convection rolls become unstable to the variety of perturbations discussed above. A discussion of the nonlinear pattern selection, the stability balloon, and the various

Table 1. Critical parameters for various conditions applied to convection in horizontal fluid layers.

Boundary condition	Ra_c	k_c
Free-free	$27\pi^4/4 \approx$ 657.51	$\pi/\pi/\sqrt{2} \approx 2.221\,4$
Rigid-free	1100.6	2.68
Rigid-rigid	1707.76	3.116 32

types of modes that destabilize convection rolls is found in the review by Busse (1985).

When the Rayleigh number is increased further (beyond secondary instability), the flow eventually becomes time dependent. Depending on the Prandtl number, this might start out as periodic in time, but for further increases of *Ra* the flow becomes irregular or chaotic. Eventually, at large Rayleigh number, the motion is turbulent, characterized by strong three dimensionality and a wide range of spatial scales.

There are some important experimental wrinkles in the theory for convection near threshold. The first of these is that the side walls joining the top and bottom plates can exert an overriding influence on the pattern chosen by the convecting rolls (Koschmieder, 1974, 1975). This is called side-wall forcing and leads, for example, to concentric rolls in cylindrical containers. It also leads to a rounding of the transition into an imperfect bifurcation, with rolls first appearing near the walls. However, by careful thermal bonding of the side walls to the end plates, horizontal temperature inhomogeneities induced by the side walls may largely be eliminated. There is still an effect due to the tendency of convection rolls to minimize dissipation by aligning perpendicular to the walls; rolls in rectangular containers tend to align parallel to the short side of the container. However, in large–aspect-ratio systems, the patterns are no longer exclusively determined by the side-wall geometry. The resulting flows can have astonishing behavior: for Rayleigh numbers not far above threshold, irregular time dependence can appear. This is due to the nucleation, drifting, and annihilation of dislocations in the roll patterns, particularly evident in cylindrical containers in which the alignment of rolls perpendicular to walls is frustrated. The complex, slow irregular motion is an example of spatiotemporal chaos and is discussed further in Newell (1989) and Manneville (1990).

There are many variations on convection between horizontal plates. Extremely precise measurements are done on liquid helium (Behringer, 1985). The effects of rotation and of magnetic fields (for conducting fluids) are discussed in Chandrasekhar (1961) and continue to be investigated. Another important variation is convection in binary fluid mixtures. As a result of the possibility of thermally induced concentration gradients (the Soret effect), the instability mechanism can be significantly altered. Consequently, it becomes possible for the conducting state to make a transition to time-dependent flow in the form of traveling waves or standing waves; see Cross and Hohenberg (1993).

2.5 Electrohydrodynamic Instabilities in Liquid Crystals

Electric fields can excite convective motion in nematic liquid crystals. From an experimental point of view, this is an attractive system because

1. the control parameters (voltage and frequency) can be set very precisely;
2. the motion is easy to visualize thanks to the optical anisotropy of the liquid-crystal medium;
3. the gap between bounding planes can be quite small (20–100 μm), meaning that extremely large aspect ratios are possible and effects having to do with large-scale modulations and/or defects in the secondary-flow patterns are readily studied (Lowe and Gollub, 1985);
4. a preferred direction may be established for the secondary-mode wave vector, so that the system is nearly one dimensional;
5. fluctuations in the system couple strongly to visible light and may therefore be studied very sensitively by light-scattering experiments.

Theoretically, however, the dynamic equations are very complex, with several physical parameters describing the fluid and with strong interaction of several fields: electric, velocity, director, space charge, and current density. The material constants are not all precisely known. The medium is anisotropic, with dielectric constants $\epsilon_\perp$ and $\epsilon_\parallel$ and conductivities $\sigma_\perp$ and $\sigma_\parallel$ depending on direction relative to the applied electric field **E**.

Electrohydrodynamic instabilities are discussed in de Gennes (1974), Stephen and Straley (1974), and Dubois-Violette *et al.* (1978).

2.6 Centrifugal Instabilities

A situation that mimics a density stratification is an angular-momentum stratification in differentially rotating fluids. Imagine a set of curved streamlines, each with a radius of curvature r about some (perhaps approximate) common center—see Fig. 11(a). We adopt cylindrical coordinates and assume only an azimuthal velocity component $V(r)\hat{\theta}$ and a corresponding angular momentum per unit volume $L(r)=\rho V(r)r$ (here the density ρ is assumed constant). This curved flow will be sustained by a pressure gradient that provides the centrifugal acceleration of the fluid:

$$\frac{dp}{dr}=\frac{\rho V^2(r)}{r}. \tag{74}$$

Let the streamline of fluid at radius r_1 be displaced to a larger radius r_2, acquiring a new velocity V'. Ignoring viscosity, conservation of angular momentum requires that the angular momentum of the streamline at its new position equal its original angular momentum,

$$V'r_2=V(r_1)r_1. \tag{75}$$

Thus the new velocity $V'=v(r_1)r_1/r_2$. The flow is unstable if the corresponding centrifugal acceleration exceeds the local pressure gradient,

$$\frac{\rho V'^2}{r_2}>\left.\frac{dp}{dr}\right|_{r_2}. \tag{76}$$

Substitution for V' and for dp/dr at r_2 leads to the conclusion that instability will occur if

$$V^2(r_1)r_1^2>V^2(r_2)r_2^2 \tag{77}$$

or, more generally,

$$\frac{d}{dr}L^2(r)<0. \tag{78}$$

Thus curved flow of an inviscid fluid is unstable if the square of the angular momentum decreases with radius; this is Rayleigh's criterion for centrifugal instability. If instability occurs but there is a bounding wall that confines the flow within an outer radius, the flow is forced to overturn and fluid flows in helical paths along vortices whose axes are aligned in the azimuthal direction [Fig. 11(b)].

2.6.1 Flow between Rotating Cylinders: The Taylor-Couette System. The flow between two coaxial independently rotating cylinders (Fig. 12) has been studied in great detail because experiments can be done very precisely and theory can take advantage of the simple geometry (DiPrima and Swinney, 1985). Suppose that the inner-cylinder radius and angular velocity are r_1 and Ω_1 and the outer-cylinder radius and angular velocity are r_2 and Ω_2. (By convention we usually choose Ω_1 to be positive.) Then, assuming the length L is infinite, an analytic solution exists for the primary velocity, vorticity, and pressure fields:

$$\mathbf{U}=V(r)\hat{\theta}=(Ar+B/r)\hat{\theta}, \tag{79a}$$

$$\nabla\times\mathbf{U}=2A\hat{\mathbf{z}}, \tag{79b}$$

$$p=p_0+\int_{r_1}^{r}\rho\frac{V^2(r)}{r}\,dr. \tag{79c}$$

The no-slip boundary conditions $V(r_1)=\Omega_1 r_1$ and $V(r_2)=\Omega_2 r_2$ determine A and B:

$$A=-\frac{\Omega_1 r_1^2-\Omega_2 r_2^2}{r_2^2-r_1^2}=-\frac{\eta^2-\mu}{1-\eta^2}\Omega_1, \tag{80a}$$

$$B=\frac{(\Omega_1-\Omega_2)r_1^2 r_2^2}{r_2^2-r_1^2}=\frac{(1-\mu)\eta^2}{1-\eta^2}\Omega_1 r_2^2. \tag{80b}$$

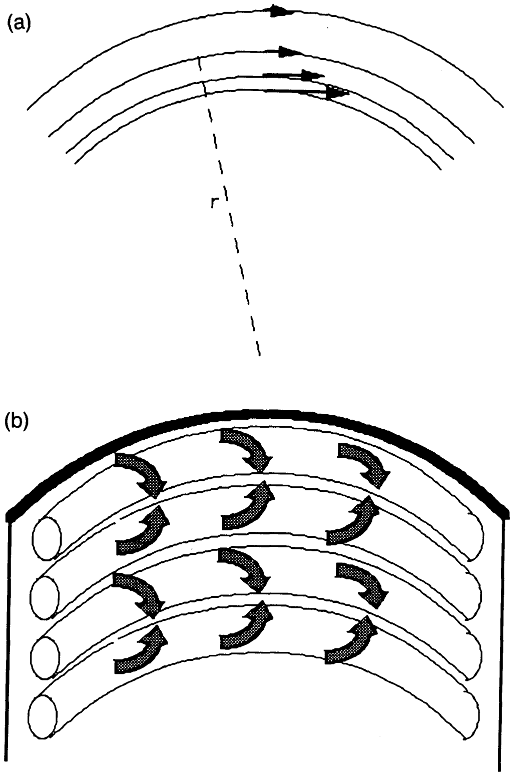

FIG. 11. Curved flows. (a) View in the r-θ plane of curved streamlines of the base flow. (b) Three-dimensional view of vortices formed by centrifugal instability when the flow is bounded by an outer wall.

The dimensionless constant $\mu \equiv \Omega_2/\Omega_1$ is the angular velocity ratio and $\eta \equiv r_1/r_2$ is the radius ratio.

Originally this system was used for measuring the dynamic viscosity $\rho\nu$ of a fluid. When the outer cylinder is rotated, the torque on the stationary inner cylinder is measured by suspending the inner cylinder from a torsion fiber. The torque G per unit length transmitted across a layer at any radius r is independent of r and is given by

$$G = \rho\nu r \frac{d(V/r)}{dr} \times 2\pi r \times r$$
$$= -4\pi\rho\nu B$$
$$= -4\pi\rho\nu \frac{\eta^2}{1-\eta^2} r_2^2(\Omega_1 - \Omega_2). \tag{81}$$

However, the linear relation between torque and differential angular velocity $\Omega_1 - \Omega_2$ is not observed for all angular velocities, suggesting that instability occurs. In fact, the Rayleigh criterion (see Sec. 2.7.2) applied to this flow says that the flow is always unstable if $\Omega_1\Omega_2 < 0$, that is, if the cylinders are oppositely rotating. If the cylinders are rotating in the same direction (with the convention that Ω_1 is positive), the Rayleigh criterion says that instability should occur for $\Omega_1 r_1^2 > \Omega_2 r_2^2$ or equivalently $\Omega_2/\Omega_1 < (r_1/r_2)^2$. If the outer cylinder is at rest, this condition is simply $\Omega_1 > 0$. These criteria are, however, for inviscid fluids. It is expected that viscosity stabilizes the flow, which is indeed the case.

In a landmark work, Taylor (1923) theoretically calculated the stability threshold for flow of a viscous fluid between independently rotating cylinders and found excellent agreement with his own experiments. Taylor assumed that the gap $d \equiv r_2 - r_1$ was small: $d/r_2 \ll 1$. He also confined his analysis to axisymmetric disturbances. Today, computers have made the generalization to arbitrary gap and nonaxisymmetric disturbances fairly straightforward. The base flow is perturbed by modes

$$\mathbf{u} = [u(r)\hat{\mathbf{r}} + v(r)\hat{\theta} + w(r)e^{i\pi/2}\hat{\mathbf{z}}]e^{i(kz+m\theta)}e^{st}, \tag{82a}$$

$$p = p(r)e^{i(kz+m\theta)}e^{st}. \tag{82b}$$

The resulting linear system leads to a dispersion relation $s = s(Re,k,m,\mu,\eta)$, and the marginality condition (real part of s vanishes) gives a family of curves $Re_{\text{marg}} = Re(k,m,\mu,\eta)$. Assuming that the speed ratio μ and radius ratio η are fixed at externally imposed values, the critical Reynolds number and wave numbers are found by minimizing over k and m. For co-rotating cylinders, stationary outer cylinder, and weakly counter-rotating cylinders ($\mu_{01} < \mu < \infty$, where $\mu_{01} < 0$) the critical mode has $m = 0$, is steady in time ($\omega = 0$), and takes the form of axisymmetric Taylor vortices. For counter-rotating cylinders with $\mu < \mu_{01}$, the critical modes are nonaxisymmetric and time periodic ($\omega \neq 0$); the resulting flows are either spiral vortices (waves traveling in the axial and azimuthal direction) or "ribbons" (standing waves in the axial direction, but traveling in the azimuthal direction). The point μ_{01} is a bicritical point where axisymmetric and nonaxisymmetric modes compete. (There are other bicritical points, $\mu_{m,m+1}$, where nonaxisymmetric modes m and $m+1$ compete.)

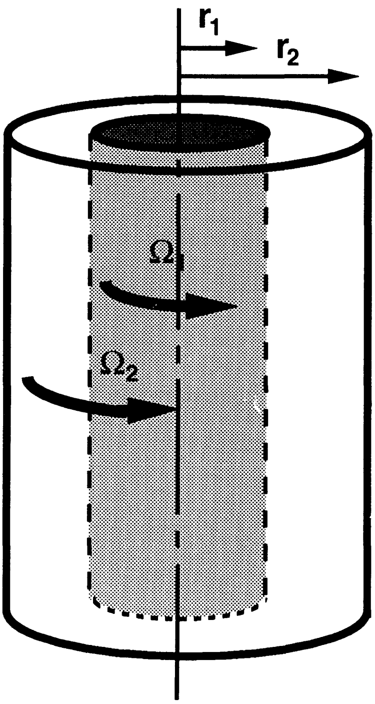

FIG. 12. Couette-Taylor geometry. Fluid flows in the annulus between two coaxial, independently rotating cylinders.

The Taylor-Couette system is remarkable for the fact that an incredible variety of qualitatively different flow patterns may be established by changing the two cylinder speeds and the radius ratio. Furthermore,

Table 2. Sequence of flow states between coaxial cylinders with the inner cylinder rotating, for radius ratio $\eta=0.88$. The imposed rotation is expressed in terms of the ratio of the Reynolds number *Re* to the critical value Re_c at which Taylor vortices first appear.

Re/Re_c	Type
0–1	Base flow (Couette flow)
1–1.2	Taylor vortices
1.2–7.5	Wavy vortices–there may be transitions within this range to a different number *N* of wavy vortices within the finite axial length, as well as to a different number *m* of waves in the azimuthal direction.
7.5–9.5	Modulated wavy vortices with small-scale modulation
9.5–12.5	Modulated wavy vortices with large-scale modulation
12.5–19	Weakly turbulent vortices, still showing modulated waves
19–40	Turbulent vortices with fast regular oscillations embedded in them
40–700	Strongly turbulent Taylor vortices
>700	Strongly turbulent flow with no remnant of Taylor vortices.

nonuniqueness of solutions to the Navier-Stokes equations under identical imposed conditions is amply demonstrated in this system (Coles, 1965): many different states are obtained by arranging different histories of the flow development. The system has been most intensively studied for the case in which the outer cylinder is at rest, usually with radius ratio $\eta\approx0.88$. Table 2 shows the sequence of flow states that results for this radius ratio as the Reynolds number is steadily increased. The ranges of values of Reynolds numbers are only rough estimates, since the precise values depend on the exact radius ratio and on the history of the flow state. Note that five qualitatively different flows are found *before* turbulence occurs, in contrast to most open flows like pipe flow and boundary-layer flow. The weakly turbulent vortices have been particularly interesting, because experiments (Fenstermacher *et al.*, 1979; Brandstater and Swinney, 1987) have shown that the flow has the characteristics of temporal chaos (see Sec. 3 below).

When the outer cylinder is rotated as well, an even greater variety of flows is found. One of the most amusing is the "barber pole" or spiral turbulence found for counter-rotating cylinders. Turbulent spots similar to those in boundary layers or channel flow may also be found. Finally, for co-rotating cylinders, a variety of time-periodic flows results from the instability of Taylor-vortex flow. For a survey with many excellent photographs, see Andereck *et al.* (1986).

2.6.2 Other Types of Centrifugal Instability. From a practical point of view, one of the most important types of centrifugal instabilities occurs in boundary layers along concave walls. Instability leads to rolls aligned with the direction of flows. These are called Görtler vortices. If, instead, one has flow forced through a curved channel by a pressure gradient, the rolls that form (again along the direction of flow) are called Dean vortices. Finally, flow impinging on a stagnation point must be diverted through curved streamlines, from which centrifugal instabilities may arise. For these variations, see Drazin and Reid (1981).

2.7 Shear Flow

Many flows of practical interest, such as flow through pipes or flow around airfoils, are mainly in one direction (say $\hat{\mathbf{x}}$) but have gradients mainly in a perpendicular direction (say $\hat{\mathbf{y}}$), with the result that vorticity is mainly in the mutually perpendicular direction ($\hat{\mathbf{z}}$); see Fig. 13. Such flows are called shear flows and the bulk of the stability literature concerns them.

Four facts make the study of transition in shear flow very challenging:

1. Viscosity plays a dual role. On one hand, it damps disturbances and thus restricts the family of unstable modes. However, it may

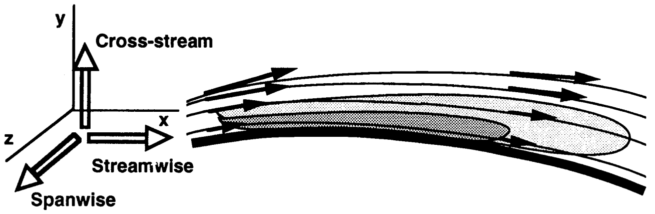

FIG. 13. Two-dimensional shear flow. The flow is mainly in the streamwise direction, the gradients mainly in the cross-stream direction, and the vorticity mainly in the spanwise direction. The streamlines shown are assumed to lie in the *xy* plane. Shaded regions show the gradation of the magnitude of the vorticity, which to first approximation is homogeneous in the streamwise direction.

also transport momentum into some modes and thereby become the *cause* of instability.

2. Transition often occurs well before linear-stability theory predicts the growth of infinitesimal disturbances. This is partly explained by the finding that many of the instabilities are subcritical bifurcations, so that there is a range of Reynolds numbers for which the flow is stable to infinitesimal disturbances but unstable to disturbances above some threshold (possibly quite small in practice.) Furthermore, it has been conjectured that disturbances, even though damped, may persist long enough to provide an altered base flow that can support instability even though the original base flow is stable. Thus environmental disturbances play a heightened role in bringing about instability. The term *receptivity* denotes the mechanisms by which normal modes of the flow are coupled to these external disturbances; examples include fluctuations in the free-stream vorticity, pressure disturbances transmitted through the walls or back up the flow from downstream obstacles, and wall-surface roughness.
3. Even when external disturbances are sufficiently controlled to observe linear-instability modes, these are usually convectively unstable: growing disturbances are "washed" downstream and possibly out of the system before they are big enough to be observed. If unstable modes *are* observed, they have irregular phase (and consequent broad peaks in power spectra) unless the launching disturbance is externally imposed—e.g., by exciting the flow with a vibrating ribbon. Indeed, successful comparison with theory for shear flow instabilities relied on two important experimental tactics: strong suppression of background disturbances through the use of settling chambers, contraction regions, etc, and imposition of an overriding external disturbance with vibrating ribbons, loudspeakers, etc.
4. There is seldom a well-differentiated sequence of instabilities. The effective control parameters (e.g., Reynolds number) evolve spatially. One band of normal modes becomes "detuned" as another is excited, so that there may be a spatially dependent competition of instability modes. A further complication is the possibility that growing secondary flows become unstable even before they equilibrate (Bayly *et al.*, 1988).

Nonetheless, careful control and interpretation of experiments shows some success for the basic stability analysis. In the following, we will first discuss a basic mechanism for instability in inviscid shear flow. Then we show how the linear stability of a wide variety of base flows can be approached within the common formalism of the parallel-flow approximation, first assuming zero viscosity and then accounting for the subtle effects that viscosity can have in flows that are inviscidly "stable." Finally, there will be a brief catalog of specific flows and some discussion of the transition to turbulence, which is largely inevitable once the initial instability sets in.

2.7.1 Kelvin-Helmholtz Instability. Consider the external case [Fig. 14(a)] of a region of inviscid fluid moving with uniform velocity $U_1\hat{\mathbf{x}}$ beneath a region of the same fluid moving with uniform velocity $U_2\hat{\mathbf{x}}$. This is an idealized, infinitesimally thin shear layer. The growth of disturbances $y=\zeta_0\, e^{i(k_x x+k_z z)+st}$ may be treated in the same way as waves on flat fluid interfaces, except that there is no density difference and no surface tension. (Also, the y

and z axes have been exchanged, in keeping with convention for shear flows.) Linear analysis gives the dispersion relation

$$s = \pm k_x \frac{U_2 - U_1}{2} - i k_x \frac{U_1 + U_2}{2}. \tag{83}$$

The result is a traveling wave with an x component of the phase velocity equal to the mean velocity of the fluid layers; for *any* velocity difference, one of the modes is unstable, the wave grows, and the shear layer deforms. The streamlines of the deformed layer seen from the frame moving with the phase velocity (which can be the laboratory frame if $U_1 = -U_2$) form a Kelvin cat's-eye pattern [Fig. 14(c)].

A useful point of view of the instability (Sherman, 1990) is to consider the shear layer, which is a vortex sheet, as a linear array of vortices [Fig. 14(b)] with circulation $\Gamma = (U_1 - U_2)a$ and undistorted positions $(x_{n0}, y_{n0}) = (na, 0)$, where $-\infty < n < \infty$ and a is the uniform spacing of the vortices along the x axis. The vortices interact through the motion they induce in the surrounding fluid:

$$\begin{pmatrix} \dfrac{dx_m}{dt} \\ \dfrac{dy_m}{dt} \end{pmatrix} = \frac{\Gamma}{2\pi} \sum_{\substack{n=-\infty \\ n \neq m}}^{\infty} \frac{1}{(x_m - x_n)^2 + (y_m - y_n)^2} \times \begin{pmatrix} -(y_m - y_n) \\ x_m - x_n \end{pmatrix}. \tag{84}$$

There is no motion of the vortices as long as they remain exactly on the x axis and are uniformly spaced. If their initial positions are perturbed by $(\delta x_{n0}, \delta y_{n0}) = (0, \epsilon \cos kx)$, then it is found that the array curls up into an intricate pattern of billows very much like that seen in real shear layers—see Sherman (1990), pp. 441–444, and references therein for results and important practical details of such computations.

For completeness, we include the dispersion relation when the two regions have different densities ρ_1 and ρ_2 and there is an interfacial tension γ:

$$s = \pm \left(\frac{k_x^2 \rho_1 \rho_2 (U_1 - U_2)^2}{(\rho_1 + \rho_2)^2} - \frac{kg(\rho_1 - \rho_2) + \gamma k^3}{\rho_1 + \rho_2} \right)^{1/2} - ik \frac{\rho_1 U_1 + \rho_2 U_2}{\rho_1 + \rho_2}, \tag{85}$$

where $k \equiv (k_x^2 + k_y^2)^{1/2}$. There can be instability for some k_x and k_y if and only if

$$|U_1 - U_2| > U_c \equiv \left(\frac{2(\rho_1 + \rho_2)}{\rho_1 \rho_2} \right)^{1/2} \times [(\rho_1 - \rho_2) g \gamma]^{1/4}, \tag{86}$$

with the first instability occurring (as the velocity difference is increased) for a wave number equal to

$$k_x = k_c \equiv [(\rho_1 - \rho_2) g / \gamma]^{1/2}, \quad k_y = 0. \tag{87}$$

Note that $1/k_c$ is just the capillary length defined in Sec. 2.1 [following Eq. (45)].

2.7.2 Parallel and Nearly Parallel Flows.

Many flows may be approximated as being parallel, with the fields given by

$$\mathbf{U} \approx U(y)\hat{\mathbf{x}}, \quad P \approx P(x) \quad \text{(two-dimensional base flow)} \tag{88a}$$

or

$$\mathbf{U} \approx U(r)\hat{\mathbf{z}}, \quad P \approx P(z) \quad \text{(axisymmetric base flow).} \tag{88b}$$

Let us then restrict our attention to two-dimensional flows. If viscosity is ignored and the geometry does not vary with x, it turns out that any profile $U(y)\hat{\mathbf{x}}$ and a constant pressure

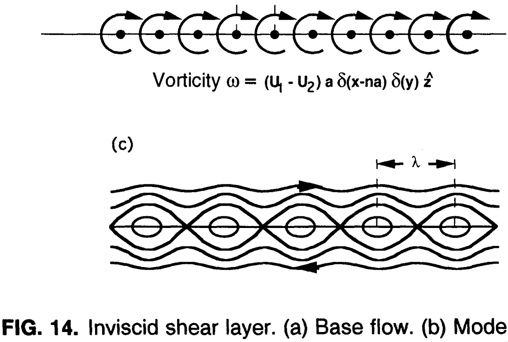

FIG. 14. Inviscid shear layer. (a) Base flow. (b) Model of base flow as an array of equally spaced vortices. (c) Kelvin cat's-eye pattern of streamlines for a disturbance of wavelength λ to the base flow, as seen in frame moving with phase velocity of the wave.

P_0 satisfy the resulting flow equations. In more general situations (like Fig. 13) and with viscosity included, we will assume that the streamwise variation and curvature effects may first be ignored: the base flow is considered to be "locally" parallel. Of course, for some flows (flows through uniform ducts), the base flow is exactly parallel. A classification of parallel and nearly parallel flows is shown in Fig. 15.

Consider a two-dimensional base flow $\mathbf{U}=(U(x,y),V(x,y),0)$. In the following, lengths are scaled by some characteristic length d—for example, the half-width $h/2$ of the channel for flow between parallel plates; velocity is scaled by a characteristic velocity U_0, e.g., the maximum velocity $U_{\max}$; the time scale is d/U_0 and the pressure scale is ρU_0^2. Assuming $V \ll U$ and $\partial U/\partial x \ll \partial U/\partial y$, the terms V and $\partial U/\partial x$ are neglected. Linear-stability analysis proceeds by considering the perturbed velocity and pressure fields: $U(y)\hat{\mathbf{x}}+\mathbf{u}(x,y,z,t)$, $P(x)+p(x,y,z,t)$. For infinitesimal disturbances $\mathbf{u}=(u,v,w)$ and p, the linearized equations are

$$\frac{\partial \mathbf{u}}{\partial t}+U(y)\frac{\partial \mathbf{u}}{\partial x}+v\frac{dU}{dy}\hat{\mathbf{x}}=-\nabla p+\frac{1}{Re}\nabla^2\mathbf{u}, \qquad (89a)$$

$$\nabla\cdot\mathbf{u}=0. \qquad (89b)$$

$\mathbf{u}(x,y,z)$ must vanish at the boundaries $y=y_1$ and y_2 (one or both of which may be at infinity). Homogeneity of the equations in x,z, and t suggests solutions of the form

$$(\mathbf{u},p)=(\hat{\mathbf{u}}(y),\hat{p}(y))e^{i(\alpha x+\beta z-\alpha ct)}. \qquad (90)$$

with four unknown functions of y: $\hat{\mathbf{u}}\equiv(\hat{u},\hat{v},\hat{w})$ and $\hat{p}$. Note that $-i\alpha c=\alpha c_i-i\alpha c_r$ is a new name for the eigenvalues $s=\sigma+i\omega$ used in previous problems (this new notation is customary in shear flow literature). Squire's transformation,

$$\tilde{\alpha}\equiv(\alpha^2+\beta^2)^{1/2},\quad \tilde{c}\equiv c,\quad \tilde{\alpha}\tilde{u}\equiv\alpha\hat{u}+\beta\hat{w},$$
$$\tilde{v}\equiv\hat{v},\quad \frac{\tilde{p}}{\tilde{\alpha}}\equiv\frac{\hat{p}}{\alpha},\quad \tilde{\alpha}\widetilde{Re}\equiv\alpha Re, \qquad (91)$$

permits the system of equations to be reduced to an equivalent two-dimensional problem solving for $\tilde{\mathbf{u}}\equiv(\tilde{u},\tilde{v},0)$ and $\tilde{p}$. For every three-dimensional disturbance satisfying the eigenvalue relation $f(Re,\alpha,\beta,c)=0$, there is a two-dimensional disturbance satisfying $f(\alpha Re/\tilde{\alpha},\tilde{\alpha},0,c)=0$. If the three-dimensional disturbance becomes marginally stable ($c_1=0$) for α and Re, then the corresponding two-dimensional disturbance is marginally unstable for $\tilde{\alpha}$ and $\widetilde{Re}=\alpha Re/\tilde{\alpha}$. Since $\alpha<\tilde{\alpha}$, we have $\widetilde{Re}<Re$, that is, the two-dimensional disturbance becomes unstable at lower Reynolds number. This important result, that the earliest instability occurs for two-dimensional modes, is known as Squire's theorem.

Having reduced the problem back to two dimensions (and dropping the tilde notation), we write u and v in terms of a stream function ψ:

$$u=\frac{\partial\psi}{\partial y},\quad v=-\frac{\partial\psi}{\partial x}, \qquad (92)$$

where

$$\psi=\phi(y)e^{i\alpha(x-ct)}. \qquad (93)$$

Then, defining $D\equiv d/dy$, some manipulation yields the Orr-Sommerfeld equation:

$$(U-c)(D^2-\alpha^2)\phi-U''\phi+\frac{i}{\alpha Re}(D^2-\alpha^2)^2\phi=0. \qquad (94)$$

The boundary conditions are

channel, $\alpha\phi=D\phi=0$ at $y=\pm 1$; (95a)

boundary layer, $\alpha\phi=D\phi=0$ at $y=0,\infty$; (95b)

mixing layer, jets, wakes,

$\alpha\phi=D\phi=0$ at $y=\pm\infty$. (95c)

The pressure $p(x,y,t)$ satisfies Poisson's equation:

$$\nabla^2 p=-2U'\frac{\partial v}{\partial x}. \qquad (96)$$

Letting $p(x,y,t)=\hat{p}(y)e^{i(\alpha x+\beta z-\alpha ct)}$ and using $v=-(\partial/\partial x)[\phi(y)e^{i\alpha(x-ct)}]$ gives

$$(D^2-\alpha^2)\hat{p}=-2\alpha^2U'\phi. \qquad (97)$$

The Orr-Sommerfeld equation [Eq. (94)], though linear, has been "notoriously difficult to solve" (Panton, 1984). Before discussing this further, we consider the inviscid limit $Re\to\infty$. The result is the Rayleigh equation:

$$(U-c)(D^2-\alpha^2)\phi-U''\phi=0. \qquad (98)$$

It must be noted, however, that viscosity can act as a singular perturbation. By taking the limit $Re\to\infty$, the highest-order derivatives have been dropped. Thus there must be fewer

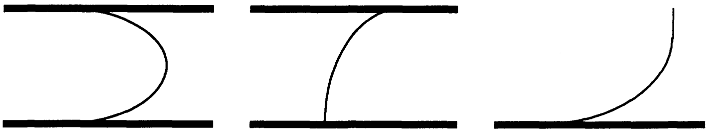
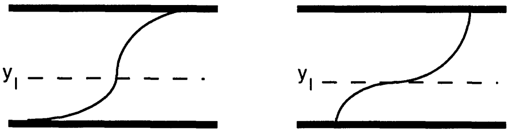
boundary conditions for the Rayleigh equation: $\phi = 0$ at the boundaries (corresponding to vanishing normal velocity component). More subtle consequences of ignoring the viscous term will be discussed below. However, the inviscid equation itself yields important insights. The most important of these is Rayleigh's stability criterion: a necessary condi-



Inviscidly stable: no inflection point



Inviscidly stable: $U''(y)[U(y)-U(y_I)] > 0$

Possibly unstable: $U''(y)[U(y)-U(y_I)] < 0$

FIG. 16. Classification of flow profiles according to Rayleigh's and Fjørtoft's inviscid stability criteria.

tion for a flow to be inviscidly unstable ($c_i > 0$) is that there be an inflection point in the base flow profile: $U''(y)$ must change sign for some y within the flow. Further necessary conditions, Fjørtoft criteria, are

1. $U''(y_I) = 0$ at the inflection point y_I must correspond to a local *maximum* in the magnitude of the vorticity $|U'(y_I)|$ rather than a minimum;
2. $U''(y)[U(y) - U(y_I)] < 0$ somewhere in the flow.

An evaluation of various flow profiles in terms of these conditions is shown in Fig. 16. It should be stressed that these are *necessary* conditions: if the conditions *are* met, this is no guarantee that the profile is unstable.

Some actual flow profiles (for example, mixing layers, wakes, jets, and boundary layers with adverse pressure gradients) satisfy Rayleigh's and Fjørtoft's criteria as candidates for being unstable in the inviscid limit. It is often the case that such flows do in fact become unstable over wave-number ranges in accord with results from Rayleigh's equation, and that the actual viscous eigenmodes with positive growth rate may be determined as a regular perturbation of the inviscid eigenmodes with positive growth rate (expanding in powers of $1/Re$). In such flows, viscosity acts mainly to delay instability.

Other flows, particularly duct flows and boundary layers, are predicted to be stable in the inviscid limit. Observation shows, however, that instability does occur, and for such flows, viscosity can play a subtle role in extracting energy from the mean flow to feed a growing eigenmode. The modes brought about by this mechanism are usually referred to as Tollmien-Schlichting waves, after the scientists who computed approximate solutions for the case of the Blasius boundary layer (the boundary layer over a flat plate placed parallel to a free stream with zero streamwise pressure gradient—see FLUID DYNAMICS, EQUILIBRIUM). The accurate solution of the Orr-Sommerfeld equation in such cases has been an extremely delicate task (both analytically and numerically) that has gone on for more than 70 years. The linear-stability results for various inviscidly "stable" flows are summarized in Table 3.

In reality, however, all of these systems undergo transition much sooner, especially when no extra precautions are taken to eliminate disturbances from the flow. In his classic experiments on transition in pipe flow, Osborne Reynolds found laminar flow up to $Re = 13\,000$. Typical transition Reynolds numbers for pipe flow are 2000, although careful experiments have maintained laminar flow up to $Re = 50\,000$.

Table 3. Critical Reynolds numbers for flows that are inviscidly stable. For the boundary layer, δ^* is the displacement thickness (Panton, 1984). The planes bounding Poiseuille flow are separated by distance h while the pipe has radius r_0. The characteristic velocity U is the maximum velocity of the base flow in each case.

Type	Re	Re_c
Blasius boundary layer	$U\delta^*/\nu$	520
Channel (plane Poiseuille) flow	$Uh/2\nu$	5772
Plane Couette flow	Uh/ν	∞
Pipe flow	Ur_0/ν	∞

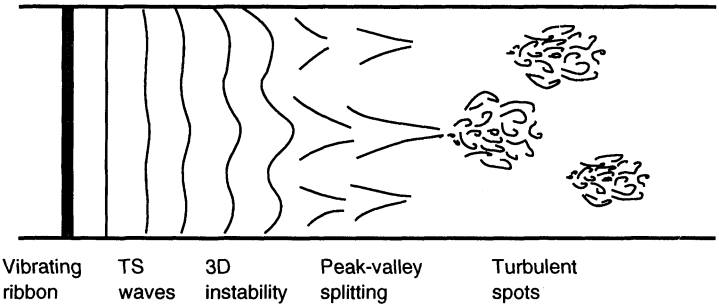


FIG. 17. Schematic of transition in boundary layers or plane channel flow.

Several classic experiments have been done on shear-flow transition. For boundary-layer transition, see Schubauer and Skramstad (1947) and Klebanoff *et al.* (1962). For plane channel flow, see Nishioka *et al.* (1975). In these experiments, free-stream disturbances were kept less than 0.1%, and the Tollmien-Schlichting (TS) waves are excited by vibrating ribbons placed in the flow. The general picture of transition that has emerged from these and other experiments is shown schematically in Fig. 17. After they are excited from the base flow, two-dimensional TS waves become unstable to three-dimensional disturbances generating streamwise vorticity; measurements show a "peak–valley" spanwise (z) variation of the intensity of the velocity fluctuations about the base flow. Associated with this are pronounced Λ-like structures in the visualized flow. Eventually, near the peaks, rapid fluctuations in velocity are observed, and there is a local burst of turbulence (Emmons spot). These turbulent spots or bursts eventually fill up the whole region and the flow completes its transition to turbulence.

For further discussion of shear-flow transition, see the textbooks and monographs in the reading list. Also, see the reviews by Bayly *et al.* (1988), Herbert (1988), Maslowe (1985), and Morkovin (1985).

3. DYNAMICAL SYSTEMS AND CHAOS APPLIED TO FLUID DYNAMICS

Fluid flows involve an infinite number of degrees of freedom, but it appears that there are cases where a dynamical description is accurately collapsed into the nonlinear interaction of a small finite number of degrees of freedom. This suggests the application of dynamical systems theory, with its powerful geometric classification of the solutions and bifurcations of evolution equations like those of the type

$$\frac{d\mathbf{x}}{dt}=\mathbf{f}(\mathbf{x},\mu). \tag{99}$$

In this context, $\mathbf{x}$ denotes a phase-space vector of n state variables $(x_1,\ldots,x_n)$ (for example, the amplitudes of critical modes near an instability), while μ is an m-component parameter-space vector $(\mu_1,\ldots,\mu_m)$, as in Sec. 1.2.8. A plot of a representative sample of possible trajectories $\mathbf{x}(t)$ in phase space is called a phase portrait; this is often more useful than an analytical solution since the qualitative behavior of whole families of solutions may be understood at once. A key feature of Eq. (99) is that it is deterministic: an initial condition $\mathbf{x}_0$ uniquely specifies the solution $\mathbf{x}(t)$ at future times.* However, some types of solutions are found to be effectively unpredictable: two arbitrarily close initial conditions will diverge exponentially fast in time, so that an inevitable small uncertainty in the initial conditions is quickly magnified to become a large uncertainty in the resulting motion. Solutions that have this sensitive dependence on initial conditions are called chaotic.

The existence of chaotic solutions to Eq. (99) has been known since Poincaré's studies in the 19th century. However, the possible application to fluid dynamics (and to physical systems in general) is relatively recent, dating from Lorenz's (1963) discovery of chaotic solutions in a severely truncated model of convection and the conjecture by Ruelle and Takens (1971) that such solutions could be related to turbulence. Since these works, a large amount of experimental evidence has supported the conclusion that some fluid flows may accurately be described as chaotic dynamical systems. Typically, though, these flows are in strongly confined geometries (or they are confined by a persistent structural feature of the flow, such as Taylor vortices). Since spatial variables are not present in Eq. (99), the irregular motion is further said to be temporal chaos. There may be a relation between such examples and fully turbulent flow, in the sense that turbulence also results from a deterministic set of equations (Navier-Stokes and continuity), but these equations depend on both space and time. Thus it is an unwarranted extrapolation to say that the origin and nature of turbulent flows are *explained* by chaos.

---

*Technically, up to some possibly finite limit T—for example, in cases where a solution diverges to infinity in finite time.

With this caveat, we proceed to describe how fluid flows may be characterized, when appropriate, in terms of dynamical systems theory. First, Eq. (99) is said to be a dissipative dynamical system if an arbitrary volume δV of points in phase space is mapped by the dynamics onto volumes steadily decreasing towards zero with time. Arbitrary initial conditions are thereby swept towards zero-volume subsets of phase space called attractors. The simplest type of attractor is a fixed point, for which $d\mathbf{x}/dt$ vanishes, that is, $\mathbf{f}(\mathbf{x},\mu)=0$. The primary fluid flow in systems subjected to steady forces is an example of a fixed-point solution. Fixed-point solutions may become unstable as μ is varied, possibly being replaced by other fixed points as attractors. Alternatively, the new attracting set could be a limit cycle, with the solution oscillating periodically in time. These are the result of a Hopf bifurcation. Limit cycles can in turn become unstable to a torus, characterized by quasiperiodic motions having two incommensurate frequencies. There can be a further succession of solutions that are "N-tori," with N incommensurate frequencies. Landau conjectured that turbulence arises from just this succession of bifurcations to modes with increasing numbers of independent frequencies (and phases). However, it has been shown (Newhouse *et al.* 1978) that arbitrarily near to a three-torus there is a much different type of solution upon which nearby trajectories exponentially diverge from one another. This is called a strange attractor, and the dynamics it represents is chaotic. Although the trajectories are stretched apart from one another, they are also folded back in a manner analogous to the stretching and folding of bread dough. For this to be possible, the phase space must be at least three dimensional. As a result, the attractor has the intricate geometric structure known as a fractal: it is a set of points in phase space that, unlike the tori, has a noninteger dimension. Lorenz's convection model had three equations that generated just such a solution for suitable values of the parameters; this is the well-known Lorenz attractor.

3.1 Scenarios for Evolution to Chaos

The above discussion outlines only one of the possible routes to chaos. This is the sequence stationary–periodic–quasiperiodic–chaotic. Experimental evidence of such a sequence includes the transitions in flow between rotating cylinders: Couette flow→Taylor vortex flow→periodic wavy vortex flow →modulated wavy vortex flow→turbulent Taylor vortices (Fenstermacher *et al.* 1979).

Another sequence is the period-doubling sequence of bifurcations of limit cycles, ending again in a chaotic phase portrait. An astonishing result is that such behavior may be understood, even quantitatively, by studying the bifurcation of attracting sets of arguments x in one-dimensional maps:

$$x(n+1)=f(x(n),\mu). \tag{100}$$

Here time has been replaced by a discrete index n. For a three-dimensional phase space, such maps can be extracted from phase portraits by means of Poincaré sections, which are cross sections of the phase portraits obtained by finding the intersections $(x(n),y(n),0)$ of a three-dimensional trajectory $(x(t),y(t),z(t))$ with some two-dimensional plane $z=0$ (only the intersections going in one direction across the plane are used). It may be that, to a good approximation, one of the coordinates x of the intersection will be a single-valued (but noninvertable) function of the value of the same coordinate for the previous intersection. (More generally, some combination of the coordinates may be found to be a single-valued function of the same combination for the previous intersection.) For small μ, all possible starting values of x will be attracted to a single stable fixed point x (which can be taken to be the origin by a coordinate transformation). Eventually, however, this can become unstable at a value

$u=\mu_1$ to a period-2 solution represented by the pair of points x_1^*,x_2^* that alternately map onto one another; these eventually become unstable to a mapping that sequentially maps four points $x_1^{**},x_2^{**},x_3^{**},x_4^{**}$ onto one another. This period-doubling cascade or subharmonic cascade proceeds over smaller and smaller intervals of μ up to some limit point μ_c where the map becomes chaotic. Furthermore, the sequence μ_1, μ_2, μ_3, etc. satisfies, for a large family of maps $f(x,\mu)$, the universal relation

$$\lim_{i\to\infty}\frac{\mu_i-\mu_{i-1}}{\mu_{i+1}-\mu_i}=\delta, \qquad (101)$$

with $\delta=4.669\,201\,609\,102\,990\,9$, known as the Feigenbaum constant. Experimental observation of such a cascade includes the study of small–aspect-ratio convection (Libchaber and Maurer, 1980; Libchaber *et al.* 1982). The cascade has been observed in other fluid experiments as well as many other nonlinear systems. It is usually only possible to follow a few period doublings because the required precision of μ increases very rapidly. Thus the experimental verification of Eq. (101) is necessarily imprecise.

Another route to chaos observed in experiments is called temporal intermittency, in which the motion remains very nearly periodic for an interval of time, then behaves irregularly for another interval, then becomes regular again, and so on. The fraction of time occupied by the irregular motion increases as some parameter μ is increased. This route to chaos was first explained by Pomeau and Manneville (1980), and an experimental example is the convection experiment of Bergé *et al.* (1980).

Unfortunately, it is seldom possible to predict *a priori* which route is followed for a given small–aspect-ratio experiment. Slightly different experimental conditions can lead to a different evolution of the dynamics.

3.2 Empirical Identification of Fluid Flows as Dynamical Systems

How can experimental data from real fluid flows be fitted into the highly abstract picture of dynamical systems theory? First, a time series of data may be recorded of, say, the velocity at a single spatial location. The square of the discrete Fourier transform of this time series yields a power spectrum that shows the dominant frequencies in the flow. Of course, a steady flow will yield data that are unchanging in time, and the corresponding spectrum will only show the level of external noise in the experiment and its instrumentation. This is useful to establish a noise "floor" for comparison to spectra obtained for time-varying flows. If the flow is periodic, there will be a dominant frequency ω_1 and its harmonics $2\omega_1$, $3\omega_1$, etc. If the flow is quasiperiodic, there will be two independent frequencies ω_1 and ω_2 along with their sums and differences $n_1\omega_1 \pm n_2\omega_2$. If the flow becomes chaotic, however, the spectrum will include broadband features (there may still be peaks in the spectrum). Though not definitive of chaos, the appearance of broadband power spectra as a parameter varies is a clue that the underlying dynamics has made a transition to chaos. A practical concern in producing power spectra is the prevention of aliasing: data must be sampled at least twice as fast as the highest frequency in the flow or else spurious components will appear in the spectra.

Of course, it is desirable to find the phase-space coordinates describing the instantaneous state of the fluid and to map trajectories of the fluid motion in phase space. For some flows, such as parametrically forced surface waves, the normal modes are readily identified and their amplitudes may be measured directly (albeit with considerable experimental ingenuity). In other flows, the identification of normal modes is theoretically intractable. Nevertheless, important features of geometry of the motion in phase space are preserved if coordinates are chosen that depend, in principle, on the mode amplitudes. One technique is the time-delay method (Takens, 1981): a phase space is constructed out of sequences of measurements of a single dynamical variable, such as one component of the velocity at a particular spatial location: $\mathbf{x}(t)=(u(t),u(t+\tau_1),u(t+\tau_2),\ldots,u(t+\tau_{n-1}))$. The choice of time delays τ_i is done either empirically or according to a variety of optimization procedures. The embedding theorem of Takens shows that the geometry of a d-dimensional attractor is faithfully represented in such a construction provided $n>2d+1$. For this procedure to be useful for further studies, the external noise level of the measurements must typically be less than 1%, and 2^{15} (32K) to 2^{18} (256K) data samples are desired.

Another method to identify a basis of modes and their amplitudes is through an adaptation of pattern-recognition techniques to fluid problems. Although developed by Lumley in the 1960s, this has only recently been applied to an understanding of fluid motions as dynamical systems. The approach is known by several names, including Karhunen-Love expansion or proper orthogonal decomposition. An ensemble of realizations of the velocity fields $\mathbf{u}(\mathbf{r})$ is obtained from experiment or from numerical simulations. (Explicit reference to time is left out to emphasize that a statistical ensemble of the spatial fields is sought; if the flow statistics are "stationary," these realizations can be samples of the flow field at different times.) An orthogonal basis $\phi_1(\mathbf{r}),\dots,\phi_n(\mathbf{r})$ is found empirically such that the projection of $\mathbf{u}(\mathbf{r})$ onto $\phi_1(\mathbf{r})$ captures, when averaged over the ensemble, the most energy; the projection of the remaining field onto $\phi_2(\mathbf{r})$ captures the next most energy, etc. Other criteria may be used, since the modes containing the most energy may not be the modes that govern the dynamics. In any case, a *given* time-dependent realization of the field $\mathbf{u}(\mathbf{r},t)$ may be projected onto this basis so that

$$\mathbf{u}(\mathbf{r},t)=\sum_{i=1}^{n} A_i(t)\phi_i(\mathbf{r}). \tag{102}$$

The sum is truncated when the energy in the remaining modes is comparable to the noise in the data. This procedure gives a phase-space trajectory of amplitudes $\mathbf{x}(t)=(A_1,A_2,\dots,A_n)$. This has been applied, for example, to the interpretation of moderately turbulent boundary layer in terms of dynamical systems (Aubry *et al.*, 1988). One drawback of the approach is that it requires huge amounts of data to generate phase portraits of sufficient length to be useful for quantitative studies of the attractors. However, it is a powerful technique and is reviewed in Berkooz *et al.* (1993).

3.3 Measurements of Low-Dimensional Chaotic Systems

Chaos and strange attractors are reviewed in CHAOTIC PHENOMENA. Further discussion, with reference to fluid dynamics problems, may be found in Bergé *et al.* (1986) and Manneville (1990). Here we simply comment on some practical matters.

Computation of fractal dimension requires sufficient experimental precision that an adequate "scaling region" may be found for the density of points on the attractor. That is, a range of radii ϵ about representative points on the attractor is sought so that, for example, the number of points within an n-dimensional hypersphere of radius ϵ about such points will accurately scale as ϵ^d across the range, where d is called the correlation dimension. The upper limit is set by the size of the attractor and the lower limit by the noise in the data. Typically, a resolution in the data greater than 10 bits is desired.

On the other hand, as the attractor dimension becomes larger, the space in which it is embedded likewise must be enlarged and it becomes more and more sparsely populated for a fixed number of data points. The number of points required to sample adequately the structure of the attractor blows up and there currently is a practical limit of $d \approx 4$ for reliable dimension computations.

Perhaps the most decisive indicator that the data come from a chaotic dynamical system is the existence of at least one positive Lyapunov exponent. This exponent measures the average rate at which nearby trajectories on a chaotic attractor diverge from one another. For example, phase-space trajectories from data for weakly turbulent Taylor vortex flow were found to have a positive Lyapunov exponent using the algorithm of Wolf *et al.* (1985).

4. SUMMARY

There are many other important classes of instabilities. For example, instabilities in wake flows have received a lot of attention since they seem to mix the properties of convective and absolute instability, depending on spatial location. See the review by Oertel (1990). For geophysical problems, instabilities affected by stratification and by Coriolis forces become very important. These are extensively discussed in the book by Pedlosky (1979); further discussion of stability problems in rotating flows is found in Greenspan (1968). It is likely that any identifiable fluid state (for example, intense vortex flow) has a retinue of instability phenomena and journals such as *Physics of Fluids*, *Journal of Fluid Mechanics*, *Physical Review E,* and *European Journal of Mechanics B/Fluids* continue to have a large share of articles on instability phenomena. The past decade has seen surges of interest in the application of dynamical systems theory to fluid problems and in nonlinear pattern formation; the extension of these areas into open flows remains a considerable challenge. Meanwhile, engineering concerns cause research in shear-flow transition to proceed unabated. Finally, the ultimate problem—turbulence—draws the attention of all researchers in nonequilibrium fluid flows. See TURBULENT FLOWS.

GLOSSARY

Absolute Instability: An instability in which a local disturbance results in a permanently altered flow at the origin of the disturbance even though the effects of the disturbance may also propagate away from the origin.

Amplitude Equations: A simplified description of the evolution of a new state of flow in terms of amplitudes of a small number of characteristic modes of instability.

Aspect Ratio: The ratio of the length of an apparatus in a direction perpendicular to the gradient in applied stresses to the width of the apparatus in the direction parallel to the gradient.

Attractor: A set in phase space that has the properties that (a) if an initial condition lies on the attractor, then the resulting trajectory remains on the attractor as time increases; (b) there is a neighborhood of the attractor such that initial conditions lying in the neighborhood have trajectories that converge on the attractor as time increases.

Basic Flow: An established state of flow that is examined for its stability with respect to perturbations.

Bifurcation: A branching, as a control parameter is varied, of the number of states of a system satisfying the governing equations; not all of the states are necessarily stable.

Boundary Layer: A thin layer in a flow near a solid wall, in which there are large gradients in flow velocity, temperature, etc.

Capillary Waves: Waves on a free surface of sufficiently short wavelength such that surface tension is the dominant restoring force.

Centrifugal Instability: Instability in flow with curved streamlines, due to the inability of the pressure gradient to provide sufficient centrifugal acceleration to fluid flowing in a streamline perturbed from its equilibrium position.

Chaos: Seemingly random motion of a system governed by deterministic equations, where the state quickly becomes unpredictable because of sensitive dependence on initial conditions.

Control Parameter: A parameter (for example, flow rate) that may be independently varied to control the state of a system.

Convective Instability: An instability in which a local disturbance results in a growing perturbation to the flow that travels away from the origin sufficiently fast that the flow at the origin returns to its original undisturbed state.

Critical Reynolds Number: The Reynolds number at which infinitesimal disturbances will render a basic flow unstable. (The same definition applies to other control parameters—for example, critical Rayleigh number.)

Critical Wave Number: The wave number [2π/wavelength] of the Fourier component of a disturbance that is the first to destabilize a basic flow state.

Dispersion Relation: The dependence of the growth rate and frequency of a mode of motion on the wave number of that mode.

Dissipative Dynamical System: A dynamical system in which arbitrary volumes of initial conditions in phase space reduce to sets of zero volume as time increases. A physical system in which there are frictional forces such as viscosity may also be called a dissipative dynamical system.

Dissipative Structures: Spontaneously ordered patterns in a nonequilibrium system that are sustained through a steady input of energy.

Dynamical System: A system of equations that describes the evolution of a state with time (usually according to a system of ordinary differential equations) or with increasing number of iterations of a mapping rule. The physical system modeled by such equations may also be considered a dynamical system.

Envelope Equations: A generalization of amplitude equations to allow variation of the amplitudes of the characteristic modes of instability over length scales long compared to the wavelength of the modes.

Equivariant: The property that equations of motion look the same after a change of coordinates arising from a symmetry operation such as translation, rotation, or reflection.

Fingering Instabilities: Instability in an interface or advancing front that causes the interface or front to deform into fingers.

Görtler Vortices: Vortices arising from the instability of a boundary layer near a curved wall; the axes of the vortices are in the streamwise direction.

Gravity Waves: Waves on a free surface, of sufficiently long wavelength such that gravity is the dominant restoring force.

Hele-Shaw Cell: An experiment configuration in which fluid is constrained to flow between two very close parallel plates.

Hopf Bifurcation: A bifurcation in which the new state of a system is characterized by an additional frequency of oscillation with time and the amplitude of the new state grows continuously from zero as a parameter is varied.

Hysteresis: The difference between the path along which a system evolves as a control parameter is increased and the path along which it evolves as the control parameter is decreased between the same two limiting values.

Imperfect Bifurcation: A smooth change in solution to the equations of motion (or in the state of a physical system) as a parameter is varied that is not a true branching from some original solution but would be a new branch if the corresponding physical system had perfect symmetry, was infinitely long, etc.

Inflectional Instability: The basic means by which many shear flows are unstable, in situations where the Rayleigh criterion is met: there is an inflection point in the plot of the streamwise velocity component versus a coordinate perpendicular to the flow direction.

Laminar Flow: A relatively simple state of fluid motion in which velocities remain either steady, periodic, or quasiperiodic in time. The flow is pictured as layers (laminae) of fluid sliding past one another, in contrast to turbulent flow in which there is a complex random eddying motion that is constantly stretching and bending elements of fluid.

Limit Cycle: An attracting set in phase space that represents a periodic solution to the equations of motion.

Linear-Stability Analysis: The solution of the equations of motion for small perturbations of a basic flow when all nonlinear terms in the perturbations are ignored. The solutions depend exponentially on either time or space: exponential growth indicates that the basic flow is unstable to the perturbations, while exponential decay indicates that the basic flow is stable.

Marangoni Convection: Motion induced in a fluid layer due to thermally induced spatial variation of the surface tension of the layer.

Marginal Stability Curve: Plot, as a function of wave number, of the Reynolds (or Rayleigh) number at which a Fourier component of a disturbance is at the threshold of growth.

Nonlinearity: Terms in the equations of motion that involve products of two or more of the dependent variables (for example, velocity components) or their derivatives; this includes products of a given dependent variable with itself.

Nusselt Number: Ratio of heat transport by a convective flow to the heat transport due to thermal conduction alone.

Open Flow: A flow in which mass is continuously passed into and then out of a system.

Parameter Space: The space of parameters selected to control or describe the flow; each coordinate represents the value of a different parameter.

Parametric Instability: Instability arising from the periodic variation of a parameter in the equations of motion that multiplies a term containing one of the state variables.

Phase Diagram: A map of regions in parameter space corresponding to various observed states of motion.

Phase Portrait: The trajectory in phase space traced by a dynamical system as time evolves, starting with one or more initial conditions. Such portraits give useful geometric meaning to the dynamics: steady states are points, periodic oscillations are closed curves, etc.

Phase Space: A space whose coordinates are the amplitudes of the various degrees of freedom of a dynamical system.

Prandtl Number: Ratio of the kinematic viscosity to the thermal diffusivity of a fluid.

Primary Flow: The unique state of flow produced when applied stresses are sufficiently small.

Quasiperiodic: Time dependence characterized by two or more independent frequencies that are not rationally related to one another (the ratio of the frequencies is not the ratio of two integers).

Rayleigh-Bénard Convection: Motion induced in a fluid layer heated from below due to the buoyancy of the warmer fluid relative to the cooler fluid.

Rayleigh Number: A dimensionless number describing the ratio of the effects of buoyancy to the effects of dissipation due to viscosity and thermal diffusion [see Eq. (2)]. $Ra \equiv \alpha g(T_2 - T_1)d^3/\nu\kappa$, where α is the thermal expansion coefficient, g is the acceleration due to gravity, $T_2 - T_1$ is the temperature difference that occurs across a gap d, ν is the kinematic viscosity, and κ is the thermal diffusivity.

Resonant Wave Interactions: Strong coupling of wave modes that satisfy the condition that the wave number of one of the modes is the vector sum of the wave numbers of the other modes and, correspondingly, the frequency of the one mode is the sum of the frequencies of the other modes.

Reynolds Number: A dimensionless number describing the ratio of inertia forces to viscous forces in a system [see Eq. (65)], $Re \equiv Ud/\nu$, where U is a characteristic velocity, d is a characteristic dimension across which changes in velocity of order U occur, and ν is the kinematic viscosity of the fluid.

Secondary Flow: The new, more complex part of a flow field that results after an instability—for example, Taylor vortices in flow between independently rotating cylinders.

Shear Flow: Flow whose dominant characteristic is a gradient in flow velocity in a direction perpendicular to the flow direction.

Side-Wall Forcing: Influence of bounding walls on the selection of patterns in secondary flows.

Slaving Principle: The idea that a few critical modes (those that have just become unstable) determine the dynamics of all the remaining degrees of freedom in a system.

Spatial Instability: An instability in which time-dependent forcing at one spatial location (or at one surface in the flow) leads to a disturbance that grows with spatial distance away from the origin.

Spatiotemporal Chaos: Chaotic motion that becomes uncorrelated in both space and time.

Stability Balloon: A confined region of stability in the space of parameters describing a flow (most readily visualized when there are three parameters, such as Rayleigh number, Prandtl number, and wave number in the case of convecting rolls).

Strange Attractor: An attractor whose geometry is fractal (has noninteger dimension) as a consequence of dynamics that stretches and folds the trajectories starting from nearby points on the attractor. Chaotic dynamics yields phase portraits that are strange attractors.

Stream Function: A scalar function of position and time from which the two velocity components of a two-dimensional flow field may be obtained as partial derivatives with respect to the two space variables: $u = \partial\psi/\partial y$ and $v = -\partial\psi/\partial x$. This formulation automatically guarantees the continuity equation $\partial u/\partial x + \partial v/\partial y = 0$. The stream function is constant along streamlines.

Streamline: A curve whose tangent is everywhere parallel to the fluid velocity.

Subcritical Bifurcation: A branching to a new solution whose amplitude increases from zero as a control parameter decreases from the point of bifurcation.

Supercritical Bifurcation: A branching to a new solution whose amplitude increases from zero as a control parameter increases from the point of bifurcation.

Symmetry-Breaking Bifurcation: A branching to a new solution that has less symmetry than the original solution.

Taylor-Couette System: The experimental system for studying flow between independently rotating coaxial cylinders. This system is characterized by a clearly distinguished sequence of bifurcations leading from the primary flow to turbulence. It is a much-studied system because of the high degree of success with which it can be modeled by mathematical analysis or numerical simulation.

Temporal Chaos: Chaotic motion that remains highly correlated in space although it quickly becomes unpredictable in time.

Temporal Instability: An instability in which an initial [time = 0] disturbance throughout the spatial domain of flow grows with time.

Tollmien-Schlichting Waves: Traveling-wave disturbances to a steady shear flow; the waves are characterized by well-defined wave number and frequency and are, at infinitesimal amplitude, the eigenmodes of the linear-stability problem for the steady shear flow.

Turbulence: A highly disordered state of fluid motion in which the velocity, pressure, and (when applicable) temperature appear to vary randomly in space and time. The flow is intrinsically three-dimensional, with local vortexlike motions that are continually being altered by stretching and reorientation of the vortices. Turbulent flows transport mass and momentum orders of magnitude more readily than nonturbulent (laminar) flows.

Turbulent Spot: A local burst of turbulence appearing in a boundary layer; analogous phenomena occur in channel flow and flow between counter-rotating cylinders. Sometimes these are referred to as "Emmons spots," after the person who observed such bursts in a shallow water channel.

Vortex Sheet: A hypothetical plane of discontinuity in the velocity of a parallel two-dimensional flow; the discontinuity may be viewed as the limit of an infinitely dense array of parallel vortices all lying in the same plane (see Fig. 14).

32.1 Introduction

Fourier analysis, which gained prominence from the work of J. B. J. Fourier in the early 1800s, led immediately to applications in mechanics and heat conduction. It also contributed to the advance of pure mathematics as regards the basic notions of limit, convergence, and integrability; the impact on mathematics and applied physics has continued to this day. Applications of transform methods were developed in connection with differential and integral equations and became very powerful; more recently, numerical analysis, aided by electronic computing, has added an extra dimension to the applied relevance of mathematical transforms and especially of the Fourier transform. The analytical and computational aspects are dealt with first; among applied examples, heat conduction, Fourier-transform spectroscopy, diffraction, sampled data, and tomography are mentioned.

When one looks for antecedents from which Fourier analysis might have evolved, they are not hard to find. Euler had published trigonometric series, and the sum to infinity, in such statements as

$$\sin x - \tfrac{1}{2}\sin 2x + \tfrac{1}{3}\sin 3x + \cdots = \tfrac{1}{2}x \tag{32.1}$$

Gauss analyzed motion in astronomical orbits into harmonics and indeed utilized the fast algorithm now favored for computing. Much earlier in Roman times, Claudius Ptolemy expressed motion in planetary orbits by the geometrical equivalent of trigonometric series and, according to Neugebauer (1983), the idea of epicycles has roots in Mesopotamian astronomy where the solar motion was matched by zigzag functions, rough approximations of the sinusoids to come.

32.2 The Fourier Transform

There are many transforms, each characterized by its own explicit operator, which we may call as **T**. The operand, or entity operated on, is a function such as $f(x)$, where x is a real variable ranging from $-\infty$ to ∞. The notation $\mathbf{T}\{f(x)\}$ signifies the outcome of applying the operator **T** to the function $f(x)$. To illustrate, the operation that converts a given function $f(x)$ to its Fourier transform, which is a different function $F(s)$, is as follows: ''Multiply the function $f(x)$ by $\exp(-i2\pi sx)$ and integrate with

ISBN: 978-3-527-40773-6

respect to x from $-\infty$ to ∞". Applying this operation to $f(x) = \exp(-|x|)$, we find that $\mathbf{T}\{f(x)\} = F(s) = 2/[1 + (2\pi s)^2]$, which is the Fourier transform of $\exp(-|x|)$. The symbolic expression of the Fourier transform operation is

$$F(s) = \int_{-\infty}^{\infty} f(x) e^{-i2\pi sx} \mathrm{d}x \qquad (32.2)$$

It is apparent that any particular value of $F(s)$ (for example, $F(2)$, which equals 0.0126) takes into account the whole range of x; that is, the value depends on the shape of $f()$ as a whole, not on any single point. Thus the Fourier operation is quite unlike the operation that converts $f(x) = \exp(-|x|)$ to $\sin[\exp(-|x|)]$; the outcome of this latter operation is referred to as a *function of a function*, and the resulting values each depend only on the single value of x. When the result depends on the shape of $f(x)$ over part or all of the range of x, an entity such as $F(s)$ is called a *functional* of $f()$. The variable s is called the *transform variable* and may have a physical meaning; if so, its units will be cycles per unit of x. A short list of Fourier transforms for illustration is shown in Table 32.1.

In this list, rect x is the unit rectangle function (equal to unity where $|x| < 0.5$, elsewhere zero) and sinc $x = (\sin \pi s)/\pi s$. The last five lines are representative theorems of the form, "If $f(x)$ has Fourier transform $F(s)$, then [modification of $f(x)$] has transform [modification of $F(s)$]". Extensive lists of such transform pairs and theorems are available from the reference texts; the short list given would cover a sizable fraction of the analytic forms encountered in the literature.

With some transforms – the Abel transform is an example – each transform value depends on only a part of, not all of, $f()$; and with other transforms, the transform variable does not necessarily have a different identity (as s is different from x) but may have the same identity (Hilbert transform). The integral from $-\infty$ to x is a transform with both of the above restrictive properties.

Tab. 32.1 Selected Fourier transforms. The quantity a is a constant.

F(x)	F(s)
$e^{-\|x\|}$	$2/[1 + (2\pi s)^2]$
$\delta(x)$	1
$\cos(2\pi x/a)$	$\frac{1}{2}\delta(s + a^{-1}) + \frac{1}{2}\delta(s - a^{-1})$
rect x	sinc s
$e^{-\pi x^2}$	$e^{-\pi s^2}$
$e^{-\pi(x/a)^2}$	$\|a\| e^{-\pi(as)^2}$
$f(x/a)$	$\|a\|\ F(as)$
$f(x + a)$	$e^{i2\pi as} F(s)$
$f'(x)$	$i2\pi s F(s)$
Autocorrelation of $f(x)$	$\|F(s)\|^2$
$\int_{-\infty}^{\infty} f(x - u) g(u) \mathrm{d}u$	$F(s)G(s)$

All the transforms dealt with here are linear transforms, which are the commonest type; they all obey the superposition rule that $\mathbf{T}\{f_1(x) + f_2(x)\} = \mathbf{T}\{f_1(x)\} + \mathbf{T}\{f_2(x)\}$ for any choice of the given functions $f_1(x)$ and $f_2(x)$. An example of a nonlinear transformation is provided by $\mathbf{T}\{f(x)\} = a + bf(x)$, as may be tested by reference to the superposition definition; clearly the term *linear* in "linear transform" does not have the same meaning as in Cartesian geometry.

32.3
Continuous versus Discrete Transforms

Before defining the main transforms succinctly by their operations $\mathbf{T}$, all of which involve integration over some range, it is worth commenting on a numerical aspect. One could take the point of view, as is customary with numerical integration, that the desired integral is an entity in its own right; that the integral may on occasion be subject to precise evaluation in analytic terms, as with $F(s) = 2/[1 + (2\pi s)^2]$; and that if numerical methods are required, a sum will be evaluated that is an approximation to the desired integral. One would then discuss the desired degree of approximation and how to reach it. Now this is quite unlike the customary way of thinking about the discrete Fourier transform. What we evaluate is indeed a sum, but we consider the sum as precise and not as an approximation to an integral. There are excellent reasons for this. Meanwhile, the important thing to realize is that there are both a Fourier transform and a discrete Fourier transform, each with its own definition. The discrete Fourier transform operation is

$$F(\nu) = \frac{1}{N}\sum_{\tau=0}^{N-1} f(\tau)e^{-i2\pi\nu\tau/N} \qquad (32.3)$$

The word "discrete" is used in antithesis to "continuous," and in the cases discussed here, it means that an independent variable assumes integer values. To understand the discrete Fourier transform, which is exclusively what we compute when in numerical mode, it is best to forget the Fourier integral and to start a fresh. Instead of starting with a complex function $f(x)$ that depends on the continuous real variable x, we start with N data (complex in general, but often real) indexed by an integer serial number τ (like time) that runs from 0 to $N - 1$. In the days when FORTRAN did not accept zero as a subscript, summation from $\tau = 0$ caused much schizophrenia, but the mathematical tradition of counting from zero prevailed and is now unanimous. In cases where $f(\,)$ is a wave form, as it often is, the quantity τ can be considered as time that is counted in units starting from time zero. Clearly, N samples can never fully represent $\exp(-|x|)$, for two reasons: the samples take no account of the function where x exceeds some finite value, and no account is taken of fine detail between the samples. Nevertheless, one may judge that, for a given particular purpose, 100 samples will suffice, and the confidence to judge may be bolstered by trying whether acquisition of 200 samples significantly affects the purpose in hand. Numerical intuition as developed by hand calculation has always been a feature of mathematical work but was regarded as weak compared with physical intuition. Nowadays, however, numerical intuition is so readily acquired that it has become a matter of choice whether to deal with questions about the size of N by traditional analytic approaches. A new mix of tools from analysis, finite mathematics, and numerical analysis is evolving.

The discrete transform variable ν reminds us of frequency. If τ is considered as time measured in integral numbers of seconds, then ν is measured in cycles per second, and is indeed like frequency (cycles per second or Hertz), but not exactly. It is ν/N that gives correct frequencies in Hertz, and then only for $\nu \leq N/2$. Where ν exceeds $N/2$, we encounter a domain where the discrete approach conflicts with the continuous. When the Fourier transform is evaluated as an integral, it is quite ordinary to contemplate negative values of s, and a graph of $F(s)$ will ordinarily have the vertical $s = 0$ axis in the middle, giving equal weight to positive and negative "frequencies." (The unit of s is always cycles per unit of x; if x is in meters, s will be a spatial frequency in cycles per meter; if x is in seconds, s will be a temporal frequency in cycles per second, or hertz.) However, the discrete Fourier transform, as conventionally defined, explicitly requires the transform variable ν to range from 0 to $N-1$, not exhibiting negative values at all. There is nothing wrong with that, but persons coming from continuous mathematics or from physics may like to know that, when ν is in the range from $N/2$ to $N-1$, the quantities $N-\nu$ correspond to the negative frequencies familiar to them as residing to the left of the origin on the frequency axis. This is because the discrete transform is periodic in ν, with period N.

In the familiar Fourier series

$$p(x) = a_0 + \sum_{1}^{\infty}(a_\nu \cos 2\pi\nu x + b_\nu \sin 2\pi\nu x) \tag{32.4}$$

for a periodic function $p(x)$ of period 2π, the first term a_0 represents the direct current, zero frequency, or mean value over one period as calculated from

$$a_0 = \frac{1}{2\pi}\int_0^{2\pi} p(x)\,\mathrm{d}x \tag{32.5}$$

Therefore, the first term $F(0)$ of the discrete Fourier transform is the average of the N data values. This is the reason for the factor $1/N$ in front of the summation sign in Eq. (32.3), a factor that must be remembered when checking. In practical computing, it is efficient to combine the factor $1/N$ with other factors such as calibration factors and graphical scale factors that are applied later at the display stage. The remaining Fourier coefficients, given by

$$a_\nu = \frac{1}{\pi}\int_0^{2\pi} p(x)\cos 2\pi\nu x\,\mathrm{d}x \tag{32.6}$$

$$b_\nu = \frac{1}{\pi}\int_0^{2\pi} p(x)\sin 2\pi\nu x\,\mathrm{d}x \tag{32.7}$$

are related to the discrete Fourier transform by $a_\nu - ib_\nu = F(\nu)$. The minus sign arises from the negative exponent in the Fourier kernel $e^{-i2\pi sx}$. The reason for the choice of the negative exponent is to preserve the convention that d/dt be replaceable by $+i\omega$ in the solution of linear differential equations, as when the impedance of an inductance L to alternating voltage of angular frequency ω is written as $+i\omega L$ (more usually as $j\omega L$).

How to decide whether the discrete Fourier transform is an adequate approximation to the Fourier transform is a very interesting question. But the question itself is open to challenge. If I am studying cyclicity in animal populations, perhaps seasonal influence on bird migration, I may start with 365 reports of how many birds were seen each day of the year. In such a case, and in many other cases, discrete data mean that the integrals, even though convenient, are themselves the approximations; the discrete Fourier transform, given N equispaced data, is a valid entity in its own right. However, unexpected discrepancies may arise over the choice of N, which may be very large or very small. Slow computing (N very large), unwanted sensitivity to measurement error (N very small), and aliasing are its negative consequences. Aliasing is the word for the following phenomenon. Measurements are made of some time-varying phenomenon at regularly spaced time intervals, perhaps temperature is recorded twice a day or perhaps speech samples are taken at a 10-kHz rate. Such data can represent harmonic components with period longer than one day or longer than 2×10^{-4} s, but cannot faithfully follow faster harmonic variation. The samples will not ignore the presence of such high frequencies, because the high-frequency variations will indeed be sampled, but the samples will be consistent with, and indistinguishable from, a long-period sinusoidal component that is not actually present. The imperfectly sampled component emerges under the alias of a lower, counterfeit frequency.

32.4
Some Common Transforms

As a convenient reference source, definitions of several transforms (Laplace, Fourier, Hartley, Mellin, Hilbert, Abel, Hankel, Radon) are presented in Table 32.2. When one has the transform, there is a way of returning to the original function in all the cases chosen. In some cases, the inverse operation $\mathbf{T}^{-1}$ is the same as the defining operation $\mathbf{T}$ (e.g., Hartley and Hilbert, which are reciprocal transforms), but the majority differ, as shown. In addition, examples of each transform are presented. These will be found to convey various general properties at a glance and may be helpful for numerical checking.

32.5
The Laplace Transform

A long and diverse history (Deakin, 1985) characterizes the Laplace transform, which was in use long before Laplace, but became known to current generations mainly through its pertinence to the linear differential equations of transient behavior in electricity and heat conduction. Many tough technological problems of electric circuits that arose in connection with telegraphy, submarine cables, and wireless, and related industrial-process problems of thermal diffusion, were cracked around the turn of the century, sometimes by novel methods such as those of Heaviside (1970), which were to be justified subsequently (Nahin, 1987) to the satisfaction of academic mathematics by systematic application of the Laplace transform. Heaviside is remembered for stimulating the application of the Laplace transform to convergence of series and for Maxwell's equations, the delta function, the Heaviside layer, impedance, nonconvergent series that are useful for computing, fractional order derivatives and integrals, and operational calculus.

Table 32.2 gives, as an example, the Laplace transform of $f(x) = \exp(-x - 1.5)\mathbf{H}(x + 1.5)$. The Heaviside unit step function $\mathbf{H}(x)$ jumps, as x increases from 0 to 1, the jump being where $x = 0$; one of its uses is as a multiplying factor to allow algebraic expression of functions that switch on. The transform of $f(x)$, which is easy to verify by integration, is $(\exp\ \ 1.5s)/(1 + s)$; the transform variable s may be complex but must lie among those numbers whose real parts are greater than -1 (otherwise the integral does not exist). It is rather cumbersome to exhibit the complex transform graphically on the complex plane, and so an illustration is omitted. To invert the transform requires integration on the complex plane along a semicircular contour with indentations if necessary to circumvent points where the integrand goes to infinity (poles). The

Tab. 32.2 Transform definitions, inverses, and examples. (Ticks are at unit spacing.

Name of transform	Nature of function domain variable	Example of function	Nature of transform variable	Nature of transform	Example of transform	Defining formula and the inverse

[a] The function cas$x = \cos x + \sin x$.

constant c in the inversion formula is to be chosen to the right of all poles.

To some extent, Laplace transforms were computed numerically, but more typically, development led to compilations of analytic transforms resembling the tables of integrals (Campbell and Foster, 1948; Erdélyi *et al.*, 1954). Programs for deriving the Laplace transform of the impulse response from electrical networks given diagrammatically are also available. Consequently, it is hardly ever necessary to analytically derive Laplace transforms today. The analytic solution of transients in electric circuits, a subject traditionally used for sharpening the minds of electrical engineers, is obsolescent because impulse responses and transfer functions have been concisely published (McCollum and Brown, 1965). Furthermore, the advent of integrated circuits has meant that inductance is seldom included in new designs, and those circuits containing more than two or three elements have become less common. Mature programs are also available for step-by-step integration of circuit differential equations.

On the numerical side, the Laplace transform has also been largely eroded by use of the Fourier transform. This is because angular frequency ω is a mathematically real quantity, and it ought to be possible to compute the behavior of an electrical, acoustical, or mechanical system without reference to a complex frequency $\omega - i\sigma$. Certainly, the Laplace transform is computable over its strip of convergence from any single slice therein. Nevertheless, practitioners of control theory find it convenient to assume the complex plane of s in terms of poles and zeros that are off the real frequency axis, and theirs is one tradition that keeps the complex plane alive; the convenience stems from the fact that the Laplace transform is analytic, and thus specifiable by its poles and isolated zeroes. There are problems that used to be handled by the Laplace transform, paying strict attention to the strip of convergence, because the Fourier integral did not converge; but these situations are now universally handled by Fourier methodology with the aid of delta-function notation for impulses and their derivatives, and no longer call for special treatment. When it comes to discrete computing, the impulse, and its associated spectrum reaching to indefinitely large frequencies, may in any case be forgotten. Thus, it has been wondered (Körner, 1988) ''whether the Laplace transform will keep its place in the standard mathematical methods course for very much longer,'' but it will never die out; a new balance between curricular segments will be struck.

32.6
Convergence Conditions

Much attention used to be given to the existence of the Fourier integral because of paradoxes with such wanted entities as $f(x) = 1, f(x) = \cos x$, or $f(x) = \delta(x)$, where $\delta(x)$ is the unit impulse at $x = 0$, none of which possessed a Fourier integral. Today, we reason as a physicist would, recognizing that a voltage waveform cannot have a value of 1 V forever, but must have turned on at some time in the past and will turn off at some time in the future. The finite-duration function does have a Fourier transform. We then consider a sequence of waveforms of longer and longer duration and the corresponding sequence of transforms, arriving at the concept of "transforms in the limit." This attitude has received mathematical respectability under the rubric of generalized functions (Lighthill, 1958) and is the basis for saying that the Fourier transform of $\delta(x)$ is 1 (while conversely the Fourier transform of 1 is $\delta(s)$). The elaborate conditions for the existence of a transform when generalized functions were excluded have thus lost interest. Even $\delta'(x)$ now has the indispensable transform $i2\pi s$; under the rules of analysis, $\delta'(x)$ was an unimaginable entity, certainly not qualifying as a function of x; it was considered as a commonplace dipole by physicists, and as a local load such as a moment applied at a point on a beam in mechanics.

The fact that the Laplace integral converged when the Fourier transform did not give the Laplace transform a certain prestige, even though convergence was achieved at the cost of tapering the given function by a real, exponentially decaying factor. In addition, the strip of convergence had to be specified for the complex transform variable s. The convenience of dealing with the real and physically intuitive frequency as the transform variable has shifted preference in favor of the Fourier and Hartley transforms. The only effective condition for the existence of a Fourier or Hartley transform today is that the given function should have a physical interpretation, or be representable by a sequence of physically interpretable functions whose individual transforms approach a limit. Consequently, it is no longer necessary to require that $f(x)$ be absolutely integrable ($\int_{-\infty}^{\infty} |f(x)| \mathrm{d}x$ exists) or that any discontinuities be finite; on the contrary, the "shah function" $\mathrm{III}(x) = \Sigma_{n=-\infty}^{n=\infty} \delta(x-n)$, which could be said to possess an infinite number of infinite discontinuities, now has a Fourier transform thanks to the theory of generalized functions (Bracewell, 1956). Interestingly, the Fourier transform of $\mathrm{III}(x)$ is $\mathrm{III}(s)$.

The function $\sin(x^{-1})$ raises a convergence question as a result of possessing an infinite number of maxima in any interval containing $x = 0$; this sort of behavior is without interest in the world of numerical computing but of considerable interest to the theory of integration. Possession of an infinite number of maxima does not in itself define the convergence condition because the Fourier integral may converge if the amplitude of the oscillation dies down so that the function exhibits bounded variation. Nor does bounded variation define the convergence condition because Lipschitz has demonstrated functions of unbounded variation whose Fourier integrals converge. However, the Lipschitz condition is not the ultimate convergence condition, as has been shown by Dini (Bracewell, 1986a). This style of analysis has lost practitioners as activity has moved in the direction of finite, or discrete, mathematics.

32.7
Why Transforms are Useful

Many problems can be posed in the form of a differential equation (or a difference equation, or an integral equation, or an integro-differential equation) that has to be solved for some wanted function subject to stated boundary conditions or initial conditions. Laplace's equation in three dimensions describes the potential distribution set up by an array of electric charges, and the diffusion equation describes the heat flow distribution set up by a given distribution of heat. By applying a transformation such as the Laplace or Fourier to each term of such an equation, we arrive at a new equation that describes the transform rather than the original wanted function. The interesting thing about this is that the new equation may be simpler, sometimes solvable just by algebra. We solve that equation for the transform of the solution and then invert. Not all differential equations are simplified in this way; those that do are characterized by linearity and coordinate invariance (such as time invariance), and the presence of these characteristics in nature is responsible for a good deal of the numerical activity with transforms. Transfer functions, such as the frequency response curves of amplifiers, are corresponding manifestations of these same characteristics. The passage of a speech waveform through an amplifier is described by a differential equation that may be hard to solve; but having used a Fourier transform to go to the frequency domain, we apply the transfer function, frequency by frequency, by complex multiplication to get the transform of the output. Then retransforming gives the output waveform.

There is also a differential equation, describing the bending of a beam under the influence of a load distribution that may be considered as a spatial input analogous to an input waveform, whereas the curve of deflection is analogous to the output waveform. Although Hooke's law, the first of the linear laws, may apply, we do not use transform methods. If we analyze the load distribution into spatially sinusoidal components and find the bending response to each component and linearly sum the responses, we will get the desired shape of the bent beam, but there is no transfer function to facilitate getting the individual responses by simple algebra. The reason is that we have linearity but not space invariance – if we shift the load, the response does not shift correspondingly without change of shape; a sinusoidal load does not produce sinusoidal deflection. If, on the contrary, we delay the input to an amplifier or a vibratory mechanical system, the response is correspondingly delayed but is unchanged as to shape; furthermore, a sinusoidal input produces a sinusoidal output.

32.8
Fields of Application

Fourier (Grattan-Guinness, 1972) originally thought of representing the temperature on a heat-conducting bar as the sum of sinusoids. To avoid a problem of integration, he considered the bar to be bent around on itself in a large circle, a distortion that is not harmful to the discussion of any given finite straight bar because the arc of interest can be made as straight as you wish by taking the circle large enough. Because the temperature distribution on the ring is of necessity now periodic in space, only a fundamental and harmonics need to be considered, plus the constant temperature a_0 representing the mean temperature. As time elapses, the temperature distribution varies as the heat flows under the influence of the temperature gradients, ultimately approaching the uniform value a_0 in the limit. Fourier found that the component sinusoids decay exponentially with a time constant proportional to the spatial period, or wavelength, the nodes of each sinusoid remaining fixed. By attenuating each component in accordance with the elapsed time and summing one gets the same result as if the spatially variable heat flow were followed in real time. This is an example of the duality of the function domain (space domain in this instance) and the transform domain (spatial frequency domain) that permeates Fourier applications.

Music can be considered in terms of the wave form of the wave that conveys the sound through the air (function domain), or in terms of the harmonic constituents (spectral domain) that are separately discernible by the ear and are treated separately by an amplifier. In crystallography, there is the arrangement of the atoms in space (crystal lattice domain) and the spatial Fourier components (reciprocal lattice domain) that under illumination by X-rays or neutron beams, evidence themselves by diffraction at defined angles. Image formation with cameras and radio telescopes can be conceived as operating on the object domain, or "sky plane," or we can think in terms of complex coherence measurements in the transform domain. All these dual modes of thought, under their respective terminologies, are fully equivalent; it helps to be familiar with both and to be able to translate from one domain to the other. In addition, it is most helpful to be able to translate between fields, converting a problem in one subject into the analogous problem in another subject where the solution may be intuitively obvious. As an example, persons who know very well that the diffraction from a pair of side-by-side pinholes is sinusoidal in space may not know that the spectrum of a pair of audible clicks in succession is sinusoidal in frequency. How much richer this knowledge becomes when they are able to translate from acoustics to optics and vice versa!

As a formal illustration of the methodology, let us calculate the response of an electric circuit consisting of an inductance L in series with a resistance R to which a voltage impulse of strength A is applied at $t = -1.5$. Equating the sum of the voltages in the circuit to zero, as taught by Kirchhoff, gives the differential equation

$$A\delta(t) = L\frac{\mathrm{d}i}{\mathrm{d}t} + Ri \tag{32.8}$$

where $i(t)$ is the current flow in response to the applied voltage. Taking the Fourier transforms term by term (Table 32.1), we find that

$$Ae^{i2\pi\times 1.5s} = i2\pi sLI(s) + RI(s) \tag{32.9}$$

where $I(s)$ is the transform of the wanted current. Solving this algebraic equation gives

$$I(s) = \frac{Ae^{i2\pi\times 1.5s}}{R + i2\pi Ls} \tag{32.10}$$

and taking the inverse Fourier transforms of both sides give

$$i(t) = \frac{A}{L}e^{-R(t+1.5)/L}\mathbf{H}(t+1.5) \tag{32.11}$$

The transform involved is illustrated in Table 32.2 for the Fourier transform. The method for solving the same problem by the Laplace transform is similar but involves reference to convergence of the integral, a complication that is circumvented when generalized function theory is combined with the Fourier integral.

Newton showed how to split sunlight into its constituent colors with a prism, where we think in the spatial domain, but there is another way that we learned from Michelson that is explicable in the time domain. We split a beam of light, and then recombine the two beams on a photodetector, but not before a controlled delay is introduced into one of the beams, for example, by retroreflection from a movable plane mirror. The detector output reveals the autocorrelation of the light beam from which, by using the autocorrelation theorem (Table 32.1) and numerical Fourier transformation, we get the spectral distribution of power.

32.9
The Hartley Transform

Table 32.2 illustrates by example that the Fourier transform in general is a complex function of the real transform variable s; consequently, two transform curves must be drawn, one for the real part and one (broken) for the imaginary part. The example $f(\tau)$ for the discrete Fourier transform is based on samples of the previous $f(x)$. Imaginary values of the discrete transform $F(\nu)$ are shown as hollow circles. Three features may be noted: no matter how closely samples are spaced, some detail can be missed; no outlying parts beyond a finite range are represented; the indexing convention 0 to $N-1$ has the effect of cutting off the left side of $F(s)$, translating it to the right, and reconnecting it. To convey the nature of this third comment, the points for $\tau > N/2$ have been copied back on the left.

The Hartley transform differs from the Fourier transform in that the kernel is the real function cas $2\pi sx$ instead of $\exp(-i2\pi sx)$. The cas function, which was introduced by Hartley (1942), is defined by cas $x = \cos x + \sin x$ and is simply a sinusoid of amplitude $\sqrt{2}$ shifted one-eight of a period to the left. The consequences of the change are that the Hartley transform is real rather than complex and that the transformation is identical to the inverse transformation. As may be obvious from the graphical example, the Hartley transform contains all the information that is in the Fourier transform and one may move freely from one to the other using the relations

$$H(s) = \text{Re}\, F(s) - \text{Im}\, F(s) \tag{32.12}$$

and

$$2F(s) = H(s) + H(N-s) - iH(s) + iH(N-s) \tag{32.13}$$

The convenience that arises from familiarity with complex algebra when one is thinking about transforms loses its value in computing. What one thinks of compactly as one complex product still means four real multiplications to computer hardware, which must be instructed accordingly.

The Hartley transform is fully equivalent to the Fourier transform and can be used for any purpose for which the Fourier transform is used, such as spectral analysis. To get the power spectrum from the complex-valued Fourier transform, one forms $[\text{Re}\, f(s)]^2 + [\text{Im}\ F(s)]^2$; starting from the real-valued Hartley transform, one forms $[H(s)]^2 + [H(-s)]^2$. The phase is obtained from

$$\begin{aligned}\tan\phi(s) &= \text{Im}(s)/\text{Re}(s)\\ &= [H(-s)/H(s)] - \pi/4\end{aligned} \tag{32.14}$$

We see that for purposes of spectral analysis by the Hartley transform, it is not necessary to work with complex quantities, because power spectrum is an intrinsic property independent of choice of kernel; the phase depends on the x origin which is locked to the peak of the cosine function in one case and the peak of the cas function in the other, hence the term $\pi/4$.

32.10
The Fast Fourier Transform

Around 1805, C.F. Gauss, who was then 28, was computing orbits by a technique of trigonometric sums equivalent to today's discrete Fourier synthesis. To get the coefficients from a set of a dozen regularly spaced data he could explicitly implement the formula that we recognize as the discrete Fourier transform. To do this, he would multiply the N data values $f(\tau)$ by the weighting factors $\exp(-i2\pi\nu\tau)$, sum the products, and repeat these N multiplications N times, once for each value of ν, making a total of N^2 multiplications. But he found that, in the case where N is a composite number with factors such that $N = n_1 n_2$, the number of multiplications was reduced when the data were partitioned into n_2 sets of n_1 terms. Where N was composed of three or more factors, a further advantage could be obtained. Gauss (1876) wrote, "illam vero methodum calculi mechanici taedium magis minuere, praxis tentatem docebit." He refers to diminishing the tedium of mechanical calculation, as practice will teach him who tries. This factoring procedure, usually into factors of 2, is the basis of the fast Fourier transform (FFT) algorithm, which is explained in many textbooks (Rabiner and Gold, 1975; IEEE, 1979; Elliott and Rao, 1982; Nussbaumer, 1982; Bracewell, 1986a; Press *et al.*, 1986) and is available in software packages. The fast method (Cooley and Tukey, 1965) burst on the world of signal analysis in 1965 and was for a time known as the *Cooley-Tukey algorithm* (IEEE, 1967), but as the interesting history (Heideman *et al.*, 1985) of prior usage in computing circles became known, the term FFT became universal.

Most FFT programs in use take advantage of factors by adopting a choice of N that is some power P of 2, that is, $N = 2^P$. The user may then design the data collection to gather, for example, $256 = 2^8$ readings. Alternatively, when such a choice does not offer, a user with 365 data points can simply append sufficient zeros to reach $512 = 2^9$ values. This might seem wasteful, but an attendant feature is the closer spacing of the resulting transform samples, which is advantageous for visual presentation. Perhaps one could do the job faster, say by factoring into 5×73. There are fast algorithms for 5 points and for many other small primes, but not for 73, as far as I know; it is simply not practical to store and select from lots of special programs for peculiar values of N. On the other hand, a significant speed advantage is gained if one elects more rigidity rather than more flexibility, tailors one's data collection to a total of 4^P values, and uses what is referred to as a *radix-4 program*. Because $1024 = 4^5$, the radix-4 approach is applicable to $N = 1024$ data samples (or to 256 for example), but not to 512 unless one appends 512 zeros. Packing with just as many zeros as there are data is commonly practiced because twice as many transform values result from the computation, and when the power spectrum is presented graphically as a polygon connecting the computed values, the appearance to the eye is much smoother.

Much practical technique is involved. If the sound level of an aircraft passing over a residential area is to be recorded as a set of measurements equispaced in time, the quantity under study begins and ends at zero value. But in other cases, such as a record of freeway noise, the noise is present when measurements begin and is still there when they cease; if the N values recorded are then packed with zeros, a discontinuity is introduced whose effects on the transform, such as overshoot and negative-going oscillation, may be undesirable. Packing with plausible (but unobserved) data can eliminate the undesired artifacts and is probably practiced in more cases than are admitted to. Authors often mitigate the effects of implied discontinuities in the data by multiplying by a tapering function, such as a set of binomial coefficients, that approaches zero at both the beginning and end of the data taken; they should then explain that they value freedom from negatives more than accuracy of amplitude values of spectral peaks or than resolution of adjacent peaks.

The FFT is carried out in P successive stages, each entailing N multiplications, for a total of NP. When NP is compared with N^2 (as for direct implementation of the defining formula), the savings are substantial for large N and make operations feasible, especially on large digital images, that would otherwise be unreasonably time consuming.

32.11
The Fast Hartley Algorithm

When data values are real, which is very commonly the case, the Fourier transform is nevertheless complex. The N transform values are also redundant (if you have the results for $0 \leq \nu \leq N/2$ you can deduce the rest). This inefficiency was originally dealt with by the introduction of a variety of efficient but unilateral algorithms that transformed in half of the time of the FFT, albeit in one direction only; now we have the Hartley transform, which for real data is itself real, is not redundant, and is bidirectional. The Hartley transform is elegant and simple and takes you to the other domain, regardless of which one you are in currently (Bracewell, 1986b; Buneman, 1989).

When a Hartley transform is obtained, there may be a further step required to get the more familiar complex Fourier transform. The time taken is always negligible, but even so the step is usually unnecessary. The reason is that although we are accustomed to thinking in terms of complex quantities for convenience, it is never obligatory to do so. As a common example, suppose we want the power spectrum, which is defined in terms of the real and imaginary parts of the Fourier transform by $P(\nu) = [\mathrm{Re}\, F(\nu)]^2 + [\mathrm{Im} F(\nu)]^2$. If we already have the Hartley transform $H(\nu)$, then it is not necessary to move first to the complex plane and then to get the power spectrum; the desired result is obtained directly as $\{[H(\nu)]^2 + [H(N - \nu)]^2\}/2$. Likewise phase $\varphi(\nu)$, which is required much less often than $P(\nu)$, is defined by $\tan\,[\varphi(\nu)] = \mathrm{Im}\ F(\nu)/\mathrm{Re}\ F(\nu)$; alternatively, one can get phase directly from $\tan\,[\varphi(\nu) + \pi/4] = H(N - \nu)/H(\nu)$, thus circumventing the further step that would be necessary to go via the well-beaten path of real and imaginary parts.

To illustrate the application to power spectra, take as a short example the data set {1 2 3 4 5 6 7 8}, whose discrete Hartley transform is

$$H(\nu) = \{4.5 - 1.707 - 1 - 0.707 \\ - 0.5 - 0.293\ 0\ 0.707\} \tag{32.15}$$

The first term, 4.5, is the mean value of the data set. The power spectrum for zero frequency is 4.5^2, for frequency $1/8(\nu = 1)$, $P(1) = (-1.707)^2 + (0.707)^2$, for frequency $2/8(\nu = 2)$, $P(2) = (-1)^2 + 0^2$. Similarly $P(3) = (-0.707)^2 + (-0.293)^2$ and $P(4) = (-0.5)^2 + (0.5)^2$. The highest frequency reached is 4/8, corresponding to a period of 2, which is the shortest period countenanced by data at unit interval.

The encoding of phase by a real transform has added a physical dimension to the interest of the Hartley transform, which has been constructed in the laboratory with light and microwaves (Villasenor and Bracewell, 1987, 1988, 1990; Bracewell, 1989; Bracewell and Villasenor, 1990) and has suggested a new sort of hologram.

32.12
The Mellin Transform

The vast majority of transform calculations that are done every day fall into categories that have already been dealt with, and much of what has been said is applicable to the special transforms that remain to be mentioned. The Mellin transform has the property that $F_M(n+1)$ is the nth moment of $f(x)$ when n assumes a finite number of integer values 1, 2, 3, ... The special value $F_M(1)$ is the zeroth moment of, or area under, $f(x)$. But the transform variable does not have to be integral or even real, so one can think of the Mellin transform as a sort of interpolate passing through the moment values. When the scale of x is stretched or compressed, for example, when $f(x)$ is changed to $f(ax)$, the Mellin transform becomes $a^{-2}F_M(s)$, a modification that leaves the position of features on the s-axis unchanged and is useful in some pattern-recognition problems.

If we plot $f(x)$ on a logarithmic scale of x, a familiar type of distortion results, and we have a new function $f(e^{-x})$ whose Laplace transform is exactly the same as the Mellin transform of $f(x)$. An equally intimate relation exists with the Fourier transform. Consequently, the FFT may be applicable in numerical situations. Because of the intimate relationship with moments and with spectral analysis, Mellin transforms have very wide application. A specific example is given by the solution of the two-dimensional Laplace equation expressed in polar coordinates, namely $\partial^2 V/\partial r^2 + r^{-1}\partial V/\partial r + r^{-2}\partial^2 V/\partial\theta^2 = 0$. Multiply each term by r^{s-1} and integrate with respect to r from 0 to ∞. We get $d^2F_M/d\theta^2 + s^2F_M = 0$. Solve this for $F_M()$ and invert the transform to get the solution. In this example, a partial differential equation is converted to a simple differential equation by the transform technique.

32.13
The Hilbert Transform

As the example in Table 32.2 shows, the Hilbert transform, or quadrature function, of a cosinusoidal wave packet is a similar, but odd, waveform sharing the same envelope. But what do we mean by the envelope of an oscillation that only touches the intuitively conceived envelope at discrete points? The Hilbert transform provides an answer in the form $\sqrt{[f(x)]^2 + [f_{Hi}(x)]^2}$. Likewise, the original wave packet reveals its phase at its zero crossings. But what is the phase at intermediate points? The Hilbert transform supplies an instantaneous phase ϕ in the form $\tan \phi = f_{\mathrm{Hi}}(x)/f(x)$. The operation **T** for the Hilbert transform is simply convolution with $-1/\pi x$. It is known that the Fourier transform of $-1/\pi x$ is $i \operatorname{sgn} s$, where $\operatorname{sgn} s$ is 1 for $s > 0$ and -1 for $s < 0$. Therefore, by the convolution theorem (last line of Table 32.1), according to which the Fourier transform of a convolution is the product of the separate Fourier transforms, it would seem that a fast Hilbert transform of $f(x)$ could be calculated as follows. Take the FFT of $f(x)$, multiply by i for $0 < \nu < N/2$ and by $-i$ for $N/2 < \nu < N$, set $F(0)$ and $F(N/2)$ equal to zero, and invert the FFT to obtain the Hilbert transform. This sounds straightforward, but the procedure is fraught with peril, for two reasons. We propose to multiply a given function $f(x)$ by $-1/\pi[(x+ \text{const})]$ and to integrate from $-\infty$ to ∞, but we are only given N samples. The extremities of $-1/\pi x$ approach zero and have opposite signs, but there is infinite area under these tails no matter how far out we start. Consequently, we ask two oppositely signed large numbers to cancel acceptably. How can we expect satisfaction when the convolving function $-1/\pi x$ is not symmetrically situated about the extremes of the data range? The second reason is that we ask for similar cancellation in the vicinity of the pole of $1/x$. Experience shows that satisfactory envelopes and phases only result when $f(x)$ is a rather narrow-band function. Under other circumstances, an N-point discrete Hilbert transform can be defined and will give valid results free from worries about the infinities of analysis, but the outcome may not suit expectation.

An optical wave packet $\exp(-\pi t^2/T^2) \sin 2\pi \nu t$ of equivalent duration T easily meets the narrow-band condition when the duration T is much greater than the wave period $1/\nu$; it has a Hilbert transform $\exp(-\pi t^2/T^2)\cos 2\pi\nu t$. The square root of the sum of the squares yields $\exp(-\pi t^2/T^2)$ for the envelope, in full accord with expectation.

32.14
Multidimensional Transforms

The two-dimensional Fourier and Hartley transforms are defined respectively by

$$F(u, v) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) \times e^{-i2\pi(ux+vy)} \mathrm{d}x\mathrm{d}y \qquad (32.16)$$

$$F(u, v) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) \times \operatorname{cas}[2\pi(ux + vy)]\mathrm{d}x\mathrm{d}y \qquad (32.17)$$

where the transform variables u and v mean spatial frequency components in the x and y directions. Work with images involves two dimensions, electrostatics and X-ray crystallography involve three, and fluid dynamics involves four. Multidimensional transforms can be handled numerically with a one-dimensional FFT subprogram or a fast Hartley as follows. Consider an $N \times N$ data array. Take the 1-D (one-dimensional) transform of each row and write the N transform values in over the data values. Now take the 1-D transform of each resulting column

(Bracewell, 1984; Bracewell *et al.*, 1986). In three and four dimensions, the procedure is analogous (Hao and Bracewell, 1987; Buneman, 1989). Further simple steps lead to the Hartley transform and to the real and imaginary parts of the Fourier transform if they are required, but usually they are not; more often the quadratic content (power spectrum) suffices.

When a 2-D function has circular symmetry, as commonly arises with the response functions of optical instruments, not so much work is required, as explained below in connection with the Hankel transform. Cylindrical symmetry in 3-D is essentially the same, while spherical symmetry in 3-D is also referred to below.

32.15
The Hankel Transform

In two dimensions, where there is circular symmetry as expressed by a given function $f(r)$, the two-dimensional Fourier transform is also circularly symmetrical; call it $F_{\mathrm{Ha}}(s)$. It can be arrived at by taking the full 2-D transform as described earlier, or it can be obtained from a single 1-D Hankel transform as defined in Table 32.2. The inverse transform is identical. There is apparently no opening for the Hartley transform because in the presence of circular symmetry the 2-D Fourier transform of real data contains no imaginary part. The kernel for the Hankel transform is a zero-order Bessel function, which is a complication that hampers the FFT factoring approach, but there is an elegant sidestep around this, which is explained below in connection with the Abel transform. Under spherical symmetry, the 3-D Fourier transform reduces to a different one-dimensional transform

$$4\pi \int_0^\infty f(r)\mathrm{sinc}(2sr)r^2\mathrm{d}r \qquad (32.18)$$

The inverse transform is identical.

To illustrate by a well-known result from optical diffraction, we consider a telescope aperture $f(r)$ representable as $\mathrm{rect}(r/D)$, a two-dimensional function that is equal to unity over a circle of diameter D. The Hankel transform is $D^2\mathrm{jinc}Ds$, the familiar Fraunhofer diffraction field of a circular aperture. The jinc function [$\mathrm{jinc}x = J_1(\pi x)/2x$], which is the Hankel transform of the unit rectangle function of unit height within a radius of 0.5, has the property that jinc $1.22 = 0$; this is the source of the constant in the expression $1.22\lambda/D$ for the angular resolution of a telescope.

32.16
The Abel Transform

Most commonly, although not always, the Abel transform arises when a 2-D function $g(x, y)$ has circular symmetry, as given by $f(r)$. The Abel transform (Table 32.2) then simplifies to $F_{\mathrm{A}}(x) = \int_{-\infty}^{\infty} g(x, y)\mathrm{d}y$. In other words, if the given $f(r)$ is represented by a square matrix of suitably spaced samples, then the Abel transform results when the columns are summed. There might not seem to be any future in trying to speed up such a basic operation, apart from the obvious step of summing only half way and doubling. However, when it is remembered that for each of $N^2/8$ matrix elements, we have to calculate $\sqrt{x^2 + y^2}$ to find r, and thence $f(r)$, it gives pause. The alternative is to proceed by equal steps in r rather than in y; then the oversampling near the x-axis is mitigated. But the variable radial spacing of elements stacked in a column needs correction by a factor $r/\sqrt{r^2 - s^2}$, which takes more time to compute than $\sqrt{x^2 + y^2}$. This is an excellent case for decision by using the millisecond timer found on personal computers. Of course, if many runs are to be made, the factors $r/\sqrt{r^2 - s^2}$ can be precomputed and the preparation time can be amortized over the successive runs.

Figure 32.1 shows a given function $g(x, y)$ and its one-dimensional projection (labeled P) which is derived by integrating along the y-axis in the (x, y) plane. Integrating along the y'-axis of a rotated coordinate system gives the projection P'. Now if $g(x, y)$ were circularly symmetrical, being a function $f(r)$ of r only, then the projections P and P' would be identical and equal to the Abel transform of $f(r)$. This is the graphical interpretation of the Abel transform.

Applications of the Abel transform arise wherever circular or spherical symmetry exists. As an example of the latter, consider a photograph of a globular cluster of stars in the outer reaches of the galaxy. The number of stars per unit area can be counted as a function of distance from the center of the cluster; this is the projected density. To find the true volume density as a function of radius requires taking the inverse Abel transform (Table 32.2) of the projected density.

With the Abel transform under control, we can now see a way of doing the Hankel transform without having to call up Bessel functions. The Abel, Fourier, and Hankel transforms form a cycle known as the *FHA cycle* (Bracewell, 1956), so that if we take the Abel transform and then take the FFT, we get the Hankel transform; the theorem is

$$\int_0^\infty \mathrm{d}rJ_0(2\pi\xi r)r \int_{-\infty}^{\infty} \mathrm{d}se^{i2\pi rs} \int_s^\infty \frac{\mathrm{d}x2xf(x)}{\sqrt{x^2 - s^2}} = f(\xi) \qquad (32.19)$$

The FFT required will not be complex, except in the extraordinary case of complex 2-D data; consequently, it will in fact be appropriate to use the fast Hartley to get the Hankel transform. Because of symmetry, the result will also be exactly the same as obtained with the FFT, if after taking the FFT we pay no attention to the imaginary parts that have been computed, which all should be zero or close to zero.

The FHA cycle of transforms is a special case of the projection slice theorem, a theorem which refers to the more general situation where $g(x, y)$ is not circularly symmetrical. Circular symmetry characterizes instruments, especially optical instruments, which are artifacts. Lack of symmetry characterizes data; tomographic data will be taken as the illustration for the projection-slice theorem.

32.17
Tomography and the Radon Transform

Consider a set of rotated coordinates (x', y') centered on the (x, y) plane, but rotated through θ. The expression $\int_{-\infty}^{\infty} g(x, y)\mathrm{d}y$ given for the Abel transform, representing a line integral in the y direction at a given value of x, would equal the line integral $\int_{-\infty}^{\infty} g(x, y)\mathrm{d}y'$ in the rotated direction y' provided $g(x, y)$ had circular symmetry as specified for the Abel transform. But when $g(x, y)$

Fig. 32.1 Illustrating the projection-slice theorem, which states that if a distribution $g(x, y)$ has a projection P', in the y' direction, its 1-D Fourier transform is the slice S' through the 2-D Fourier transform of $g(x, y)$. The set of projections P' for all inclination angles of the (x', y') coordinates constitutes the Radon transform. In the presence of circular symmetry where $g(x, y) = f(r)$, the projection P in any direction is the Abel transform of $f(r)$. The 1-D Fourier transform of P is the slice S in any direction; this slice S is then the Hankel transform of $f(r)$. Thus the Abel, Fourier, and Hankel transforms form a cycle of transforms.

does not have symmetry, then the line-integral values depend both on x' and on the angle θ (Figure 32.1). The set of integrals with respect to dy' is the Radon transform of $g(x, y)$, named after Johann Radon (1917). Such integrals arise in computed X-ray tomography, where a needle beam of X-rays scans within a thin plane section of an organ such as the brain with a view to determining the distribution of absorption coefficient in that plane. If there are N^2 pixels for which values have to be determined, and because one scan will give N data, at least N different directions of scan spaced $180°/N$ apart will be needed to acquire enough data to solve for the N^2 unknowns. In practice, more than $2N$ directions are helpful to compensate for diminished sample density at the periphery. To compute a Radon transform is easy; the only tricky part is summing a given matrix along inclined directions. One approach is to rotate all the matrices and interpolate onto a rotated grid, for each direction of scan; but this may be too costly. At the other extreme one sums, without weighting, the matrix values lying within inclined strips that, independently of inclination, preserve unit width in the direction parallel to the nearer coordinate direction. How coarse the increment inclination angle may be dependent on acceptability as judged by the user in the presence of actual data.

The harder problem is to invert the line-integral data to retrieve the required absorption coefficient distribution. A solution was given by Radon

(1917). Later Cormack (1963, 1964, 1980), working in the context of X-ray scanning of a solid object, gave a solution in terms of sums of transcendental functions. Other solutions include the modified back-projection algorithm (Bracewell, 1956; Bracewell and Riddle, 1967) used in CAT scanners (Brooks and Di Chiro, 1976; Rosenfeld and Kac, 1982; Deans, 1983). The algorithm depends on the projection-slice theorem (see Figure 32.1). According to this theorem, (Bracewell, 1956) the 1-D Fourier transform of the projection P' (or scan) of $g(x, y)$ in any one direction is the corresponding central cross section or slice S' through the 2-D Fourier transform of the wanted distribution $g(x, y)$. The proof is as follows. Let the 2-D Fourier transform of $g(x, y)$ be $G(u, v)$ as defined by

$$G(u, v) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(x, y) \times e^{-i2\pi(ux+vy)} \mathrm{d}x\mathrm{d}y \quad (32.20)$$

Setting $v = 0$, so as to have the representation $G(u,0)$ for the slice S, we get

$$\begin{aligned} G(u, 0) &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(x, y) e^{-i2\pi ux} \mathrm{d}x\mathrm{d}y \\ &= \int_{-\infty}^{\infty} \left[\int_{-\infty}^{\infty} g(x, y) \mathrm{d}y \right] \times e^{-i2\pi ux} \mathrm{d}x \\ &= \int_{-\infty}^{\infty} P(x) e^{-i2\pi ux} \mathrm{d}x \quad (32.21) \end{aligned}$$

where $P(x)$ is the projection of $g(x, y)$ onto the x-axis. Thus, the 1-D transform of the projection $P(x)$ is the slice $G(u, 0)$ through the 2-D transform of $g(x, y)$. If we rotate the coordinate axes to any other orientation (x', y'), we see that the same proof applies.

Because the density of polar coordinate samples is inversely proportional to the radius of the Fourier transform plane, a simple correction factor followed by an inverse 2-D Fourier transform will yield the solution. However, a solution was found (Bracewell and Riddle, 1967; Brooks and Di Chiro, 1976), based on this theoretical reasoning, to avoid numerical Fourier transforms entirely. An equivalent correction term, arrived at by convolving each projection P' with a few coefficients, can be directly applied to each P', after which the modified projections are accumulated on the (x, y) plane by back projection to reconstitute $g(x, y)$. Back projection means assigning the projected value at x' to all points of the (x, y) plane which, in the rotated coordinate system, have the abscissa x'. Accumulation means summing the back-projected distributions for all inclination angles.

32.18
The Walsh Transform

A function defined on the interval (0, 1) can be expressed as a sum of sines and cosines of frequency 1,2,3,. . ., but can also be expressed as a sum of many other sets of basis functions. Among the alternatives, Walsh functions (Walsh, 1923; Elliott and Rao, 1982; Hsu and Wu, 1987) are particularly interesting because they oscillate between values of +1, 0, and −1, a property that is most appropriate to digital circuits, telecommunications, and radar. Furthermore, multiplication by a Walsh function value takes much less time than multiplication by a trigonometric function. Walsh functions, not being periodic, are not to be confused with the periodic square cosine and sine functions $C(x) = \mathrm{sgn}(\cos x)$ and $S(x) = \mathrm{sgn}(\sin x)$; but on a finite support they do form a complete set from which any given function can be composed. They are also orthonormal (mutually orthogonal and with fixed quadratic content, as with Fourier components), which leads to simple relations for both analysis and synthesis. The Walsh (or Walsh-Hadamard) transform has found use in digital signal and image processing and for fast spectral analysis. Fast algorithms are available that use only addition and subtraction and have been implemented in hardware. A vast, enthusiastic literature sprang into existence in the 1970s, a guide to which can be found in the text by Elliott and Rao (1982).

32.19
The *Z* Transform

In control theory, in dealing with signals of the form

$$f(t) = \sum_{-\infty}^{\infty} a_n \delta(t-n) \qquad (32.22)$$

and systems whose response to $\delta(t)$ is

$$h(t) = \sum_{0}^{\infty} h_n \delta(t-n) \qquad (32.23)$$

the response $g(t)$ is the convolution integral

$$g(t) = \int_{-\infty}^{\infty} f(t')h(t-t')\mathrm{d}t' \qquad (32.24)$$

This response is a series of equispaced impulses whose strengths are given by $\Sigma_i a_i h_{n-i}$, an expression representable in asterisk notation for convolution by $\{g_n\} = \{a_n\} * \{h_n\}$ (in this notation the sequence $\{a_n\}$ sufficiently represents $f(t)$). For example, a signal $\{1\ 1\ 1\ 1\ 1\ 1\ \ldots\}$ applied to a system whose impulse response is $\{8\ 4\ 2\ 1\}$ produces a response

$$\{1\,1\,1\,1\,1\,1\ldots\} * \{8\,4\,2\,1\}$$
$$= \{8\ 12\ 14\ 15\ 15\ 15\ldots\} \qquad (32.25)$$

This is the same rule as that that produces the coefficients of the polynomial that is the product of the two polynomials $\Sigma a_n z^n$ and $\Sigma h_n z^n$, as may be verified by multiplying $1 + z + z^2 + z^3 + z^4 + z^5 + \ldots$ by $8 + 4z + 2z^2 + z^3$. The z transform of the sequence $\{8\ 4\ 2\ 1\}$ is, by one definition, just the polynomial $8 + 4z + 2z^2 + z^3$; more often one sees $8 + 4z^{-1} + 2z^{-2} + z^{-3}$. If, conversely, we ask what applied signal would produce the response $\{8\ 12\ 14\ 15\ 15\ 15\ldots\}$, we get the answer by long division:

$$(8 + 12z + 14z^2 + 15z^3 + 15z^4 + 15z^5$$
$$+ \cdots)/(8 + 4z + 2z^2 + z^3) \qquad (32.26)$$

Occasionally, one of the polynomials may factor, or simplify, allowing cancellation of factors in the numerator and denominator. For example, the z transform of the infinite impulse response $\{8\ 4\ 2\ 1\ 0.5\ldots\}$, where successive elements are halved, simplifies to $8/(1 - z/2)$. But with measured data, or measured system responses, or both, this never happens and the z notation for a polynomial quotient is then just a waste of ink compared with straightforward sequence notation such as $\{8\ 12\ 14\ 15\ 15\ 15\ldots\} * \{8\ 4\ 2\ldots\}^{-1}$. Whenever sampled data are operated on by a convolution operator (examples would be finite differences, finite sums, weighted running means, and finite-impulse-response filters), the z transform of the outcome is expressible as a product of z transforms. Thus to take the finite difference of a data sequence, one could multiply its z transform by $1 - z$ and the resulting polynomial would be the z transform of the desired answer; in a numerical environment one would simply convolve the data with $\{1 - 1\}$. In control theory and filter design, the complex plane of z is valued as a tool for studying the topology of the poles and zeroes of transfer functions.

32.20
Convolution

Sequences to be convolved may be handled directly with available subprograms for convolution and inverse convolution that operate by complex multiplication in the Fourier transform domain. When two real sequences are to be convolved, you can do it conveniently by calling the two Hartley transforms, multiplying term by term, and calling the same Hartley transform again to get the answer. Some subtleties are involved when the sequences are of unequal length or in the unusual event that neither of the factors has symmetry (even or odd) (Bracewell, 1986b). If one of the sequences is short, having less than about 32 elements, depending on the machine, then slow convolution by direct evaluation of the convolution sum may be faster, and a shorter program will suffice. When the Fourier transform is used, the multiplications are complex but half of them may be avoided because of Hermitian symmetry. Software packages such as CNVLV (Press *et al.*, 1986) are available that handle these technicalities by calling two unilateral transforms, each faster than the FFT, or two equivalent subprograms; one fast Hartley transform, which is bilateral and, conveniently for the computer, real valued, now replaces such packages. Fast convolution using prime-factor algorithms is also available if general-purpose use is not a requisite.

As an example, suppose that $\{1\ 2\ 1\}$ is to be convolved with $\{1\ 4\ 6\ 4\ 1\}$, a simple situation where we know that the answer is the binomial sequence

$$\{1\ 6\ 15\ 20\ 15\ 6\ 1\} \tag{32.27}$$

If we select $N = 8$ for the discrete transform calculation, the given factors become in effect

$$f_1(\tau) = \{1\ 2\ 1\ 0\ 0\ 0\ 0\ 0\} \tag{32.28}$$

and

$$f_2(\tau) = \{1\ 4\ 6\ 4\ 1\ 0\ 0\ 0\} \tag{32.29}$$

respectively, where the boldface emphasizes the zeroth elements $f_1(0)$ and $f_2(0)$. The sequence $\{1\ \ 2\ \ 1\}$ is commonly used to apply some smoothing to a data sequence, but because the center of symmetry at the element 2 is offset from the origin at $\tau = 0$, a shift will be introduced in addition to the smoothing. Therefore it makes sense to permute the sequence cyclically and use

$$f_1(\tau) = \{2\ 1\ 0\ 0\ 0\ 0\ 0\ 1\} \tag{32.30}$$

To compute the convolution

$$\begin{aligned} f_3 &= f_1 * f_2 \\ &= \{2\ 1\ 0\ 0\ 0\ 0\ 0\ 1\} \\ &\quad * \{1\ 4\ 6\ 4\ 1\ 0\ 0\ 0\} \end{aligned} \tag{32.31}$$

we take the two 8-element Hartley transforms to get the values H_1 and H_2 tabulated in Table 32.3. Multiply the corresponding values as shown under H_1H_2 and take the Hartley transform again. The result is as expected; notice

Tab. 32.3 Performing convolution by multiplying Hartley transforms.

F_1	F_2	H_1	H_2	H_1H_2	F_3
2	1	0.5	2	1	6
1	4	0.427	1.457	0.622	15.008
0	6	0.25	−0.5	−0.125	20
0	4	0.073	−0.043	−0.003	15.008
0	1	0	0	0	6
0	0	0.073	0.043	0.003	0.992
0	0	0.25	−0.5	−0.125	0
1	0	0.427	−1.457	−0.622	0.992

that the peak value 20 occurs where the peak value 6 of $f_2(\tau)$ occurs; this is a result of the precaution of centering {1 2 1} appropriately. The noninteger results are a consequence of rounding to three decimals for demonstration purposes, and these errors will be present, though smaller, if more decimals are retained.

32.21
Summary

A great analytic tradition of mathematical transform theory has gained far-ranging everyday importance by virtue of new numerical possibilities opened up by automatic computing machines.

Glossary

Alias: A sinusoid of low frequency spuriously introduced by insufficient sampling in the presence of a sinusoidal component of semiperiod shorter than the sampling interval.

Convolution of Two Functions: A third function composed by spreading each element of one given function out into the form of the second function and superimposing the spread components.

Discrete Transform: One suited to functions, such as those constituted by equispaced data samples, where the function values occur at discrete intervals and are usually finite in number.

Fast Fourier Transform (FFT): An algorithm for computing the discrete Fourier transform in less time than would be required to evaluate the sum of the products indicated in the defining formula.

Frequency, Negative: A convenient fiction arising from the representation of real sinusoids by complex quantities. The representation of the real function cos $2\pi ft$ in the form $\frac{1}{2}\exp[i2\pi ft] + \frac{1}{2}\exp[i2\pi(-f)t]$ involves clockwise rotation at frequency f and counterclockwise rotation at frequency $-f$.

Frequency, Spatial: The reciprocal of the period of a periodic function of space. Values of spatial frequency are expressed in cycles per meter, or in cycles per radian, according to whether the spatial variable is distance or angle.

Frequency, Temporal: The reciprocal of the period of a periodic function of time. Values are expressed in cycles per second, or hertz.

Heaviside Unit Step Function: A function $\mathbf{H}(x)$ that is equal to zero to the left of the origin and equal to unity to the right. The value $\mathbf{H}(0)$ at the origin has no effect on the value of integrals but may conventionally be taken as 0.5.

Inverse Transformation: An operation that, when applied to the transform of a function, effectively recovers the function.

Linear Transformation: A transformation with the property that the transform of the sum of any two functions is the sum of the separate transforms.

Tomography: Originally, a photographic technique for obtaining an X-ray image of a slice of tissue within the body; now applied in many fields to a technique of combining projections in many orientations to reconstruct an image.

Transform: A mathematical function, each value of which is derived from a set of values of a given function by an explicit operation.

INTRODUCTION

A quantitative description of the structure of physical objects plays an important role in our understanding of a wide range of phenomena. In many areas such as spectroscopy, solid-state physics, and engineering physics, the symmetry properties associated with this geometric description lead to important insights that would be difficult to obtain in other ways. Until recently structures have been described in terms of Euclidean geometry (straight lines, planar surfaces, spherical particles, etc.) and the associated symmetries of invariance to rotation, reflection, translation, and inversion. However, many systems of practical importance (colloids, rough surfaces and interfaces, polymer molecules, etc.) cannot be described satisfactorily in such terms. In the decade or so following the development and popularization of fractal geometry by Mandelbrot (1977, 1982) it has been shown that fractal geometry and the associated symmetry of scale invariance can be used to describe a wide variety of disorderly structures.

1. SELF-SIMILAR FRACTALS

1.1 The Cantor Set, A Simple Example

The first and perhaps the most simple example of a fractal (the Cantor set) is illustrated in Fig. 1. The Cantor set can be constructed by first taking a line and removing the middle third. In the next stage of this process the middle third from each of the remaining line segments is removed, etc. After n generations the number of line segments has grown to 2^n but their total length has decreased to $(\frac{2}{3})^n$. In the limit $n \rightarrow \infty$ a self-similar fractal has been constructed. If this fractal is dilated by a factor of 3, it can be covered by two replicas of itself. Such self-similar fractals can be characterized in terms of their fractal dimensionality D given by $D = \log n / \log \lambda$, where n is the number of replicas required to cover the fractal after dilation by a factor of λ. For the Cantor set illustrated in Fig. 1 the fractal dimensionality is $\log 2 / \log 3$, or about 0.6309. This is intuitively reasonable; the Cantor set is clearly more than a point ($D=0$), since it contains an infinite number of them, but less than a line

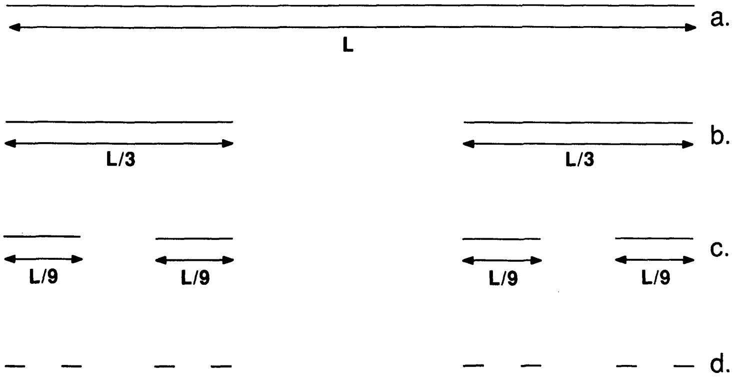

FIG. 1. Three stages in the construction of a Cantor set with a fractal dimensionality of log 2/log 3. The bottom line shows the third-generation prefractal.

$(D=1)$, since its total length is zero. In many applications the fractal dimension can be thought of as the exponent that relates mass M to length L,

$$M \sim L^D. \tag{1}$$

Here, L is a characteristic length, such as the radius of gyration R_g or maximum diameter, that describes the overall spatial extent. Equation (1) is also appropriate for Euclidean shapes where D is now the ordinary, Euclidean, dimensionality d.

After they were first introduced, fractals such as the Cantor set were considered to be very unusual objects with no possible applications in the physical sciences. In some areas fractals are still referred to by terms such as "strange sets"; this no longer seems to be appropriate. There is no precise definition of a fractal, but in general terms a fractal is an object that has the same degree of complexity on different length scales.

In real systems the geometric scaling relationships that characterize fractal objects do not extend over an infinite range of length scales. There are in general both lower (ϵ) and upper (L) cutoff lengths that limit the range of fractal scaling. For example, in the case of a flexible polymer molecule ϵ might correspond to the monomer size and L to the radius of gyration. If the ratio L/ϵ is large, then fractal geometry can be a very important asset in our attempts to understand complex, disorderly systems. If L/ϵ is small (say less than one order of magnitude), then fractal geometry is not likely to be of much practical importance. However, it may still be of considerable conceptual value if the structure was assembled by a mechanism that would lead to a fractal structure if it were not perturbed by other processes.

1.2 Statistically Self-Similar Fractals

Highly organized regular fractals such as the Cantor set (Fig. 1) that can be mapped exactly onto themselves after a change of length scales do not provide realistic models for describing most natural structures. Such natural fractals have a more complex disorderly structure that is self-similar only in a statistical sense. Statistically self-similar fractals can be described in terms of the scaling relationships such as Eq. (1) that describe regular, hierarchical fractals, but these equations must now be interpreted statistically (for example L might be the average radius of gyration for a large ensemble of structures of mass M).

Figure 2 shows an example of a statistically self-similar fractal structure. It is a projection, onto a plane, of a cluster of spherical particles generated by a three-dimensional model for the diffusion-limited cluster-cluster aggregation (colloidal flocculation: Meakin, 1988; Jullien and Botet, 1986). The fractal dimensionality of this structure is about 1.8. Since $D<2$, the projection also has a fractal dimensionality of 1.8 (see Sec. 1.4).

The use of correlation functions has, for a long time, been a valuable approach toward the quantitative characterization of disorderly systems. For example, density correlation functions such as $C^n(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_n)$ defined as

$$C^n(\mathbf{r}_1,\mathbf{r}_2,\ldots,\mathbf{r}_n) = \langle \rho(\mathbf{r}_0)\rho(\mathbf{r}_0+\mathbf{r}_1)\cdots\rho(\mathbf{r}_0+\mathbf{r}_n)\rangle \tag{2}$$

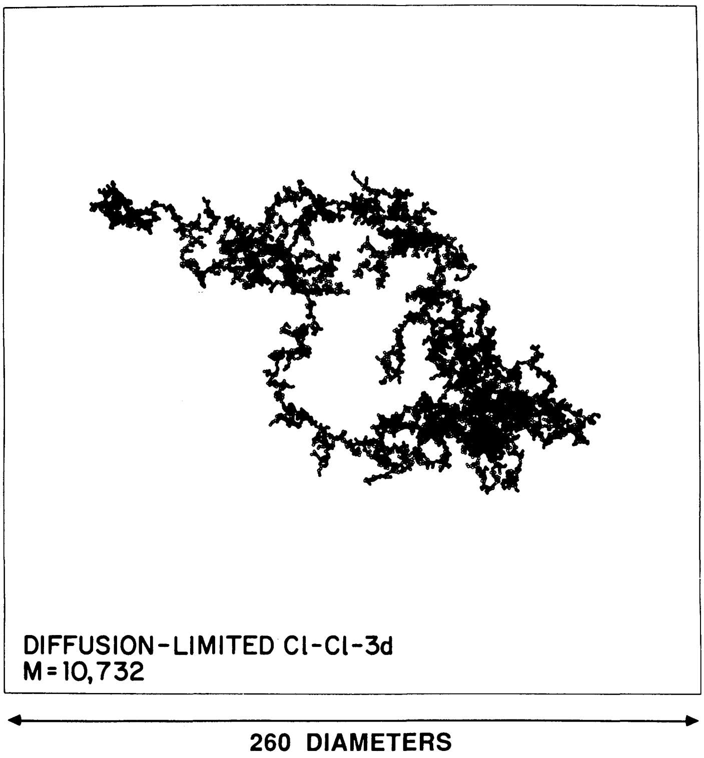

FIG. 2. A cluster of 10,732 particles generated using a three-dimensional off-lattice diffusion-limited cluster-cluster aggregation model. In this model the cluster size distribution is allowed to evolve in a natural way.

can be used to describe both fractal and nonfractal structure. Here $\rho(\mathbf{r})$ is the density at position $\mathbf{r}$ and the averaging is over all possible origins ($\mathbf{r}_0$). For self-similar fractals these correlation functions have a homogeneous power-law form,

$$C^n(\lambda\mathbf{r}_1,\lambda\mathbf{r}_2,\ldots,\lambda\mathbf{r}_n)=\lambda^{-n\alpha}C^n(\mathbf{r}_1,\mathbf{r}_2,\ldots,\mathbf{r}_n). \quad (3)$$

The exponent α (called the co-dimensionality) in Eq. (3) is $d-D$, where d is the Euclidean dimensionality of the embedding space.

By far the most frequently used correlation function is the two-point density-density correlation function $C(r)$ given by

$$C(r)=\langle\langle\rho(\mathbf{r}_0)\rho(\mathbf{r}_0+\mathbf{r})\rangle\rangle_{|\mathbf{r}|=r}\,. \quad (4)$$

Here $\langle\langle\ \rangle\rangle$ implies averaging over all origins ($\mathbf{r}_0$) and orientations. In addition $C(r)$ may be averaged over an ensemble of samples. For a simple self-similar fractal $C(r)$ has the power-law form

$$C(r)\sim r^{-\alpha} \quad (5)$$

and the fractal dimensionality D_α is equal to $d-\alpha$.

1.3 The Characterization of Self-Similar Fractals

Correlation functions such as those described above can be used to measure the fractal dimensionality. In practice only the two-point density-density correlation function has been used extensively for this purpose. Figure 3(a) shows the two-point density-density correlation functions for clusters of different sizes generated using the three-dimensional diffusion-limited cluster-cluster aggregation model illustrated in Fig. 2. These correlation functions have the form

$$C(r)=r^{-\alpha}f(r/L), \quad (6)$$

where L is the cutoff length. The cutoff function $f(x)$ has the form $f(x)=\text{const}$ for $x\ll 1$ and $f(x)$ decays faster than any power of x with increasing x for $x\gg 1$. Figure 3(b) shows that the density-density correlation function can be represented by the scaling form

$$C(r)=N^{(D-d)/D}g(r/N^{1/D}), \quad (7)$$

where N is the number of particles in the cluster. Since $L\sim N^{1/D}$ and $\alpha=d-D$, the scaling forms in Eqs. (6) and (7) are equivalent.

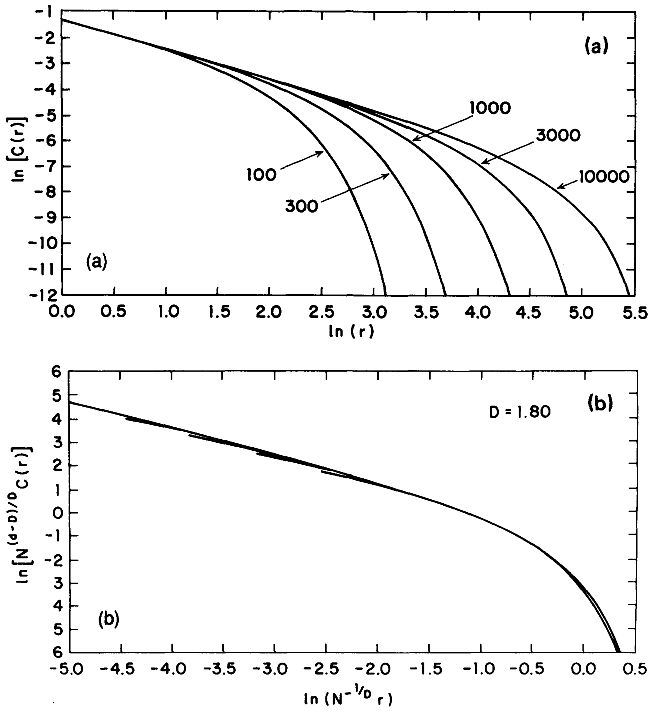

FIG. 3. Scaling of the two-point density-density correlation function for clusters generated using an off-lattice diffusion-limited cluster-cluster aggregation model illustrated in Fig. 2. (a) The correlation functions obtained from 10,000 100-particle clusters, 1000 300-particle clusters, 100 1000-particle clusters, 39 3000-particle clusters, and 13 10,000-particle clusters. (b) How these correlation functions can be scaled onto a common curve using the scaling form given in Eq. (7).

[The functions $f(x)$ and $g(x)$ are related by $g(x) \sim x^{-\alpha} f(x)$]. The results shown in Fig. 3 demonstrate that the internal structure of the clusters and their global mass-length scaling can be described in terms of the same fractal dimensionality ($D \simeq 1.8$).

Most approaches to the characterization of self-similar fractals are based on Eq. (1). For example, if we are concerned with structures formed by growth processes or systems in which a large number of objects of different sizes are present, then the fractal dimensionality can be obtained from the dependence of the radius of gyration on the mass. For an ensemble of statistically self-similar fractals we have

$$\langle R_g \rangle \sim M^{\beta}, \tag{8}$$

where $\langle R_g \rangle$ is the mean radius of gyration for structures of mass M. The corresponding fractal dimensionality D_β is then given by $D_\beta = 1/\beta$. In practice D_β is obtained by fitting the dependence of $\log R_g$ on $\log M$ by a straight line and taking the slope of the straight line as the exponent β. If data are available from many realizations over a broad range of length scales, the exponent β can be measured over a number of mass intervals to assess how accurately Eq. (8) represents the dependence of R_g on M.

Another popular approach to the measurement of the fractal dimension of self-similar fractals is to cover the fractal by a series of grids with elements having sides of length ϵ. The number of elements completely or partially occupied by the fractal is then given by

$$N(\epsilon) \sim \epsilon^{-D_\epsilon} \tag{9}$$

so that the fractal dimensionality (D_ϵ) can be obtained by plotting $\log N(\epsilon)$ against $\log \epsilon$. In practice this method appears to be quite sensitive to corrections associated with a limited range of accessible length scales, and it is difficult to obtain reliable results.

In many cases structures grow from a unique "seed" or nucleation site. In this case the fractal dimensionality can be obtained by measuring the mass $M(l)$ contained within a distance l measured from this unique point. For a self-similar fractal $M(l)$ is given by

$$M(l) \sim l^{D_\gamma} \tag{10}$$

so that D_γ can be obtained by fitting a straight line to the dependence of $\log M(l)$ on $\log l$ over a suitable range of length scales.

In principle all of the methods described above (and many other methods) should lead to the same value for the fractal dimensionality ($D_\alpha = D_\beta = D_\gamma = D_\epsilon = D$, where D is the "all purpose" fractal dimensionality) for simple self-similar fractals. In practice it is a good idea to use several approaches to measure D. This provides an assessment of the uncertainty in D and some indication of whether or not the structure is indeed a self-similar fractal. These methods can be applied equally well to fractal structures generated by physical phenomena or computer simulations.

1.4 Simple Rules for Self-Similar Fractals

The ability to describe complex, disorderly structures in quantitative terms (via fractal geometry) has stimulated scientific interest in problems that only a decade or so ago were thought to lie outside of the realm of quantitative scientific investigation. For a variety of model systems we now have quantitative (frequently exact but rarely rigorous) results and at least the beginnings of a sound theoretical understanding. In attempting to apply the concepts of fractal geometry to self-similar systems the following simple rules or ideas have been found to be useful (Vicsek, 1989; Meakin, 1990).

1. Two fractals with dimensionalities D_1 and D_2 can be placed together in the same region of a d-dimensional embedding space or lattice without contacting each other if $d > D_1 + D_2$. If the two fractals are following a relative trajectory with a fractal dimensionality of D_t, then they will not contact each other (except by accident) if $d > D_1 + D_2 + D_t$. An important implication of this rule is that fractals with $D < 2$ will be asymptotically transparent in three-dimensional space since they will not be contacted by "point" objects ($D = 0$) such as photons or electrons following linear ($D = 1$) trajectories. For such fractals one part is (in general) not hidden by another, and the fractal dimensionality of a projection onto a plane is the same as that of the fractal itself. If $D > 2$, then the structure is asymptotically opaque and the fractal dimensionality cannot be determined by analyzing a projection onto a plane. It follows from this that the projection of a D-dimensional fractal onto a d-dimensional space will have a fractal dimension of D if $D < d$. In this event the area (measure) of the projection will be proportional to the mass (measure of the fractal in the d-dimensional space).
2. A d_1-dimensional cross section of a D-dimensional fractal in a d_2-dimensional space will have a fractal dimensionality of $D + d_1 - d_2$.
3. The (set theoretical) intersection of two fractals with dimensionalities D_1 and D_2 in a d-dimensional space is given by $D_1 + D_2 - d$. This rule can be applied repeatedly to obtain the dimensionality of the intersection of three ($D_1 + D_2 + D_3 - 2d$) or more fractals.
4. The union of two fractals with dimensionalities D_1 and D_2 has a fractal dimensionality of max (D_1, D_2).
5. The product of two fractals with dimensionalities D_1 and D_2 has a dimensionality of $D_1 + D_2$. For example, the region swept out by a fractal of dimensionality D following a trajectory of dimensionality D_t is $D + D_t$ (if $D + D_t < d$).
6. Many random fractals can be described in terms of a power-law distribution of unoccupied "holes,"

$$N_s \sim s^{-\tau}, \tag{11}$$

where N_s is the number of holes of size s (s would be the number of sites contained in the hole for a lattice model). For such fractals the size distribution exponent τ is given by $\tau = (d + D)/d$.

2. SELF-AFFINE FRACTALS

2.1 The Brownian Process, A Simple Example

Fractals that have different scaling structures in different directions are said to be self-affine. Perhaps the most simple and most important example of a self-affine fractal is the Brownian process $B(t)$ that describes the distance moved by a Brownian particle in time t. It is well known that (on average) the distance moved by a Brownian particle in time t is proportional to $t^{1/2}$ so that the Brownian process can be rescaled by simultaneously changing the time scale by a factor of b and the distance scale by a factor of $b^{1/2}$.

More formally this symmetry property of the Brownian process can be written as

$$B(t) \equiv b^{-1/2} B(bt). \tag{12}$$

In this equation the symbol "≡" should be interpreted as meaning "statistically equivalent to."

Figure 4 shows different "lengths" of the same discretized Brownian process in which the distance is increased randomly by $+1$ or -1 each time the time is incremented by 1. In each part of the figure the horizontal (time) scale is proportional to the total time T and the vertical (distance) scale is proportional to $T^{1/2}$. The observation that the four rescaled curves in Fig. 4 look "similar" illustrates the self-affine scaling of the Brownian process.

The Brownian process can be generalized to give the "fractal" Brownian process $B_H(t)$, for which the self-affine scaling properties can be represented as

$$B_H(t) \equiv b^{-H} B(bt), \tag{13}$$

where the exponent H is referred to as the Hurst exponent (roughness exponent or wandering exponent). Values of H larger than $\frac{1}{2}$ correspond to persistent processes and $H<\frac{1}{2}$ implies antipersistent fluctuations. This is il-

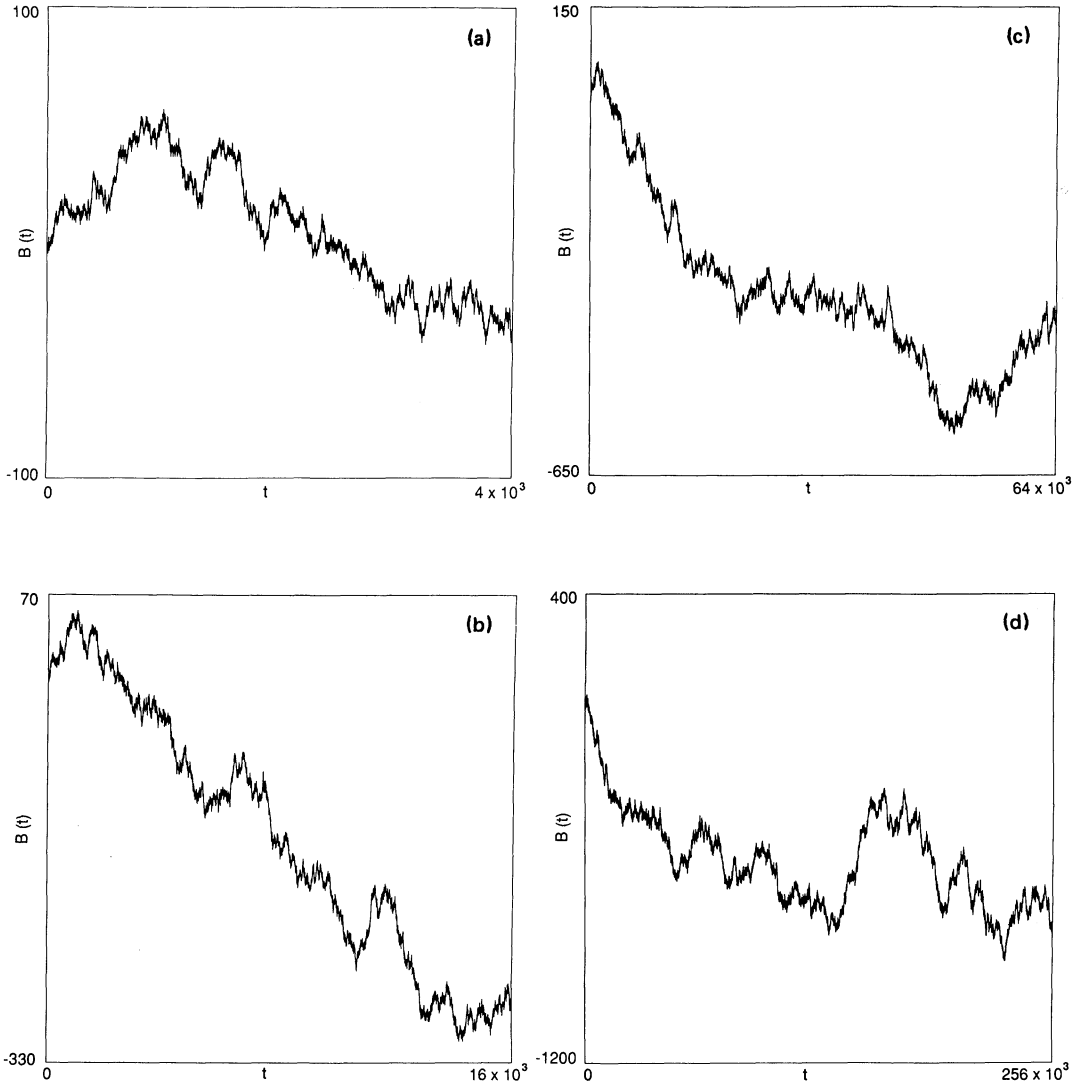

FIG. 4. Four sections of the same (discretized) Brownian process starting at the point [$t=0$, $B(t)=0$]. In each successive stage the time scale is increased by a factor of 4 and the vertical scale by 2 ($4^{1/2}$).

lustrated in Fig. 5 where fractal Brownian curves with Hurst exponents of 0.1, 0.5, and 0.9 are shown.

2.2 The Characterization of Self-Affine Fractals

In many cases (such as the Brownian process described above) self-affine fractals can be represented as single-valued functions $z(\mathbf{x})$ of the coordinates $x_1, x_2, \ldots, x_n$. For this class of self-affine fractals the scaling properties can be described in terms of the correlation functions $C_q(x)$ defined as

$$(C_q(x))^q = \langle |z(\mathbf{x}_0) - z(\mathbf{x}_0+\mathbf{x})|^q \rangle_{|\mathbf{x}|=x} . \tag{14}$$

In this case it has been assumed that all of the coordinates $(x_1, \ldots, x_n)$ are equivalent. In general the self-affine fractal $z(\mathbf{x})$ can be characterized by taking cross sections through the function $z(\mathbf{x})$ in the direction x_m, $y(x_m)$, and measuring the correlation function

$$(C_q(x_m))^q = \langle |y(x_m^0) - y(x_m^0 - x_m)|^q \rangle . \tag{15}$$

For self-affine fractals the correlation functions $C_q(x)$ or $C_q(x_m)$ have the form

$$C_q(x) \sim x^H \tag{16a}$$

or

$$C_q(x_m) \sim x_m^{H_m} . \tag{16b}$$

3. FRACTAL SURFACES AND INTERFACES

3.1 Some Applications

One of the most important applications of fractal geometry is the quantitative description of irregular surfaces and the development of a better understanding of their behavior. During the past few decades the technological importance of rough surfaces has motivated the development of a large

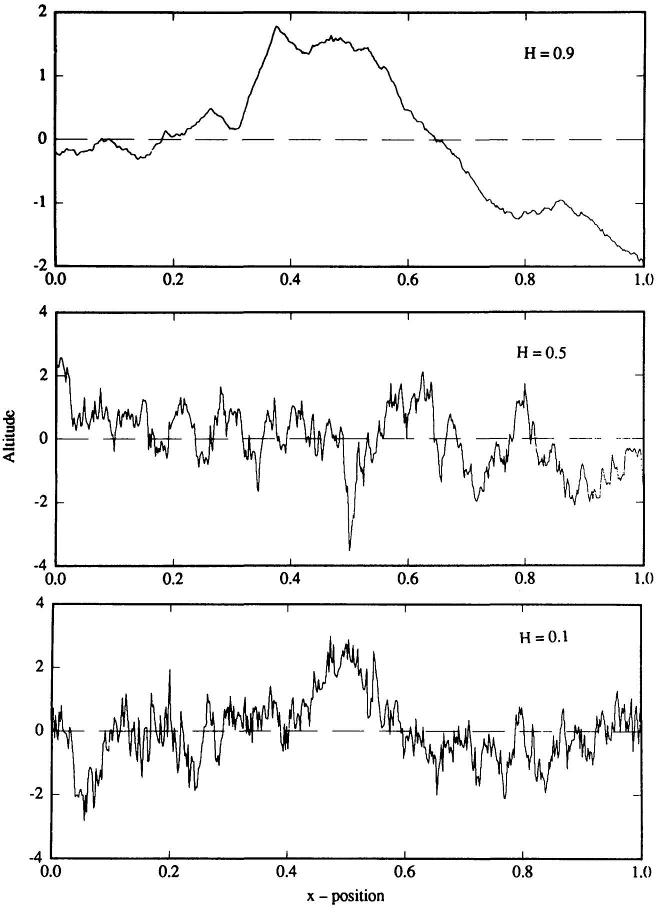

FIG. 5. Fractal Brownian curves generated using three different values for the Hurst exponent [$H=0.9$ (top), $H=0.5$, and $H=0.1$]. This figure is taken from Feder (1988) and was provided by J. Feder.

number of procedures for characterizing their structure. Many of these approaches involve a large number of parameters that are of little fundamental importance. In a recent review (Nowicki, 1985) 32 parameters and/or functions that have been used to characterize rough surfaces are described. More recently it has been shown that a wide variety of rough surfaces generated by processes such as fracture (Mandelbrot *et al.*, 1984; Charmet *et al.*, 1989; Herrmann and Roux, 1990), corrosion (Oppenheim *et al.*, 1991; Holland-Moritz *et al.*, 1991), deposition (Meakin, 1987; Family and Vicsek, 1991; Krug and Spohn, 1991), or fluid-fluid displacement (Feder, 1988) can be described in terms of fractal geometry. Both self-similar and self-affine fractal surfaces are common but most surfaces appear to be self-affine.

3.2 The Growth of Rough Surfaces

In many processes of practical importance rough surfaces are generated from a more or less smooth surface. Under these circumstances the surface roughness can often be described in terms of the correlation lengths $\xi_\perp$ and $\xi_\parallel$ and the manner in which they grow. The correlation length $\xi_\perp$ describes the amplitude of the surface roughness in a direction perpendicular to the general direction of the surface and $\xi_\parallel$ is the distance over which fluctuations in the surface height persist in a direction parallel to the coarse-grained surface. The length $\xi_\perp$ can be defined as

$$\xi_\perp^2=\langle h^2\rangle-\langle h\rangle^2, \qquad (17)$$

where $h(\mathbf{x})$ is the height of the surface above (or below) position $\mathbf{x}$ on the initially smooth surface.

For many simple processes the correlation length $\xi_\perp$ grows algebraically with increasing time

$$\xi_\perp\sim t^\omega. \qquad (18)$$

For self-affine surfaces the correlation lengths $\xi_\perp$ and $\xi_\parallel$ are related by

$$\xi_\perp\sim\xi_\parallel^H, \qquad (19)$$

where H is the Hurst exponent. In some cases surface properties in the x and y directions parallel to the surface may be quite distinct so that Eq. (17) may be replaced by

$$\xi_\perp\sim\xi_x^{H_x}\sim\xi_y^{H_y}. \qquad (20)$$

In some simple cases the amplitude of the surface roughness ($\xi_\perp$) may grow indefinitely according to Eq. (18); but in many cases $\xi_\perp$ is limited by other physical processes, and this limits the range of length scales over which fractal scaling can be observed.

Simple model systems that are quite well understood are used to illustrate how rough surfaces can be characterized using fractal geometry and scaling ideas in Secs. 3.3 and 3.4.

3.2.1 Self-Similar Rough Surfaces. The invasion percolation model (Lenormand and Bories, 1980; Wilkinson and Willemsen, 1983; Feder, 1988) provides a simple description of the slow displacement of a wetting fluid by a nonwetting fluid in a porous medium. In the site-invasion percolation model the sites on a lattice are assigned random "threshold" values at the start of a simulation. At each step in the simulation the unoccupied perimeter site with the lowest threshold value is filled to represent the fluid-fluid displacement process (unoccupied perimeter sites are unoccupied sites with one or more occupied nearest neighbors). In the two-dimensional version of this model the displacement pattern is self-similar with a fractal dimensionality of $\frac{91}{48}$ (about 1.89), or about 1.82 if growth is not allowed to take place in regions that have been surrounded by the growing cluster. The invasion front (outer perimeter) has a fractal dimensionality of $\frac{4}{3}$ (Grossman and Aharony, 1986; Saleur and Duplantier, 1987; Coniglio *et al.*, 1987) for both versions of the model (with and without "trapping").

If the fluid-fluid displacement processes take place in a vertical or inclined cell and the two fluids have different densities, the process may be either stabilized (Birovljev *et al.*, 1991) or destabilized by gravity. In this situation the invasion percolation process can be simulated using thresholds given by

$$t_i=x_i+gh_i, \qquad (21)$$

where t_i is the threshold associated with the ith site, x_i is a random number (in the most simple model, used here, the random numbers are uniformly distributed over the range $0<x_i<1$), and h_i is the height of the ith site. Figure 6 shows the displacement fronts generated during simulations carried out using the gravity-stabilized invasion percolation model. In this model the invasion front evolves

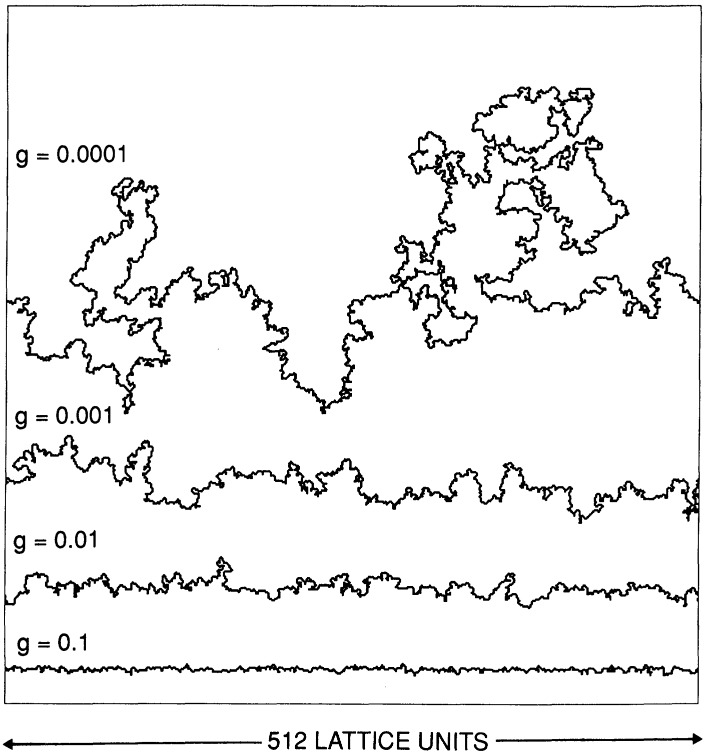

FIG. 6. Invasion fronts (unoccupied external perimeter sites) obtained from two-dimensional gradient-stabilized invasion percolation simulations. Fronts generated using four values of the stabilizing gradient g (10^{-1}, 10^{-2}, 10^{-3}, and 10^{-4}) are shown.

toward an asymptotic regime in which the statistical properties become stationary. The fronts shown in Fig. 6 were recorded in this asymptotic regime.

Self-similar fractal surfaces can be described in terms of the correlation functions defined in Eqs. (2) and (4). For structures generated by physical processes, Eqs. (3) and (5) are accurate over a limited range of length scales ($\epsilon \ll r \ll \xi$). For the invasion percolation simulations described in this section, the inner cutoff length ϵ is one lattice unit and the outer cutoff length ξ is related to the stabilizing gradient g by

$$\xi \sim g^{-\gamma}, \tag{22}$$

where the exponent γ is given by (Wilkinson, 1984)

$$\gamma = \nu/(\nu+1), \tag{23}$$

where ν is the correlation length exponent for ordinary percolation. The exponent ν has a value of exactly $\frac{4}{3}$ for two-dimensional percolation (Stauffer, 1985).

Figure 7(a) shows the density-density correlation functions $C(r)$ for the invasion fronts obtained from two-dimensional invasion percolation simulations with five values for the stabilizing gradient (g): $g=0.1$, 0.01, 0.001, 0.0001, 0.00001. In these plots a crossover from a slope of $-\frac{2}{3}$ on short length scales (corresponding to a fractal dimensionality of $\frac{4}{3}$) to a slope of -1 on longer length scales ($D=1$) can be seen. The results shown in Figs. 6 and 7 were obtained by starting with a flat surface and allowing the simulations to proceed until the vertical correlation length $\xi_\perp$ has grown to a stationary value $\xi_\perp(\infty)$ given by Eq. (22). In this stationary regime the growth of the invasion front exhibits large fluctuations, but the mean statistical properties such as $\xi_\perp$ and $C(r)$ do not change.

Figure 7(b) shows how the correlation function $C(r)$ shown in Fig. 7(a) can be collapsed onto a single curve. This figure illustrates that $C(r)$ (in the stationary regime) can be represented by the scaling form

$$C(r) = g^{(8/21)} f(g^{4/7} r) \tag{24}$$

or

$$C(r) = g^{\alpha\gamma} f(g^{\gamma} r), \tag{25}$$

where the scaling function $f(x)$ has the form $f(x) \sim x^{-2/3}$ for $x \ll 1$ and $f(x) \sim x^{-1}$ for $x \gg 1$.

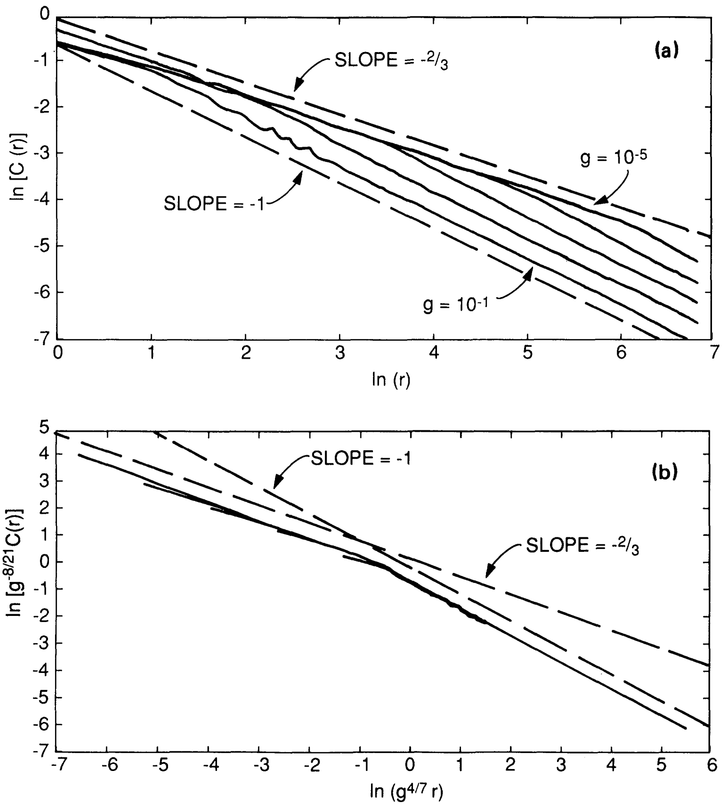

FIG. 7. Two-point density-density correlation functions for invasion fronts similar to those shown in Fig. 6. Each correlation function was obtained from 20 simulations carried out using a strip width L of 2048 lattice units. (b) How these correlation functions can be scaled using the scaling form given in Eq. (24).

This means that the surface appears to be self-similar ($D=\frac{4}{3}$) for $x \ll 1$ and flat ($D=1$) for $x \gg 1$.

3.2.2 Self-Affine Rough Surfaces. The Brownian process described above provides a valuable paradigm for the geometry of rough surfaces. The correlation functions $C_q(x)$ [Eq. (14)] can be used to measure the Hurst exponent (by least-squares fitting of straight lines to the dependence of $\log C_q(x)$ on $\log x$. For $q=1$ and 2 the value for the Hurst exponent is well within the 1% of the expected value ($H=\frac{1}{2}$).

In many real systems the correlation length $\xi_\perp$ may be finite because $\xi_\perp$ has not had enough time to grow or because it is limited by physical processes or finite size effects. Figure 8 shows "surfaces" generated using a simple modification of the discrete Brownian process model in which the probability of moving toward the origin is $0.5+k|x|$ and the probability of moving away from the origin is $0.5-k|x|$, where x is the displacement from the origin. This may be regarded as a model for the motion of a Brownian particle in a harmonic potential. Figure 9(a) shows the height-difference correlation functions $C_2(t)$ [Eq. (13)] obtained from simulations carried out using this model for six values of the parameter k (and $k=0$). Figure 9(b) shows that these correlation functions can be represented quite well by the scaling form

$$C_2(t)=k^{-1/2}h(kt), \tag{26}$$

where the scaling function $h(x)$ has the form $h(x) \sim x^{-1/2}$ for $x \ll 1$ and $h(x)=\text{const}$ for $x \gg 1$. This means that the surface appears to be self-affine ($H=\frac{1}{2}$) for $x \ll 1$ and flat for $x \gg 1$.

If a cross section is taken through a self-affine curve or surface parallel to the coarse-grained direction of the surface, then the intersection between the self-affine surface and the d-dimensional intersecting plane is a self-similar fractal with a dimensionality D_s given by

$$D_s=d-H. \tag{27}$$

Consequently, the relatively reliable methods that have been used to analyze self-similar fractals can be used [via Eq. (27)] to measure

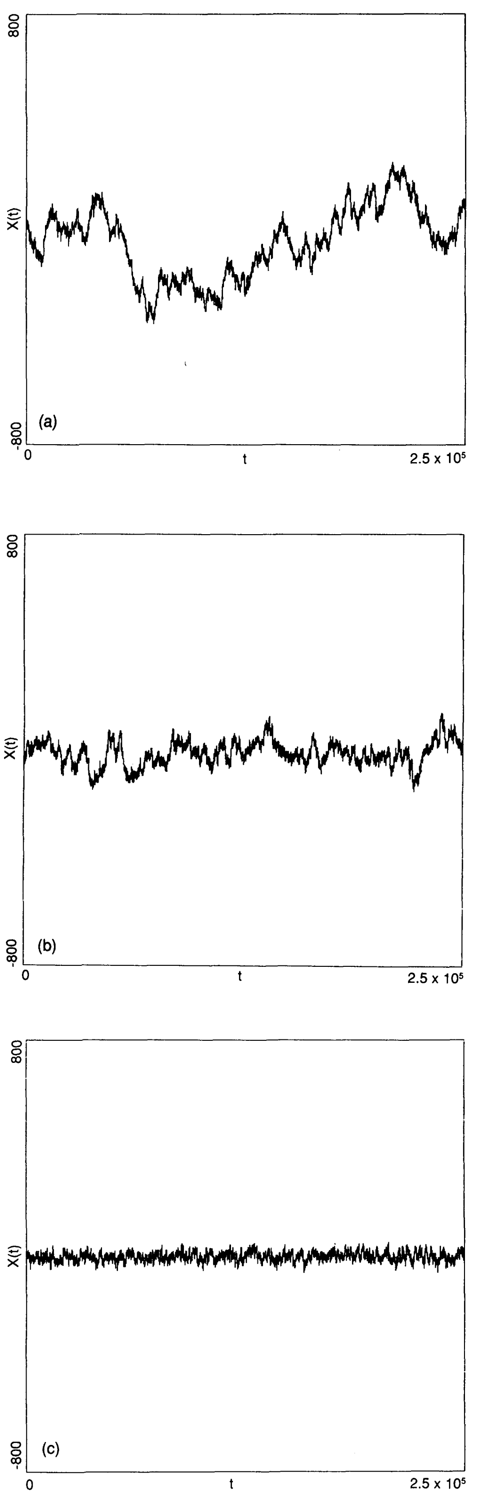

FIG. 8. Displacement curves $x(t)$ obtained from a simple model for Brownian motion in a harmonic potential. (a)–(c) Results for $k=10^{-2}$, 10^{-3}, and 10^{-4}, respectively.

the Hurst exponent of self-affine fractal surfaces. This is the basis of the slit island method (Mandelbrot *et al.*, 1984) that has been applied successfully to a variety of rough surfaces.

4. PRACTICAL CONSIDERATIONS

In Sec. 3 it was shown that quite accurate values for the fractal dimensionality can be obtained for self-similar and self-affine surfaces using simple procedures. Very similar approaches can be used for other types of fractal structures. However, large quantities of data spanning a large range of length scales were available from the simple models used in Sec. 3. In practice the statistical uncertainties may be larger and the range of length scales smaller for experiments or more realistic models. In most cases statistical uncertainties can be reduced to quite tolerable levels by averaging, but systematic uncertainties due to correlations to the asymptotic scaling behavior and other finite-size effects may be much more difficult to detect and control. In addition, real systems may have a much more complex scaling structure than that of the examples used here.

An account of the geometric properties of systems that must be described in terms of multifractal geometry and related concepts such as multiscaling and multiaffinity is beyond the scope of this survey. Information on those topics may be found in recent books (Feder, 1988), reviews (Paladin and Vulpiani, 1987; Stanley and Meakin, 1988; Meakin, 1990), and conference proceedings (Pietronero, 1988). In general, there is no well-established general procedure for characterizing the scaling structure of these more complex systems. In some cases it appears that the corrections to the asymptotic scaling behavior are large and convergence is slow.

One of the main difficulties in the past has been a failure to distinguish carefully between self-similar and self-affine fractals. This is particularly true in the case of surfaces and interfaces. As a consequence much of the literature in this area is subject to reinterpretation and/or is ambiguous.

Finally, there are no simple standards or criteria for determining whether a structure is fractal or not. To some extent this depends on

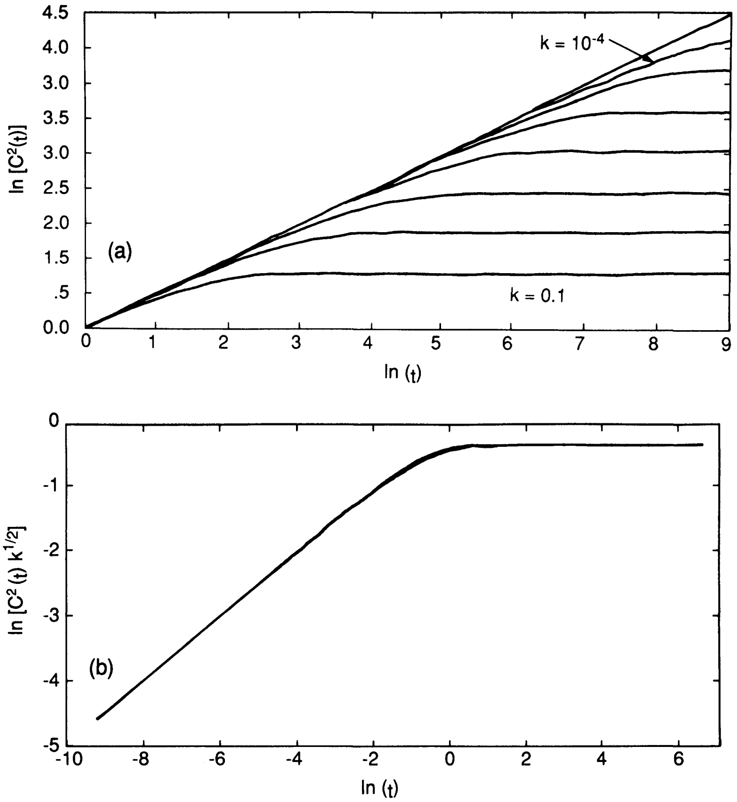

FIG. 9. (a) Correlation functions $C_2(t)$, obtained from simulations carried out using the model illustrated in Fig. 8 for eight values of k (0, 10^{-4}, 3×10^{-4}, 10^{-3}, 3×10^{-3}, 10^{-2}, 3×10^{-2}, and 10^{-1}). (*b*) How these curves can be collapsed onto a common curve using the scaling form given in Eq. (24).

the application and on theoretical considerations. However, geometric scaling (power-law behavior) over at least a decade of length scales combined with some understanding of the deviations from scaling outside of this range is probably a minimum requirement for fractal analysis to be a useful practical tool. In practice, scaling over more than two orders of magnitude of the length scale is rare.

GLOSSARY

Dimensionality: Dimensionality can be defined in many ways, but in practical terms it is the exponent relating mass (or measure) to length.

Embedding Space: The Euclidean space in which a structure resides. In most practical cases this is ordinary three-dimensional space ($\mathbb{R}^3$), but two-dimensional embedding spaces are common in computer simulations and for processes occurring at smooth interfaces.

Fractal: A structure that exhibits geometric scaling. In general terms a fractal is a structure that has similar complexity on all length scales; it "looks the same" on different length scales or at different magnifications.

Percolation: The transition associated with the formation of a continuous path spanning an arbitrarily large ("infinite") range. Site percolation on a lattice is a simple model for percolation. In this model the sites on a lattice are selected randomly and filled. For an infinitely large lattice an infinite cluster will be formed when a fraction p_c (the site percolation threshold probability) of the lattice sites have been filled. This cluster is a self-similar fractal. However, the entire system (including all the smaller clusters) has a finite density (p_c) and is uniform on all but small length scales.

Prefractal: An intermediate (nonasymptotic) stage in the construction of a regular fractal.

Radius of Gyration: The root mean square (rms) radius measured from the center of mass.

Self-Affine Fractal: A fractal that can be rescaled by a transformation that requires different changes of length scale (with different exponents) in different directions.

Self-Similar Fractal: A fractal that can be rescaled by an isotropic change of length scales (by the same amount in all directions).

Further Reading

At the present time several dozen books concerned with fractal geometry and its applications in the physical sciences have appeared. The Mandelbrot (1977, 1982) classics (particularly *The Fractal Geometry of Nature,* Mandelbrot, 1982) are still a primary source of information. For those interested in the applications of fractal geometry to physical processes the books by Feder (1988) and Vicsek (1989) are highly recommended. A recent reprint collection (with useful commentaries) assembled by Family and Vicsek (1991) provides an up-to-date account of the rapidly developing surface growth area. Surveys of the applications to growth phenomena may be found in the books by Feder and Vicsek and recent reviews (Meakin, 1988, 1990). A collection of reviews concerned with application in chemistry has been edited by Avnir [D. Avnir (Ed.) (1989), *The Fractal Approach to Heterogeneous Chemistry: Surfaces, Colloids, Polymers,* Chichester: Wiley]. Many conference proceedings have appeared during the past decade. A selection of those most relevant to applied physics include A. Aharony and J. Feder (Eds.) (1989), *Fractals in Physics, Essays in Honour of Benoit B. Mandelbrot,* Amsterdam: North Holland; M. Fleischmann, D. J. Tildesley, and R. C. Ball (Eds.), (1990), *Fractals in the Natural Sciences,* Princeton: Princeton Univ. Press; and the proceedings edited by Pietronero (1988).

INTRODUCTION

Fullerenes denote large closed-cage polyhedral molecules of carbon atoms, the most common fullerene being C_{60}. In an early Japanese-language publication it was suggested that an icosahedral C_{60} molecule might be stable chemically (Osawa, 1970). Independent of this Japanese work, early Russian workers showed theoretically that C_{60} should have a large electronic gap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) (Bochvar and Gal'pern, 1973; Stankevich *et al.*, 1984). These early theoretical suggestions for icosahedral C_{60} were not widely recognized and were only rediscovered after the experimental work of Kroto, Smalley, and co-workers in the middle 1980s (Kroto *et al.*, 1985) established the stability of the C_{60} molecule in the gas phase.

In the early gas-phase work, carbon clusters were synthesized by the laser ablation of a graphite surface, using a pulsed laser to generate a hot plasma of carbon atoms and radicals with temperatures over 10 000 °C. Pulses of helium gas were used to cool the plasma rapidly to form carbon clusters. The first to report clusters containing 40–100 carbon atoms was the EXXON group (Smalley, 1992), who showed mass spectra with prominent peaks at C_{60} and C_{70} and only clusters with even numbers of carbon atoms (see Fig. 1). Soon thereafter, Kroto, Smalley, and co-workers in their landmark paper (Kroto *et al.*, 1985) identified C_{60} with a molecule containing 60 carbon atoms located on equivalent sites at the vertices of a regular truncated icosahedron (Fig. 2), and identified other C_n species with polyhedral closed-cage clusters (Smalley, 1992). They gave the name buckminsterfullerene to C_{60} (Kroto *et al.*, 1985) because of its resemblance to the geodesic domes designed and built by R. Buckminster Fuller (Fuller, 1984). With time and usage, the nomenclature for this family of carbon-based molecules has been shortened to fullerenes. This early gas-phase work kindled considerable experimental and theoretical interest in fullerenes, though the activity worldwide was limited initially by the low availability of suitable samples to carry out the experiments suggested by the early work.

Starting in the 1970s astrophysicists were trying to identify some unusual infrared (ir) emissions from interstellar dust and from

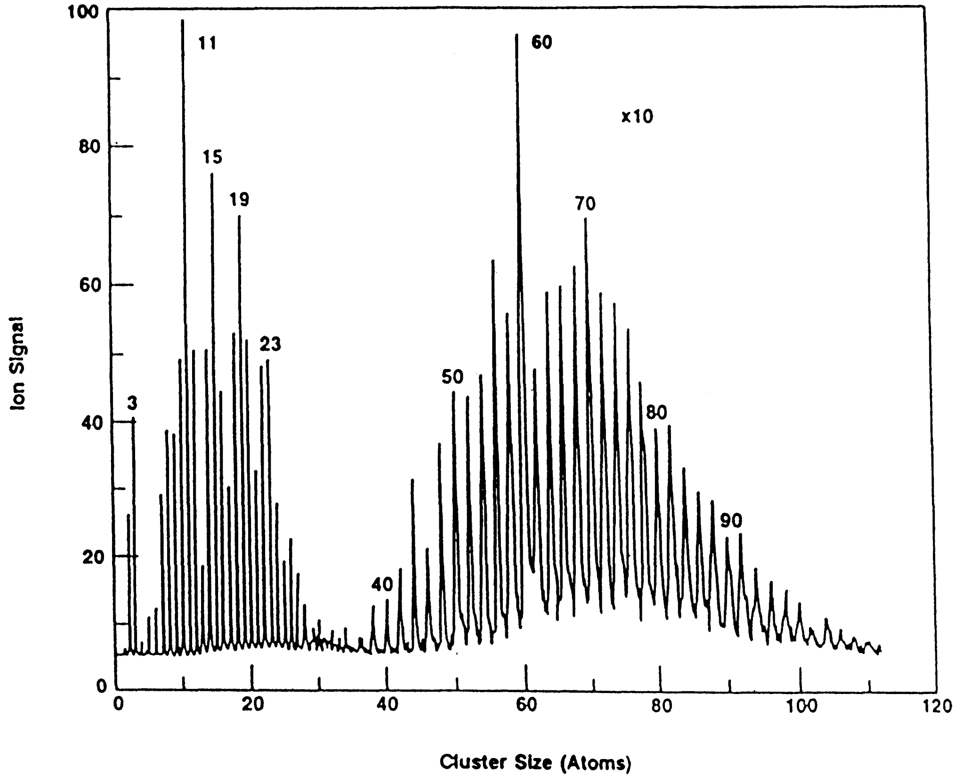

FIG. 1. Time-of-flight mass spectrum of carbon clusters produced in a supersonic beam by laser vaporization of graphite (from Rohlfing *et al.*, 1984).

carbon-rich stars. This work also suggested the possibility of larger carbon clusters (Hare and Kroto, 1992) and the linkage of these astronomical carbon clusters with carbon soot and with concentric polyhedral shell structures observed in carbon microparticles by Iijima using transmission electron microscopy (Iijima, 1991). Hare and Kroto (1992) have argued that carbon clusters similar to fullerenes play a role in the galactic carbon cycle.

In the fall of 1990 a new type of condensed matter, based on C_{60}, was synthesized for the first time. This was made possible by the breakthrough of Krätschmer, Huffman, and co-workers (Krätschmer *et al.*, 1990) in finding a simple method using a carbon arc discharge and liquid chromatography for preparing gram quantities of C_{60}, which had previously only been available in trace quantities in the gas phase (Kroto *et al.*, 1985; Smalley, 1992).

It was soon found by Haddon and co-workers at AT&T Bell Laboratories (Haddon *et al.*, 1991) that the intercalation of alkali metals into C_{60} to a stoichiometry M_3C_{60} (where M=K,Rb,Cs) greatly modifies the electronic properties of the host fullerene solid and yields relatively high-transition-temperature ($18 \leqslant T_c \leqslant 33$ K) superconductors. The discovery of superconductivity (Haddon, 1992) in these compounds clearly spurred a great deal of interest in C_{60}-related materials.

This review discusses the structure of fullerenes in Sec. 1, the techniques of synthesis in Sec. 2, the various doping techniques in Sec. 3, the crystalline structure of fullerene solids in Sec. 4, the spectroscopic results on vibrational modes in fullerenes in Sec. 5, the electronic structure in Sec. 6, the optical properties in Sec. 7, the results of carrier transport experiments in Sec. 8, and the superconducting properties of the alkali-metal–doped fullerenes in Sec. 9, while in Sec. 10 we review the structure and electronic properties of nanometer-diameter graphene tubules terminated with hemispherical fullerene caps, and finally in Sec. 11 we discuss some possible applications of fullerenes.

1. STRUCTURE OF FULLERENES

Many independent experiments discussed in this review show that crystalline materials formed from the fullerenes are molecular solids. Therefore the structure and properties of these solids are strongly dependent on the structure and properties of the constituent fullerene molecules.

From a structural standpoint, the 60 carbon atoms in C_{60} are at the vertices of a regular truncated icosahedron, where every atomic site is equivalent to every other site [see Fig. 2(a)]. Since the average nearest-neighbor carbon-carbon (C–C) distance a_{C-C} in C_{60} (1.44 Å) is almost identical to that in graphite (1.42 Å), and since most of the faces on the regular truncated icosahedron are hexagons, we can think of the C_{60} molecule as a "rolled up" graphene sheet (a single layer of crystalline graphite) in which the pentagonal faces are substituted for some of the hexagons to form a closed surface. A regular truncated icosahedron has in fact 20 hexagonal faces and 12 additional pentagonal faces to form a closed surface, in keeping with Euler's theorem, discussed below. The diameter of the C_{60} molecule is 6.83 Å, treating the carbon atoms as points (Fischer *et al.*, 1992). When one takes account of the size of the π-electron cloud associated with the carbon atoms, the outer diameter of the C_{60} molecule becomes 10.18 Å (see Table 1), consistent with a π-electron cloud of thickness 3.35 Å, which is the interlayer separation in graphite. The symmetry operations of the C_{60} molecule include 12 fivefold axes passing through the centers of a pair of pentagonal faces on opposite sides of the molecule, 20 threefold axes likewise passing through centers of a pair of hexagonal faces, 15 twofold axes going through the centers of the edges connecting two hexagons, and invariance of the entire molecule under inversion.

In the Huffman-Krätschmer arc method larger fullerenes are also formed. The most

Compressibility ($-d\ln V/dP$)	6.9×10^{-12} cm^2/dyn
Bulk modulus	14 GPa
Structural phase transitions	255 K, 165 K
Binding energy per atom	7.40 eV
Electron affinity	2.65 eV
Ionization potential (first)	7.58 eV
Ionization potential (second)	11.5 eV
Heat of formation	40 kcal/mol
Band gap (HOMO-LUMO)	1.75 eV
Spin-orbit splitting of C($2p$)	0.00022 eV
Velocity of sound v_t	2.1×10^5 cm/s
Velocity of sound v_l	3.6×10^5 cm/s
Debye temperature	165 K
Thermal conductivity (300 K)	0.4 W/mK
Phonon mean free path	50 Å
Static dielectric constant	3.9–4.2

abundant of the higher fullerenes is C_{70} [Fig. 2(b)], but significant quantities of C_{76}, C_{78}, and C_{84} have also been isolated and studied in some detail (Diederich and Whetten, 1992). Groups of large-mass carbon clusters as large as C_{240}, C_{330}, and clusters in the range C_{600}–C_{700} have been identified by mass spectroscopy (Smalley, 1992), but these larger fullerenes have not yet been isolated or studied in detail.

All of these closed-cage carbon clusters contain 12 pentagonal faces necessary to close the molecular cage and follow Euler's theorem for polyhedra,

$$f+v=e+2 \tag{1}$$

where f, v, and e are respectively the number of faces, vertices, and edges of a polyhedron. If we consider polyhedra formed by h hexagonal faces and p pentagonal faces, then

$$f=p+h,$$

$$2e=5p+6h,$$

$$3v=5p+6h, \tag{2}$$

so that

$$6(f+v-e)=p=12, \tag{3}$$

from which we conclude that all fullerenes must have 12 pentagonal faces, and the number of hexagonal faces is arbitrary. These arguments further show that the smallest possible fullerene is C_{20}, which would form a regular dodecahedron with 12 pentagonal and no hexagonal faces. Furthermore, since the addition of a single hexagon adds two carbon atoms, all fullerenes must have an even number of carbon atoms, in agreement with the observed mass spectra for fullerenes shown in Fig. 1 (Smalley, 1992).

Of the larger fullerenes, C_{70} is the easiest to make and to isolate. C_{70} is formed by adding a ring of five hexagons around the equatorial plane of the C_{60} molecule, normal to one of the fivefold axes [see Fig. 2(b)]. In contrast to the C_{60} molecule with I_h symmetry, the C_{70} molecule has the lower symmetry D_{5h}, which lacks inversion symmetry but rather has a mirror plane at the equator. Fullerenes have been found to form isomers, that is, polyhedra with a given number n of carbon atoms C_n arranged in different geometrical structures (Diederich and Whetten, 1992). For example, C_{80} might be formed in the shape of an elongated rugby ball prepared by adding two rows of five hexagons normal to a fivefold axis of C_{60} at the equator [see Fig. 2(c)]; an icosahedral form of C_{80} can also be specified as shown in Fig. 2(d). As another example of fullerene isomerism, Diederich and Whetten have reported that C_{78} has five distinct isomers.

Generally speaking, each carbon atom has four valence electrons that can participate in bonding to other atoms. In C_{60} each carbon atom has three nearest-neighbor carbon atoms and forms bonds to each of these atoms. Two of the bonds are located at the fusion of a hexagon and a pentagon [see Fig. 2(a)] and are single bonds. The third bond is located at the fusion between two hexagons and must be a double bond occupied by two (rather than one) valence electrons [see Fig. 2(a)]. The molecular structure is further stabilized by introducing a small distortion of the bond lengths to form the Kekulé structure of alternating longer single and shorter double bonds around the hexagonal face. The full icosahedral I_h symmetry is, however, preserved under these distortions. The single bonds that define the pentagonal faces are increased from the average bond length of 1.44 to 1.46 Å, while the double bonds are decreased to 1.40 Å (Johnson *et al.*, 1992). Since each carbon atom has its valence requirements fully satisfied, a crystalline solid of C_{60} is expected to be an insulator or a semiconductor. The semiconducting behavior is further stabilized by the above-mentioned distortions in the intramolecular C–C bond lengths.

2. SYNTHESIS OF FULLERENE SOLIDS

C_{60} molecules can be prepared by several methods, though many workers use a method first developed by Krätschmer and Huffman based on an alternating-current (ac) discharge between graphite electrodes in approximately 200 Torr of He (Krätschmer *et al.*, 1990). This discharge produces a carbon soot, which can contain up to ~15% of the fullerenes C_{60} and C_{70}. The smaller fullerenes are separated from the soot using Soxhlet extraction with a toluene solvent. Separation of C_{60} from C_{70} and the higher-molecular-weight fullerenes is typically accomplished by liquid chromatography (LC) (Diederich *et al.*, 1991; Chen *et al.*, 1991). The identity of the separated fractions from the LC column is verified, for example (Diederich and Whetten, 1992), by the comparison of the observed optical spectra (Sec. 7) and NMR data with published results. Further characterization by vibrational spectroscopy (including both infrared transmission and Raman spectroscopy; see Sec. 5) allows an assessment to be made of the compositional purity of a fullerene sample. Liquid chromatography using organic solvents as the elutant generally allows separation of the fullerenes according to their molecular weights, but can also separate isomers, e.g., C_{78} with C_{2v} symmetry from C_{78} with D_3 symmetry (Diederich *et al.*, 1991).

For experiments where rigid exclusion of solvent impurities is necessary, it is possible to separate C_{60} and C_{70} from the arc-derived soot without the use of solvents by heating the soot in vacuum and in a temperature gradient. In this method, the C_{60} and C_{70} both are sublimed from the soot placed in the hottest part of the furnace, and these molecules drift toward the cold end of a quartz tube connected to a vacuum line. The C_{60} and C_{70} condense in separate bands on the tube wall, and the positions of these bands are related to the different sublimation temperatures for C_{60} and C_{70}.

Actual property measurements of fullerenes are made on either microcrystalline powder samples, films, or single crystals. Microcrystalline C_{60} powder is obtained by vacuum evaporation of the solvent from the solution obtained from the LC column. These powders are further heated to ~300 °C for several hours in vacuum to remove residual solvent. Pristine C_{60} films can be deposited onto a substrate such as clean silicon (100) by sublimation of the C_{60} powder in a vacuum of $\sim 10^{-6}$ Torr. Single crystals can be grown either from solution or by vacuum sublimation (Meng *et al.*, 1992). The solution growth method tends to yield larger single crystals, but such crystals tend to contain trapped solvent. The smaller crystals (~0.5 mm in size) grown by sublimation (in vacuum or in an inert gas such as argon) tend to be more perfect structurally.

3. DOPING METHODS AND NEW COMPOUNDS

There are three distinct ways to introduce foreign atoms into a C_{60}-based solid (Smalley, 1991). One method is "endohedral" doping, which involves the addition of a rare earth, an alkaline earth, or an alkali-metal ion into the interior of the fullerene ball. Smalley (1992) has proposed that this endohedral configuration be denoted, for example, by $La@C_{60}$ to represent one endohedral lanthanum in C_{60}, or $Y_2@C_{82}$ for two Y atoms inside a C_{82} fullerene. For the large fullerenes, the endohedral addition of up to three metal ions has been demonstrated by mass-spectroscopy techniques (Smalley, 1991). It has been shown that when La is inside the fullerene ball, it has a valence of +3 (Smalley, 1991), indicating the presence of three delocalized electrons on the C_{60} ball in antibonding states that could be available for conduction in a solid of endohedrally doped C_{60}.

A second method is the substitutional doping of an impurity atom with a different valence state for a carbon atom on the surface of a fullerene ball. Since a carbon atom is so small, and since the average nearest-neighbor C–C distance $a_{C\text{–}C}$ on the C_{60} surface is only 1.44 Å (Johnson *et al.*, 1992), the only species that can be substituted for a carbon atom on the C_{60} ball surface is boron, making the charged ball *p* type. Smalley and co-workers have demonstrated that it is possible to replace more than one carbon atom by boron on a given ball (Smalley, 1991). Also for graphite, the only substitutional dopant is boron, and for the same reasons as for C_{60}. However, for diamond, which has a larger C–C nearest-neighbor distance of $a_{C\text{–}C}=1.544$ Å, both boron and nitrogen can enter the lattice substitutionally (Field, 1979). It has also been reported that it is possible to place a potassium atom endohedrally inside the C_{60} ball while at the same time substituting a boron for a carbon atom on the surface of the ball (Smalley, 1991).

In the third method of doping fullerene solids (also called intercalation), the dopant (e.g., an alkali metal or an alkaline earth, *M*) is introduced into the interstitial positions between adjacent balls (exohedral locations). In this doping method, charge transfer can take place between the *M* atoms and the balls. This method of doping forms exohedral fullerene solids and closely parallels the process of intercalating an alkali-metal ion between carbon layers in graphite (Dresselhaus and Dresselhaus, 1981).

Among the alkali metals, Li, Na, K, Rb, and Cs have all been used as exohedral dopants for C_{60}, as well as intermetallic mixtures of these alkali metals such as Na_2K and Rb_xCs_y (Haddon, 1992). These guest atoms are called "donor-type intercalants" in analogy to the graphite intercalation compound nomenclature (Dresselhaus and Dresselhaus, 1981).The doping of C_{60} with alkali metals can be achieved in a two-zone furnace, similar to the apparatus used to prepare alkali-metal graphite intercalation compounds (Dresselhaus and Dresselhaus, 1981). The intercalation of alkali metals works well in the preparation of powdered samples, whereby the stoichiometry is controlled by the number of moles of alkali metal introduced into the sealed ampoule (quartz or Pyrex) relative to the number of moles of C_{60}, the temperatures of the reagents, and the duration of the reactions. Alkali-metal doping of thin (~1000 Å) C_{60} films can be carried out similarly, using a sealed quartz (or Pyrex) tube (with approximate dimensions 25 cm long × 1 cm diameter) which contains the C_{60} film/Si substrate sample and the alkali metal at opposite ends. The films are maintained at a higher temperature (200 °C) than the alkali metal (*M*) (100–180 °C) to avoid condensation of the alkali metal on the film surface. The progress of the reactions can be monitored qualitatively by the color change observed in the films (see Sec. 7) and more quantitatively by the doping-induced downshift of the strongest C_{60} Raman line (see Sec. 5) or by the magnitude of the electrical conductivity (see Sec. 8). The doping reaction in C_{60} single crystals is carried out in a two-zone furnace for long times (~1 to 2 weeks) because of the larger distances that the dopant must travel (Xiang *et al.*, 1992).

Some success has also been achieved with the intercalation of alkaline-earth metal dopants, e.g., Ca, for which charge transfer also takes place (Kortan *et al.*, 1992; Chen *et al.*, 1992). The intercalation of alkali-metal and rare-earth metal atoms into C_{60} leads to the transfer of their valence electrons to the C_{60} ball and the formation of positive ions (i.e., K^+ or Ca^{2+}).

Doping fullerenes with acceptor-type dopants, which become negatively charged ions inside the host material, has been more difficult because of their high electron affinities (see Table 1). A stable crystal structure has nevertheless been identified upon doping C_{60} with iodine, where the iodine atoms form a sheet between layers of C_{60} balls; no measurable conductivity has, however, been observed in the case of iodine doping of fullerenes, indicating that charge transfer between the iodine and C_{60} probably does not occur (Fischer *et al.*, 1992).

In a totally different approach to the doping problem, varying numbers of fluorine atoms have been added via radial F—C bonds to the outside of the C_{60} ball, where the attachment of a F atom converts a double bond in C_{60} into a single bond (Fischer *et al.*, 1992). A report has been given of adding up to 60 fluorine atoms per ball exohedrally to form the compound $C_{60}F_{60}$ (Fischer *et al.*, 1992). Similar bonding arrangements of C_{60} to hydrogen have also been observed up to a maximum hydrogen concentration, $C_{60}H_{60}$ (Fischer *et al.*, 1992). However, it is not known whether all the H bonds are directed radially outward or whether some may perhaps be endohedrally bonded. Several stable bromine-doped fullerenes have also been reported including $C_{60}Br_6$, $C_{60}Br_8$, and $C_{60}Br_{24}$, and proposals for their structures have also been made (Birkett *et al.*, 1992).

Synthetic fullerene chemistry has become a very active research field, largely because of the novelty of the C_{60} molecule and the variety of chemical modifications to the C_{60} shell that appear to be possible. Since many of the fullerene reactions appear to be reversible, and the amount of the fullerene material available to most chemists is small, research in this field has been especially challenging. Some of the simplest of the fullerene compounds, such as $C_{60}H_x$, $C_{60}F_x$, and $C_{60}Br_x$, have already been mentioned. More complex compounds have also been synthesized, and many of these are based on forming covalent bonds to each of the two carbon atoms joining two hexagons [Fig. 2(a)]. As various moieties bond to these two carbons, the latter are pulled out of their equilibrium positions, and the local structure of the fullerene is modified.

One of the simplest compounds that distorts carbon bonds on the C_{60} molecule is the epoxide $C_{60}O$ (Fischer *et al.*, 1992), which crystallizes in the same simple-cubic space group as pristine C_{60} as discussed in Sec. 4. Many more complicated moieties can also be attached at the double-bond site. The addition of phenyl groups through a carbon bridge atom has formed the basis of a large number of new and interesting compounds (Wudl *et al.*, 1992; Fagan *et al.*, 1992). In some cases the bonding at the double-bond sites is done through a metal atom such as Pt, Os, or Ir to which other groups attach. The first structurally characterized metal complex of C_{60} was $(t\text{-BuC}_5H_5N)_2OsO_4$. More recently, many metal-containing derivatives of C_{60} have been synthesized (Fagan *et al.*, 1992; Hammond and Kuck, 1992). In preparing many of these compounds, specific groups are added for special chemical reasons, while other chemical species are used to achieve a chemically stable compound. From these synthesis studies, it is concluded that C_{60} behaves as an electron-deficient species. Since the double bonds of C_{60} are strained by the curvature of the C_{60} ball, it is expected that C_{60} will be reasonably reactive. The effect of forming a metal derivative complex is to remove one double C=C bond, lengthen that bond (e.g., to 1.50 Å for Pt attachment), modify the charge distribution locally, raise the energy of the lowest unoccupied molecular orbital, and lower the electron affinity (Fagan *et al.*, 1992). The attachment of aromatic groups has also been shown to link fullerenes (Wudl *et al.*, 1992). Most of the novel fullerene synthetic chemistry has been done in solution. As new fullerene compounds are prepared, physical chemists are measuring their properties. Thus, the preparation of new chemical compounds based on fullerenes and the study of their physical properties are now important topics in chemical research.

One especially interesting direction that this synthetic research has taken is the preparation of an organic ferromagnet with a Curie temperature of 16.1 K by Wudl and co-workers (Allemand *et al.*, 1991). This material, exhibiting almost no magnetic hysteresis, was synthesized by the reaction of the organic donor TDAE [tetrakis(dimethyl-amino)ethylene] complex with C_{60} (Wudl, 1992). The "soft ferromagnetism" for this material showed no Curie-Weiss behavior of the susceptibility for the temperature range above the Curie temperature. The significance of this work is the demonstration of magnetism in systems having only *s* and *p* orbitals. Typically magnetic materials are identified with systems having unfilled *d* and *f* orbitals, such as transition metals (e.g., Fe, Ni, Co) and rare-earth elements (e.g., Sm, Eu, Ce).

4. CRYSTALLINE STRUCTURE

In the solid state, C_{60} molecules crystallize into a cubic structure with a lattice constant of 14.17 Å (Fischer *et al.*, 1992) and a density of 1.72 g/cm^3 (corresponding to 1.44×10^{21} C_{60} molecules/cm^3). At room temperature the molecules are rotating, and the crystal structure is face-centered cubic (fcc) with four equivalent spinning C_{60} balls per unit cell. The pertinent space group is denoted by O_h^5 or $Fm\bar{3}m$. This structure has been established directly by x-ray diffraction. The equivalence of each carbon site on a C_{60} ball is confirmed by a single sharp line in the NMR spectrum

(Johnson *et al.*, 1992). Relative to the other allotropic forms of carbon, solid C_{60} is relatively more compressible, with an isothermal volume compressibility (see Table 1) of 6.9 $\times 10^{-12}$ cm^2/dyn (Fischer *et al.*, 1992), approximately three times larger than graphite because the van der Waals charge cloud around the C_{60} balls can easily be compressed in three dimensions, rather than in one dimension as in the case of graphite perpendicular to the carbon layers.

Below about 250 K, the C_{60} balls become oriented, and the structure becomes simple cubic (space group T_h^6 or $Pa\bar{3}$), with four C_{60} molecules per unit cell as the four balls within the fcc unit cell become inequivalent (Fischer *et al.*, 1992). We can understand the crystal structure of the idealized ordered phase by referring to Fig. 3(a), where the standard orientation of a C_{60} molecule is shown with respect to a cubic coordinate system. Here [100] axes pass through three mutually orthogonal twofold molecular axes (the centers of the hexagon–hexagon edges) and four [111] axes pass through the centers of the hexagonal faces. The alternative standard orientation is shown in Fig. 3(b), which is obtained from Fig. 3(a) through rotation by $\pi/2$ about the [100] axes. In the low-temperature idealized ordered phase, the centers of four C_{60} molecules are located at coordinate locations (0,0,0), $(\frac{1}{2},0,\frac{1}{2})$, $(\frac{1}{2},\frac{1}{2},0)$and $(0,\frac{1}{2},\frac{1}{2})$, and each molecule is rotated from the standard orientation shown in Fig. 3(a) by 22° about the threefold [111], $[\bar{1}\,\bar{1}\,1]$, $[\bar{1}1\bar{1}]$, and $[1\,\bar{1}\,\bar{1}]$ axes, respectively. This idealized orientation is stabilized by bringing the electron-rich double-bond hexagon-hexagon edge of one C_{60} molecule adjacent to the electron-poor pentagonal faces of the adjacent C_{60} molecule. Supporting evidence for a phase transition of the C_{60} molecules associated with orientational ordering is provided by many property measurements, such as differential scanning calorimetry, resistivity, NMR, ultrasonic attenuation, Raman spectroscopy, and thermal conductivity (Fischer *et al.*, 1992). An additional phase transition has also been reported to occur at still lower temperatures ($\sim$160 K), and some authors have proposed additional phase transitions. As-prepared powdered C_{70}, on the other hand, has been reported to form a hexagonal structure at room temperature with lattice constants $a=10.63$ Å and $c=17.39$ Å (Fischer *et al.*, 1992), though other structures are stable in different temperature ranges.

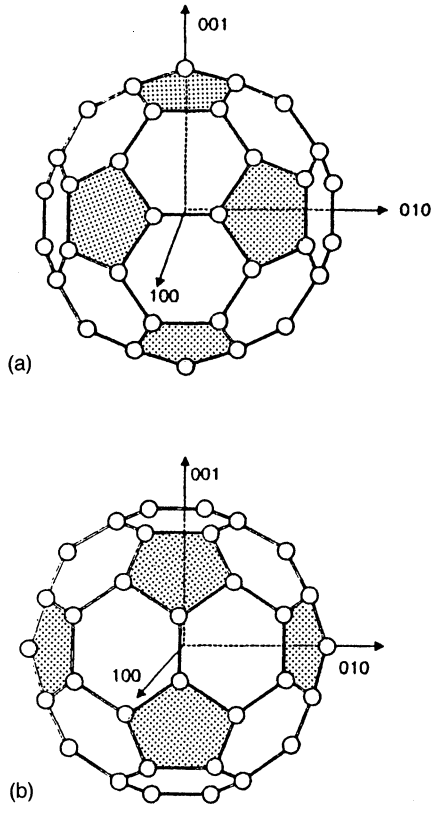

FIG. 3. (a) The C_{60} molecule shown in one of two "standard" orientations such that the Cartesian axes in a cubic crystal pass through three orthogonal twofold axes. (b) The other "standard" orientation, related to that in (a) by a rotation of $\pi/2$ about the (100) Cartesian axis.

Several stable crystalline phases for doped C_{60} have been identified. Most widely studied are the crystalline phases formed with alkali metals, though some structural work has also been done, for example, with alkaline-earth metals (Kortan *et al.*, 1992) and halogen intercalants (Zhu *et al.*, 1992). Fleming *et al.* at AT&T Bell Laboratories first reported that when C_{60} is doped with the alkali metals (M=K,Rb,Cs), stable crystalline phases are formed for the compositions M_3C_{60}, M_4C_{60}, and M_6C_{60} (Haddon, 1992). One electron is transferred to the C_{60} ball per M-atom dopant, resulting in M^+ ions at the tetrahedral and/or octahedral interstices of the C_{60} host structure (see Fig. 4). For the composition M_3C_{60}, the resulting metallic crystal exhibits a fcc arrangement for the C_{60} balls (see Fig. 4). Within this fcc host structure the alkali-metal ions can be

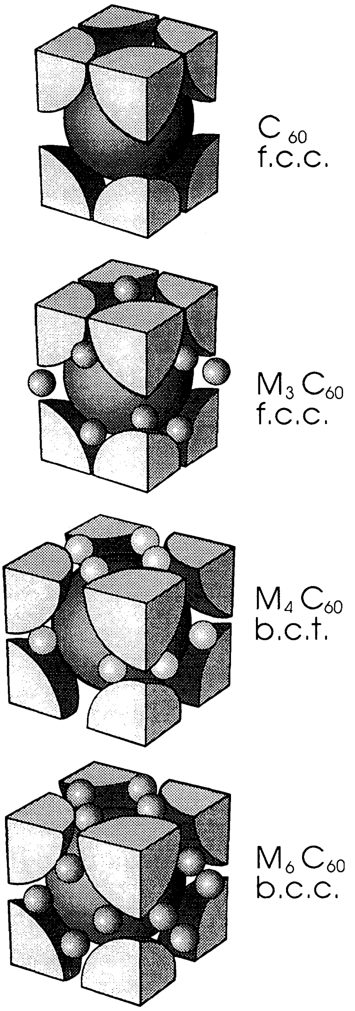

FIG. 4. Structures for solid C_{60}, M_3C_{60}, M_4C_{60}, and M_6C_{60} (M=K,Rb,Cs). The large balls denote C_{60} molecules and the small balls are alkali-metal atoms. For fcc M_3C_{60}, which has four C_{60} balls per cubic unit cell, the M atoms can be on either octahedral or tetrahedral sites. Undoped solid C_{60} above 250 K also exhibits an fcc crystal structure, but in this case all tetrahedral and octahedral sites are unoccupied. For bcc M_6C_{60} all the M atoms are on distorted tetrahedral sites. For bct M_4C_{60} the dopant is also found on distorted tetrahedral sites (from Fleming *et al.*, 1991b).

located either at tetrahedral $(\frac{1}{4},\frac{1}{4},\frac{1}{4})$ sites or at octahedral $(\frac{1}{2},0,0)$ interstitial sites (referenced to a simple cubic coordinate system). In the fcc structure, x-ray diffraction data indicate that the positively charged alkali-metal ions lie adjacent to an electron-rich C=C double bond. For example, from the standpoint of the near neighbors, the K guest species in K_3C_{60} are located in the cavity between adjacent C_{60} balls, on any one of four tetrahedral sites or two octahedral sites. For the tetrahedral sites, the radius of the cavity available to a K^+ ion is 1.12 Å, while for an octahedral site it is 2.07 Å (Stephens *et al.*, 1991). The shortest distance between a K^+ ion at a tetrahedral site and the carbon atom on a freely rotating C_{60} ball is 2.66 Å (Stephens *et al.*, 1991). It is of interest to note that the Cs^+ ion is apparently too large to form a stable Cs_3C_{60} compound with the fcc structure, and this is believed to be the reason why Cs_3C_{60} [which crystallizes in a body-centered cubic (bcc) structure] is not superconducting (see Sec. 9).

The two other stable phases for M_xC_{60} (namely, M_4C_{60} and M_6C_{60}) each have different crystalline structures. The M_4C_{60} phase, which is more difficult to prepare than M_3C_{60} or M_6C_{60}, has a body-centered tetragonal structure (bct) with a tentatively assigned space group *I4/mmm* (Fleming *et al.*, 1991b). The compound M_6C_{60} has a bcc structure (see Fig. 4) and corresponds to the space group T_h^5 or *Im*3. The compounds K_6C_{60}, Rb_6C_{60}, and Cs_6C_{60} all correspond to alkali-metal–saturated compounds, which are all semiconductors. A list of lattice constants for the various stable C_{60}-related structures is given in Table 2 for pristine C_{60} and alkali-metal–doped M_xC_{60} compounds (Fleming *et al.*, 1991b).

Since the ionic radii of the alkali-metal ions Na^+ and Li^+ are much smaller than those of the K^+, Rb^+, and Cs^+ ions, a number of unusual structural phenomena are observed. First, it is possible to fit more than one Na^+ ion in an octahedral site (Rosseinsky *et al.*, 1992; Tanigaki *et al.*, 1992), so that the fcc structure can be preserved upon adding up to six Na atoms per C_{60} with two Na ions going into tetrahedral sites and up to four on octahedral sites to form Na_6C_{60}. There is no stable Na_3C_{60} crystal, and materials prepared with this stoichiometry tend to phase separate (disproportionate) into Na_2C_{60} and Na_6C_{60} (Rosseinsky *et al.*, 1992). Also because of the small ionic radius of Na, the Na ions tend to fill the smaller tetrahedral sites when alloys of Na with heavier alkali metals are used as dopants, while the heavier alkali metals tend to be on octahedral sites. One unusual effect (Stephens, 1992) is that alkali-metal doping with Na_2Cs, Na_2Rb, Na_2K, and Li_2Cs results in a crystal with closer ball–ball separation than is present in undoped C_{60} (see Table 2), presumably due to the attractive forces of the

Table 2. Lattice constants and superconducting T_c values for stable C_{60}-related materials.

M_xC_{60}	Phase	Site Sym.[a]	Lattice constants (Å)	T_c (K)
C_{60}	fcc	-	14.11	-

[a] The octahedral and tetrahedral site symmetries are denoted by O and T, respectively.

[b] Distorted tetragonal site. For the body-centered-tetragonal structure (bct), the in-plane and *c*-axis lattice constants are denoted by *a* and *c*, respectively.

[c] To compare a_{fcc} to a_{bcc}, use the relation $a_{\text{bcc}} = a_{\text{fcc}}/\sqrt{2}$.

electrostatic interactions between the alkali-metal ions and the charged C_{60} molecules.

The structure of the alkaline-earth compound Ca_yC_{60} (for $y \leqslant 5$) has the same fcc space-group symmetry as the heavy alkali-metal M_xC_{60} compounds ($x \leqslant 3$) (Kortan *et al.*, 1992), and the Ca atoms occupy both tetrahedral and octahedral sites. Because of the smaller size of the Ca^{2+} ion [as is also the case for the Na^+ ion (Rosseinsky *et al.*, 1992)], the octahedral sites can accommodate multiple Ca ions, and it is believed that up to three Ca ions can be accommodated in a single octahedral site (Kortan *et al.*, 1992). Also for Ca_5C_{60}, the lattice constant $a_0 = 14.01$ Å is smaller than that for C_{60} prior to doping (see Table 2). Unlike alkali-metal–doped C_{60}, where each *M* atom transfers one electron to C_{60}, the alkaline-earth metal dopants (such as Ca) have been reported to transfer two electrons per metal dopant for low metal concentrations, but less than two electrons per metal dopant for the highest dopant concentrations (Kortan *et al.*, 1992).

The high electronegativity of pristine C_{60} hinders acceptor doping. Consequently, relatively few C_{60}-based structural studies have thus far been made with acceptors. Solid-state C_{60} structure studies by Fischer and co-workers (1992) show an uptake of iodine to a composition $C_{60}I_4$, and in this compound the iodine molecules lie in planes between layers of C_{60} balls. Calculations of the electronic structure of other proposed halogenated C_{60} materials (Oshiyama *et al.*, 1992) suggest that such phases would be thermodynamically stable. The prototypical acceptor dopant would appear to be oxygen. The epoxide $C_{60}O$ crystallizes in the same crystal structure as C_{60} (i.e., space group $Pa\overline{3}$) and undergoes a first-order phase transition at ~280 K from a phase above, in which the $C_{60}O$ balls are spinning, to a phase where the molecules are ordered. We note that the transition temperature in $C_{60}O$ is about 30 K higher than the corresponding transition temperature in C_{60} (Heiney *et al.*, 1992). Heiney and co-workers have argued that the physical basis for the similarity in crystal structure between C_{60} and $C_{60}O$ is related to the high probability that the attached oxygen is directed to an octahedral or tetrahedral cavity in the cubic structure, leaving an essentially unaltered C_{60} ball at each lattice site.

5. VIBRATIONAL MODES

Because of the high symmetry of the C_{60} molecule (point group I_h), there are only 46 distinct mode frequencies corresponding to the $180-6=174$ degrees of freedom for the isolated C_{60} molecule, and of these, only 4 are infrared active (all with T_{1u} symmetry) and 10 are Raman active (2 with A_g symmetry and 8 with H_g symmetry). Raman and infrared spectroscopies provide sensitive methods for distinguishing C_{60} from higher fullerenes with lower symmetry (e.g., C_{70} has D_{5h} symmetry). Since most of the higher-molecular-weight fullerenes have lower symmetry as well as more degrees of freedom, they have many more infrared- and Raman-active modes.

The simplicity of the infrared (ir) spectrum of solid C_{60} [see Fig. 5(a)], which shows four prominent spectral lines, provides a convenient method for characterizing the compositional purity of C_{60} samples, especially with regard to their contamination with C_{70} [see Fig. 5(b)]. The ir spectrum of solid C_{60} remains almost unchanged relative to that of the isolated C_{60} molecule, with only the addition of a few weak features, such as the peak at 1539 cm^{-1} in Fig. 5(a). This is indicative of the molecular nature of solid C_{60}. The ir spectra shown in Fig. 5 are for thin C_{60} and C_{70} films on alkali halide substrates. The positions of the toluene bands indicate how ir spectroscopy might be used to monitor residual sol-

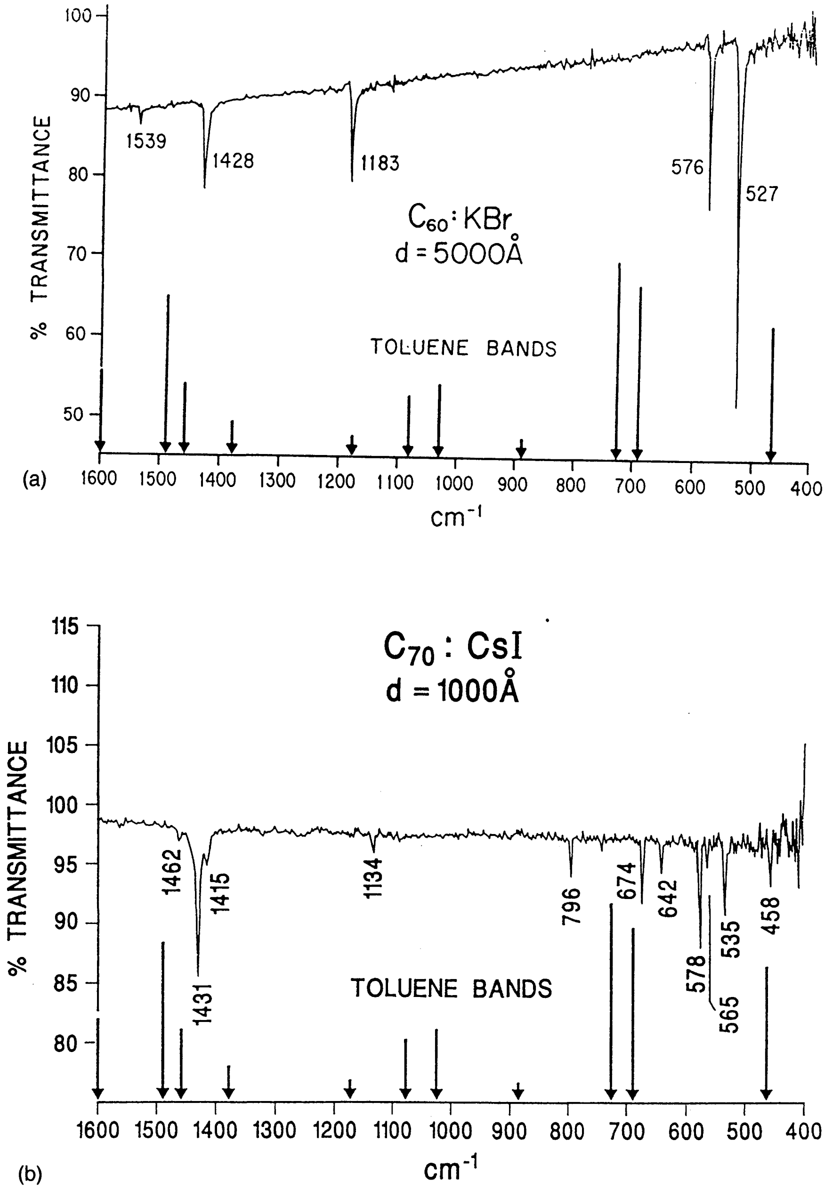

FIG. 5. The infrared spectra of (a) C_{60} (on a KBr substrate) and (b) C_{70} (on a CsI substrate) for the indicated fullerene film thicknesses. Also shown schematically are the ir bands for toluene, a common solvent for fullerenes.

vent in fullerene-based solid-state samples at the 1%–2% level.

Likewise, Raman spectroscopy (see Fig. 6) provides valuable information about intramolecular and intermolecular bonding in solid C_{60} and C_{60}-related compounds (K. A. Wang *et al.*, 1992). The Raman spectrum in Fig. 6 for solid C_{60} shows 10 strong Raman lines, the number of Raman-allowed vibrational modes expected for the free molecule. These spectral lines are therefore assigned to intramolecular modes. The normal modes in molecular C_{60} above about 1000 cm^{-1} involve carbon-atom displacements that are predominantly tangential to the C_{60} ball surface, while the modes below $\sim$800 cm^{-1} involve predominantly radial motions. The A_g breathing mode (1469 cm^{-1}) corresponds to breathing-type tangential displacements of the five carbon atoms around each of the 12 pentagons. Under high laser flux from an Ar-ion laser, this mode frequency shifts down irreversibly to 1458 cm^{-1}, which has been interpreted as a signature of a photoinduced transformation of undoped solid C_{60} (Zhou *et al.*, 1992a).

In the solid phase, cubic crystal-field interactions lower the symmetry of the molecule, causing a splitting of the fivefold-degenerate H_g-derived molecular modes into threefold (T_g) and twofold (E_g) lattice modes (Dresselhaus *et al.*, 1992a). The study of spectral line splittings and their symmetry in solid C_{60} requires the use of well-annealed single crystals, polarization studies, and studies of the temperature dependence of the Raman spectra to uncover the nature of the solid state interaction. These techniques are also needed to monitor the effect of the 250-K phase transition on the spectral line shifts, linewidths, line splittings, and their symmetries.

The addition of alkali-metal dopants to the metal-saturated stoichiometry M_6C_{60} (where M=K,Rb,Cs) perturbs the Raman spectra only slightly (Eklund *et al.*, 1992), with very little change from one alkali-metal dopant to another. For metallic K_3C_{60} (see Fig. 6) and Rb_3C_{60}, the coupling between the phonons and a low-energy electronic continuum in these metallic systems strongly broadens the

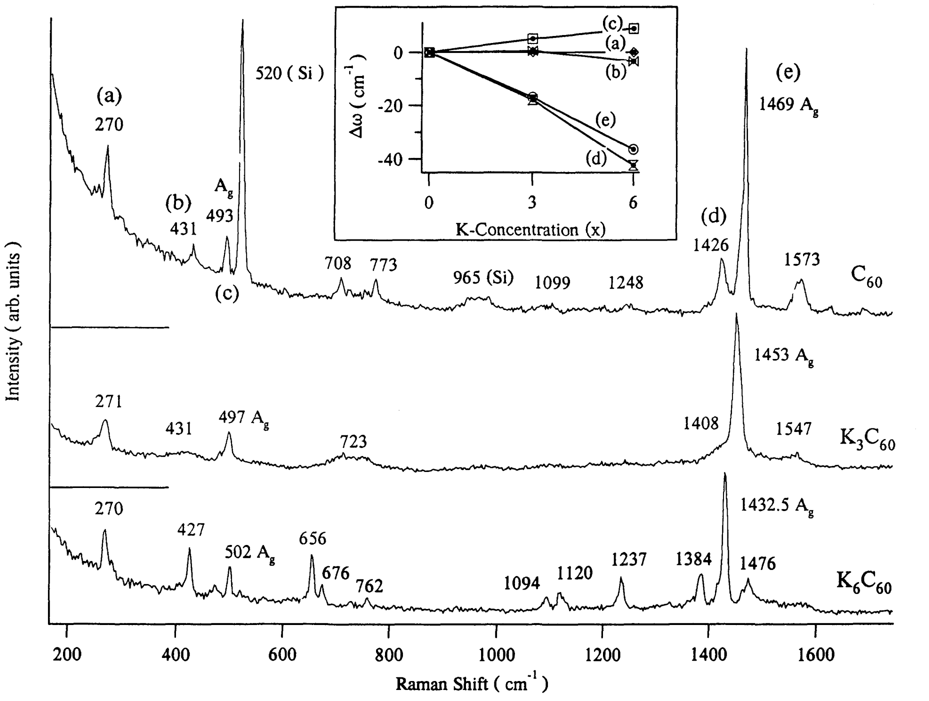

FIG. 6. Room-temperature Raman spectra (resolution $\sim$6 cm^{-1}) from films of undoped C_{60}, K_3C_{60}, and K_6C_{60} (from K. A. Wang *et al.*, 1992). Si denotes the silicon substrate. The inset shows the potassium concentration (x) dependence of five representative Raman modes in K_xC_{60} ($0 \leqslant x \leqslant 6$). Several of the peaks for K_6C_{60} (and M_6C_{60}, M=Rb,Cs) films are doublets, which are not resolved in these data.

H_g-derived modes (K. A. Wang *et al.*, 1992) and gives rise to modifications in the Raman line shape.

As a result of alkali-metal doping, electrons are transferred to the π-electron orbitals on the surface of the C_{60} molecules, elongating the C–C bonds and downshifting the intramolecular tangential modes. In the inset in Fig. 6, the dependence of the Raman frequencies on K concentration x for five dominant modes in K_xC_{60} is presented (Zhou *et al.*, 1992b). The softening of the 1469-cm^{-1} tangential A_g mode by alkali-metal doping is used as a convenient method to characterize the stoichiometry x of K_xC_{60} samples. The radial A_g mode, on the other hand, stiffens slightly because of competing effects associated with a mode softening arising from charge-transfer effects (similar to the situation for the tangential modes) and a larger mode-stiffening effect due to electrostatic interactions between the negatively charged C_{60} ion and the surrounding positively charged alkali-metal ions as their atomic separations change during a normal-mode vibrational displacement (Eklund *et al.*, 1992).

The low-frequency acoustic and rotational-librational modes associated with the displacements and rotations of the C_{60} balls in a cubic lattice have been calculated (Y. Wang *et al.*, 1991), and experimental low-frequency Raman scattering measurements on single crystals of C_{60} have been performed.

Closely related to these spectroscopic studies of the lattice properties are measurements of the bulk modulus, the pressure-dependent Raman spectra, the ultrasonic propagation and attenuation, and the specific heat (see Table 1). Models for the intramolecular modes have been used to study the electron–phonon interaction, with particular emphasis on its connection to the observed superconductivity in the M_3C_{60} compounds.

6. ELECTRONIC STRUCTURE

On the basis of the spectroscopic studies discussed in Sec. 5, we conclude that the fullerenes form molecular solids. Thus we expect their electronic energy band structures to be closely related to the electronic levels of the isolated molecules. Each carbon atom in C_{60} has two single bonds along adjacent sides of a pentagon and one double bond between two adjoining hexagons. If these bonds were coplanar, they would be very similar to sp^2 trigonal bonding in graphite. The curvature of C_{60} causes the planar-derived trigonal orbitals to hybridize with the remaining radial p orbitals, thereby giving rise to different electronic states than in graphite. The shortening of the double bonds and lengthening of the carbon atoms in the single bonds in the Kekulé arrangement of the carbon atoms in the C_{60} molecule also strongly influence the electronic structure.

The most extensive calculations of the electronic structure of fullerenes thus far have been done for C_{60}. To obtain the molecular orbitals for C_{60}, the multielectron problem must be solved (Herzberg, 1945). Results for C_{60} are shown in Fig. 7(a) for the free molecule (Saito and Oshiyama, 1991). Because of the molecular nature of solid C_{60}, the electronic structure for the solid phase would be expected to be closely related to that of the free molecule, and some authors have followed this approach. More attention has, until recently, been given to a band-structure approach. An example of a band-structure model is shown in Fig. 7(b) where we see results for the fcc solid, based on total-energy calculations using the local-density approximation (Saito and Oshiyama, 1991). Various band calculations for C_{60} yield a narrow-band ($\sim$0.4–0.6 eV bandwidth) solid, with a HOMO-LUMO–derived direct band gap of $E_{HL} \sim 1.5$–1.7 eV separating the lowest unoccupied molecular orbital (LUMO) from the highest occupied molecular orbital (HOMO). Since the HOMO and LUMO levels have the same odd parity, electric dipole transitions between these levels are symmetry forbidden in the free C_{60} molecule. In the solid, transitions between the direct band gap states at the Γ and X points in the fcc Brillouin zone are also forbidden, although they may be allowed at many other lower symmetry points in the Brillouin zone. The allowed electric dipole transitions for the free C_{60} molecule are indicated by arrows in Fig. 7(a). Experiments, such as luminescence emission and optical absorption, show different photon threshold energies, since both processes require assistance by vibrational excitations.

Photoemission and inverse photoemission experiments reported by Weaver and coworkers on M_xC_{60} for M=K, Rb, and Na and

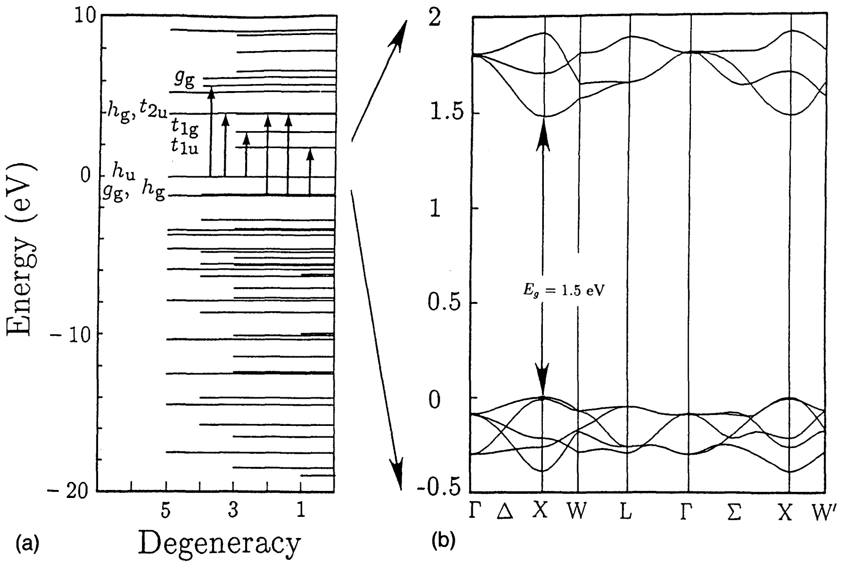

FIG. 7. Calculated electronic structure for (a) an isolated C_{60} molecule and (b) the fcc solid C_{60} where the direct band gap at the X point is 1.5 eV (from Saito and Oshiyama, 1991).

their alloys (Weaver, 1992) show direct evidence for filling of the LUMO levels upon alkali-metal doping, consistent with optical and transport measurements. The implied energy gap in the density of states for these experiments is, however, sensitive to screening and correlation effects.

Doping C_{60} with an alkali metal transfers electrons to the LUMO levels, which, because of their T_{1u} symmetry (Fig. 7), can accommodate three spin-up and three spin-down electrons. Total-energy calculations on K_xC_{60} show that the tetrahedral sites fill up before the octahedral sites (Saito and Oshiyama, 1991). Assuming one electron to be transferred to the C_{60} ball per alkali-metal atom dopant, the LUMO (T_{1u}-derived) levels are expected to be half occupied at the alkali-metal stoichiometry M_3C_{60} and totally full at M_6C_{60}, leading to a filled-shell configuration with A_g symmetry. Thus M_6C_{60} would be expected to be semiconducting with a band gap between the T_{1u} and T_{2g} levels (see Fig. 7), while M_3C_{60} should be metallic provided that no band gap is introduced at the Fermi level by a Peierls distortion or a Jahn-Teller distortion of the molecule.

Fermi-surface calculations for K_3C_{60} indicate a small hole Fermi surface around the Γ point and a larger and more complicated Fermi surface consisting of both electron and hole orbits (see Table 3) (Erwin and Pederson, 1991). No results from direct measurements of the Fermi-surface topology for any of the M_3C_{60} materials are yet available. Because of the weak interaction of the balls with each other and with the alkali-metal dopants, solid M_3C_{60} should also be viewed as a molecular metallic solid having energy bands with little dispersion. This gives rise to a very high density of states near the Fermi level, which is important in understanding superconductivity in M_3C_{60} (see Sec. 9).

Table 3. Physical constants for M_3C_{60} (M=K,Rb).

Quantity	K_3C_{60}	Rb_3C_{60}
T_c	19.3 K	29.6 K
fcc lattice constant	14.253 Å	14.436 Å
$-d \ln a/dP$	1.20×10^{-2} GPa^{-1}	1.52×10^{-2} GPa^{-1}
Bulk modulus	28 GPa	22 GPa
Cohesive energy	24.2 eV	-
Heat of formation	4.9 eV	-
Density of states	25 states/ (eV/C_{60})	35 states/ (eV/C_{60})
Electron effective mass	$1.3m_e$	-
Hole effective mass	$1.5m_e$,$3.4m_e$	-
Resistivity	2.5×10^{-3} Ω cm	-
Radial A_g mode frequency	493.0 cm^{-1}	495.0 cm^{-1}
Tangential A_g mode frequency	1468.5 cm^{-1}	1449 cm^{-1}

7. OPTICAL PROPERTIES

During early research on the separation of C_{60} from impurities and higher fullerenes using liquid chromatography (Ajie *et al.*, 1990), it became apparent that fullerenes in solution (organic solvents) exhibited characteristic colors that would be useful for identifying and purifying these fullerenes. For example, C_{60} and C_{70} appear magenta and reddish-orange, respectively, in toluene and benzene solutions.

More detailed studies show that the optical properties of fullerenes are complex and provide important insights into the electronic structure of the fullerenes. Since the HOMO–LUMO optical transitions in C_{60} and C_{70} are symmetry forbidden, a great deal of attention has focused upon understanding the optical behavior near the fundamental absorption edge, which is very sensitively studied by optical transmission spectra. Such spectra are shown in Figs. 8(a) and 8(b) versus wavelength in the ultraviolet (uv)–visible range (200–700 nm) for C_{60} and C_{70}, respectively, in hexane solution (Ajie *et al.*, 1990). The strong absorption bands in the solution spectra are identified with electric-dipole-allowed transitions between occupied (bonding) and empty (antibonding) sp^2-hybridized molecular orbitals above the LUMO level. For a C_{60} molecule, electric dipole transitions between the one-electron HOMO level with h_u symmetry and the one-electron LUMO level with t_{1u} symmetry are forbidden.

Using many-electron molecular states (Herzberg, 1945), we identify the fully occupied ground-state HOMO level with a singlet S_0 state with A_g symmetry. Allowed electric

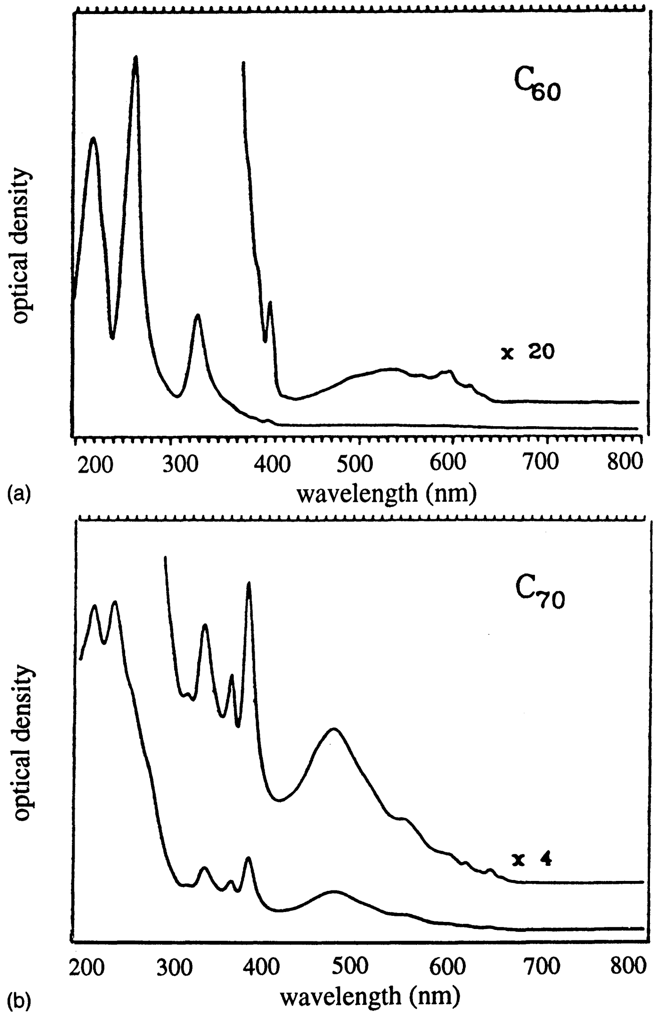

FIG. 8. UV-visible absorption spectra shown as optical density vs wavelength for (a) C_{60} and (b) C_{70} in hexane solutions. For both of these molecular solution spectra, the data near the absorption edge are shown more clearly by using solutions containing higher concentrations of fullerenes as indicated (from Ajie *et al.*, 1990; Ebbesen *et al.*, 1991).

dipole transitions can likewise be described in terms of either a one-electron picture or a many-electron (exciton) picture. In a one-electron picture, the lowest allowed electric dipole transition occurs by exciting an electron from the filled h_u orbital to the unoccupied t_{1g} level (see Fig. 7), or in terms of a many-electron picture from a singlet S_0 ground state to a singlet exciton state denoted by S_1. In terms of the many-electron molecular description, the weak absorption observed between 490 and 640 nm for C_{60} in solution [Fig. 8(a)] is assigned to transitions between the singlet ground state S_0 and the first excited singlet state S_1 (which, for the one-electron molecular orbital description, corresponds to the t_{1u} orbital, activated by vibronic coupling). From the long-wavelength limit (~ 640 nm) of this weak absorption, the energy of the S_1 state can be estimated to be ~ 1.9 eV (Haddon, 1992). Referring to Fig. 8(a), the broad weak absorption band is identified with the $h_u \rightarrow t_{1u}$ forbidden one-electron transition between multiplets associated with the S_0 and S_1 singlet excitonic states. The strong transition starting at ~ 2.9 eV relates to the dipole-allowed transition between the h_u and the t_{1g} one-electron states (see Fig. 7). An analysis of the C_{70} absorption spectrum (plotted as the optical density vs. wavelength) [see Fig. 8(b)] is more difficult than for C_{60} since molecular-orbital calculations for C_{70} reveal a large number of closely spaced orbitals both above and below the HOMO–LUMO gap $E_{HL} = 1.65$ eV (Saito and Oshiyama, 1991).

Further insight into the electronic structure is provided by pulsed-laser studies of C_{60} and C_{70}, which probe the photodynamics of the optical excitation spectra. The importance of these dynamic studies in C_{60} is to show that photoexcitation in the long-wavelength portion of the UV–visible spectrum leads to the promotion of the system from the singlet S_0 state into a singlet S_1 state, which decays quickly with nearly 100% efficiency via an intersystem crossing to the lowest excited triplet state T_1, which has the same orbital quantum numbers as the S_1 state, and therefore the S_1 and T_1 states are strongly coupled. Once in the lower T_1 triplet excitonic state, a luminescence recombination emission to the ground state may be possible, but has not yet been observed directly. This suggests that nonradiative decay from the $T_1 \rightarrow S_0$ levels is much more efficient in returning the system to the ground state. Luminescence emission at 1.7 eV has, howver, been observed and has been identified with $S_1 \rightarrow S_0$ singlet fluorescence. The luminescence contains vibrational sidebands at 0.18 and 0.09 eV associated with the two vibrational A_g modes of C_{60}. In the presence of oxygen, the lifetime of the triplet state becomes very short, and the decay to the ground state becomes very rapid. Furthermore, once C_{60} reaches the T_1 triplet state, efficient electronic dipole excitation to other excited triplet states can occur with high efficiency, thereby greatly increasing the absorption coefficient and providing a mechanism for achieving efficient optical limiting (see Sec. 11).

To date, most of the optical studies on pristine fullerene solids have been carried out in transmission on thin solid films deposited on various substrates (such as quartz, Si, or KBr). The uv–visible transmission spectra for C_{60} and C_{70} solid films are observed to be remarkably similar to the respective solution spectra, thus providing further evidence for the molecular nature of fullerene solids (Ren *et al.*, 1991). The optical properties of solid C_{60} and C_{70} have been studied over a wide frequency range using the variable-angle spectroscopic ellipsometry (VASE) technique. From the VASE measurements the complex refractive index $\tilde{n}(\omega) = n(\omega) + ik(\omega)$ is determined, which is related to the optical dielectric function $\epsilon(\omega) = \epsilon_1(\omega) + i\epsilon_2(\omega) = \tilde{n}^2(\omega)$. In Fig. 9 we show the results for $\epsilon_1(\omega)$ and $\epsilon_2(\omega)$ obtained from VASE and transmission–Fourier-transform ir studies on thin solid films of C_{60} at $T = 300$ K (Rao *et al.*, 1992). The strong, sharp structure at low energy is identified with infrared-active optic phonons, and at higher energies the structure is due to electronic transitions, as discussed below.

Vibronic coupling of the vibrational molecular modes to the LUMO states provides a mechanism by which optical absorption across the HOMO–LUMO gap can be observed. No absorption threshold was detected down to 0.5 eV in the M_6C_{60} materials, establishing an experimental upper bound for the band gap between the t_{1u}- and t_{1g}-derived one-electron bands.

Photoemission and inverse photoemission experiments have been especially useful (Haddon, 1992; Weaver *et al.*, 1991) in providing information on the density of states within a

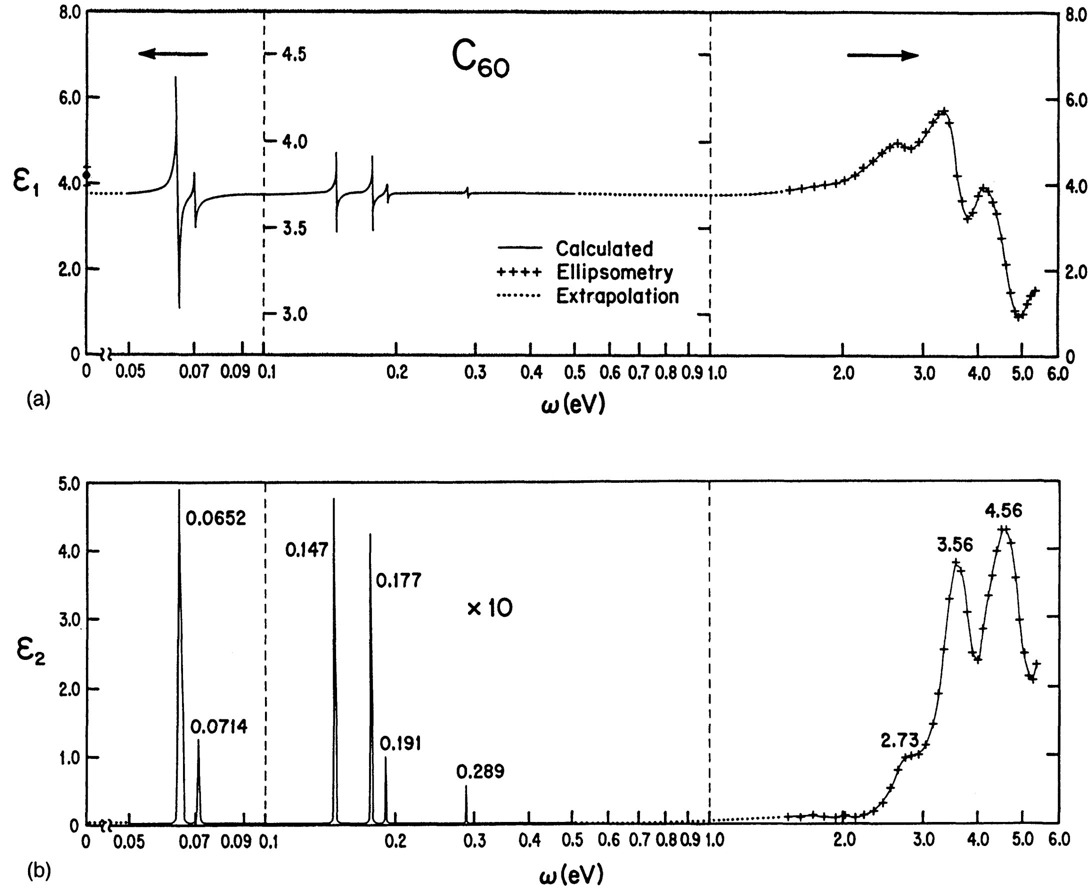

FIG. 9. (a) Real and (b) imaginary parts of the dielectric function $\epsilon(\omega)$ determined from variable-angle spectroscopic ellipsometry (VASE) and Fourier-transform infrared (FTIR) measurements for C_{60} (from Rao *et al.*, 1992).

few electron volts of the Fermi level for both undoped and doped fullerenes. Typical photoemission spectra ($E<E_F$, where E_F is the Fermi energy) and inverse-photoemission spectra ($E>E_F$) are shown in Fig. 10 for C_{60} and $K_xC_{60}(0\leqslant x\leqslant 6)$ (Weaver, 1992), where the intensity maxima correspond to peaks in the density of states, which is here compared to calculations based on a one-electron picture and a constant-optical-matrix element approximation. Photoemission and inverse-photoemission spectra (PES and IPES) provide convincing evidence for charge transfer and for band filling as x in K_xC_{60} increases. Referring to Fig. 10, we can see the peak in the density of states, associated with the t_{1u}-derived band just above the Fermi level E_F in the C_{60} trace, move closer to E_F as K is added and some K_3C_{60} phase is introduced. Upon further addition of potassium, the t_{1u}-related peak crosses the Fermi level, and eventually, for $5.8\leqslant x\leqslant 6.0$, the t_{1u}-derived peak falls below E_F, indicating complete filling of the t_{1u}-derived level; the data for this composition further show a small band gap to the next higher-lying t_{1g}-derived level. Photoemission and inverse-photoemission (Jost *et al.*, 1991) studies have confirmed strong similarities between electronic structure of K_xC_{60} and both Rb_xC_{60} and Cs_xC_{60}. However, differences have also been clearly demonstrated between the density of states for K_xC_{60} and for both Na_xC_{60} and Ca_xC_{60}, for which multiple metal ions can be accommodated in the octahedral sites (see Sec. 4).

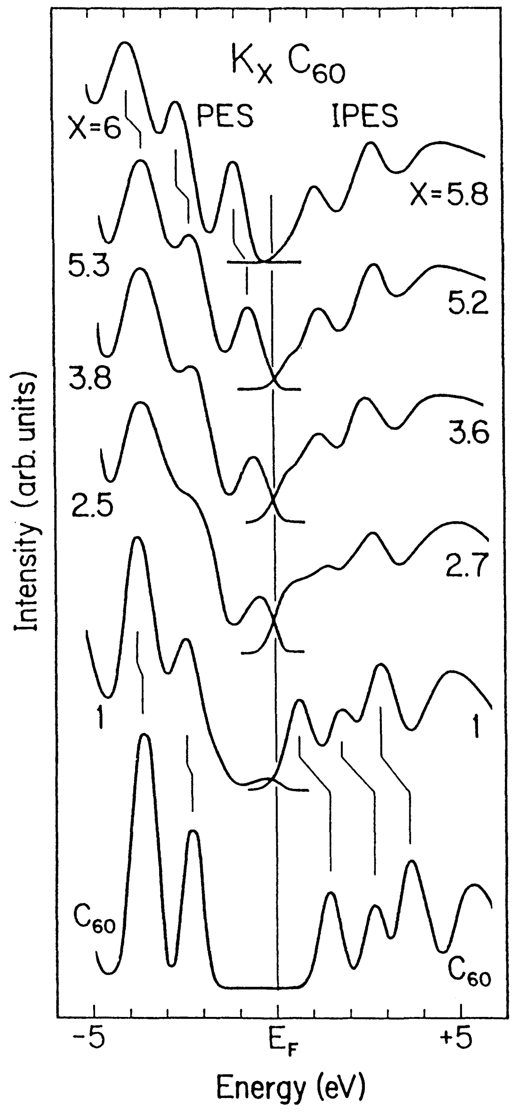

FIG. 10. Photoemission (PES) and inverse photoemission (IPES) (from Weaver, 1992). The spectra are given for K_xC_{60} and show the effects of K incorporation in C_{60} films. The $x=1$ spectra show emission at E_F from grains of K_3C_{60}. Adding more K results in an increase of emission below E_F and a decrease of intensity above E_F. The top spectra show that E_F shifts into the gap when the LUMO bands are filled.

8. ELECTRICAL AND THERMAL TRANSPORT

Because of the high resistivity of undoped C_{60}, the doping of C_{60} with alkali metals creates carriers at the Fermi level and decreases the electrical resistivity ρ of C_{60} by several orders of magnitude. As x in M_xC_{60} increases, the resistivity ρ approaches a minimum at $x=3.0\pm0.05$ (Haddon, 1992), corresponding to a half-filled t_{1u}-derived conduction band. Then upon further increase in x from 3 to 6, ρ again increases, as is shown in Fig. 11 (Kochanski *et al.*, 1992). It should be noted that stable M_xC_{60} compounds (M =K,Rb,Cs) only occur for $x=0$, 3, 4, and 6. (For Na_xC_{60}, stable compounds have been reported for $x=2$ and $x=6$.) Since $x=4$ for M_xC_{60} (M=K,Rb,Cs) is less stable than the others, samples with $x\neq3$ often phase separate into the more stable compounds with $x=0$, 3, and 6. The compounds corresponding to filled molecular levels (C_{60} and M_6C_{60}) are the most stable structurally and correspond to maxima in the resistivity. Furthermore, even at the minimum resistivity in M_xC_{60}, a high value of ρ is found for K_3C_{60} ($\rho_{\min}\cong2.5\times10^{-3}$ Ω cm), typical of a high-resistivity metal (Haddon, 1992). Furthermore, no structure is observed (Fig. 11) in the $\rho(x)$ data near $x=4$, indicating that K_4C_{60} may not be a metallic phase.

Studies of the temperature dependence of the resistivity of polycrystalline M_xC_{60} samples in the normal state show that conduction is by a thermally activated hopping process except for a small range of x near 3 where the conduction is metallic (Haddon, 1992). The magnitude of the arrows in Fig. 11, corresponding to the magnitude of the activation energy E_a, indicate that E_a increases as x deviates further and further from the resistivity minimum at $x=3$, and E_a has, for example, a magnitude of 0.12 eV for $x=1$ (Kochanski *et al.*, 1992). In the metallic regime, $\rho(T)$ results for a superconducting single-crystal K_3C_{60} sample (see Fig. 12) show a linear T dependence of $\rho(T)$ above T_c (Maruyama *et al.*, 1991; Xiang *et al.*, 1992), although the linear T dependence is much weaker than that for the high-T_c cuprates (Ginsberg, 1990). In contrast, many *thin-film* superconducting M_3C_{60} samples have been shown to have a negative slope in $\rho(T)$ vs T for $T\geqslant T_c$. The observed temperature dependence of the resistivity for films of M_xC_{60} (for $0<x\leqslant6$) has been interpreted in terms of a granular conductor with grain sizes in the 60–80-Å range

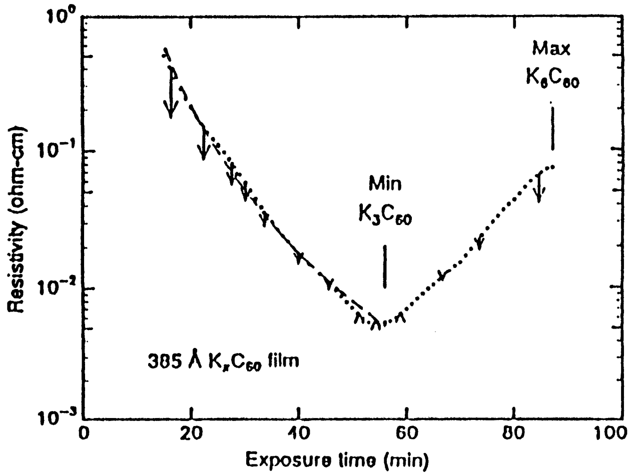

FIG. 11. Dependence of the resistivity of a K_xC_{60} film on exposure time to a K molecular beam. The experiment is carried out in ultrahigh vacuum at an ambient temperature near 74 °C. The arrows show changes in the resistivity of a similar sample as it was heated from 60 to 134 °C (from Kochanski *et al.*, 1992).

(Palstra *et al.*, 1992). This granularity strongly affects the superconducting properties of the M_3C_{60} films, as well as their transport properties in the normal state.

The small value of the observed Hall coefficient suggests the existence of multiple carrier types in K_3C_{60} including both electrons and holes (Palstra *et al.*, 1992). This interpretation is corroborated by the observed sign change in R_H from negative below 220 K to positive above, and by Fermi-surface calculations (Erwin and Pederson, 1991; Oshiyama *et al.*, 1992).

The high electrical resistivity and the magnitude of the optical band gap of C_{60} can be reduced by the application of high pressure, with decreases in resistivity of about one order of magnitude observed per 10 GPa of pressure (Nuñez-Regueiro *et al.*, 1991). At a pressure of ~20 GPa, a phase transition to a more insulating phase has been reported. As the interball C–C distance decreases upon application of pressure and becomes comparable to the intraball C–C distance, an electronic transition might be expected to occur.

Thermal conductivity measurements from 30 to 300 K on single-crystal C_{60} by Yu *et al.* (1992) show a low value of the thermal conductivity κ, and this small magnitude of κ is attributed to both a high density of defect states and a low Debye temperature in C_{60}. In addition, a discontinuity is observed at 260 K, associated with a first-order structural phase transition (see Sec. 4).

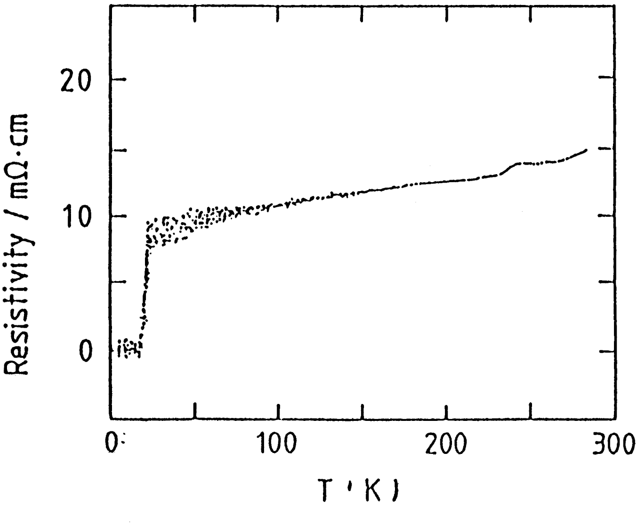

FIG. 12. Temperature dependence of the resistivity ρ of single-crystal K_3C_{60}, showing a linear increase in ρ above the T_c (from Maruyama *et al.*, 1991).

9. SUPERCONDUCTIVITY

Perhaps the most striking property of the C_{60}-related materials is the observation of high-temperature superconductivity. The first observation of superconductivity in an alkali-metal–doped carbon material dates back to 1965 when superconductivity was observed in the first-stage alkali-metal graphite intercalation compound (GIC) C_8K (Hannay *et al.*, 1965). Except for the novelty of observing superconductivity in a compound having no superconducting constituents, this observation did not attract a great deal of attention, since the T_c was very low ($\sim$140 mK). Later, higher T_c's were observed in other GICs [e.g., $KHgC_8$, $T_c = 1.9$ K (Dresselhaus and Dresselhaus, 1981)].

The early observation of superconductivity at 18 K in K_3C_{60} (Haddon *et al.*, 1991) was soon followed by observations of superconductivity at even higher temperatures; in Rb_3C_{60} ($T_c = 30$ K) and $Rb_xCs_yC_{60}$ ($T_c = 33$ K) (Tanigaki *et al.*, 1992). A large increase in T_c is achieved on going to compounds with larger intercalate atoms, resulting in unit cells of larger size and with larger lattice constants as seen in Tables 2 and 4. As the lattice constant increases, the coupling between adjacent C_{60} molecules decreases, narrowing the width of the LUMO level, and thereby increasing the corresponding density of states. Several experiments and calculations (Oshiyama *et al.*, 1992) provide supporting evidence for an increased density of states at the Fermi level resulting from an increase in lattice constant. Figure 13 shows an empirical, nearly linear relation between T_c and the lattice constant a_0 for superconducting alkali-metal–doped samples with a_0 greater than that for undoped C_{60} (see Table 2) (Tanigaki *et al.*, 1992). This correlation includes compounds derived from alkali-metal dopants, alloys of different alkali metals (Fleming *et al.*, 1991a), and samples under pressure (Sparn *et al.*, 1992). Because of the connection between the electronic density of states at the Fermi level $N(E_F)$ and the lattice constant, similar plots of T_c vs $N(E_F)$ have been made (Oshiyama *et al.*, 1992). The increase in T_c is consistent with the BCS expression relating the transition temperature to the density of states $N(E_F)$ and to the electron–phonon coupling V,

$$T_c \sim \omega_{ph} \exp[-1/VN(E_F)]. \qquad (4)$$

However, for the donor C_{60} compounds intercalated with Li, Na, and Ca where a_0 falls below that for C_{60} itself (see Table 2), the linear correlation between T_c and a_0 breaks down.

The reason why T_c is so much higher in the M_3C_{60} materials relative to other carbon-based superconductors such as C_8K appears to be closely related to the higher density of states expected in a molecular solid with little dispersion in the electronic energy-band diagram. This is achieved in the M_3C_{60} compounds at the Fermi level when the T_{1u} LUMO molecular level is half filled with carriers. In addition, several authors have found some

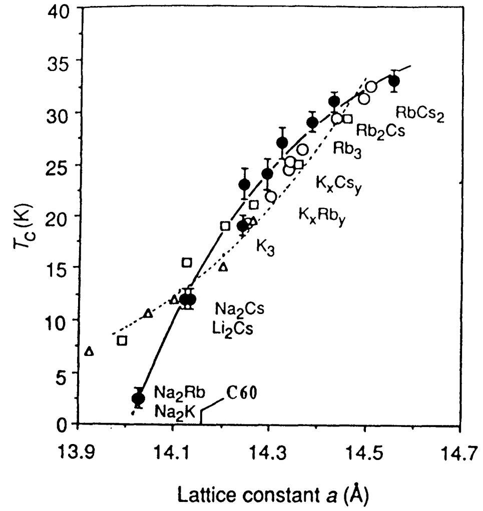

FIG. 13. Dependence of T_c for various M_3C_{60} compounds on the lattice constant (from Tanigaki *et al.*, 1992). The open triangles and squares relate to pressure-dependent studies. The solid line is a fit to the experimental data and the dashed curve is predicted from density-of-states calculations.

Table 4. Superconductivity parameters in M_3C_{60} (M=K,Rb).

Parameter	K_3C_{60}	Rb_3C_{60}
fcc a_0 (Å)	14.253	14.436
T_c (K)	19.3	29.6
$2\Delta(0)/kT_c$	5.2	5.3
$(dT_c/dP)_{p=0}$ (K/GPa)	−7.8	−9.7
$H_{c1}(0)$ (mT)	13	12
$H_{c2}(0)$ (T)	49	78
$H_c(0)$ (T)	0.38	0.44

enhancement in the electron–phonon coupling in C_{60}-related materials. If the electron–phonon interaction provides the pairing mechanism for superconductivity in C_{60}-based materials, it is believed that it is the H_g-derived phonons that play the dominant role in the coupling. The observation of broad H_g-derived Raman lines in M_3C_{60} is consistent with a strong electron–phonon coupling. Calculations of the contributions of the various phonon modes to the electron–phonon interaction strength (Schlüter *et al.*, 1992) show that the high-frequency intramolecular phonons can account for the high T_c values that are observed experimentally.

Using scanning tunneling microscopy (STM), the temperature dependence of the superconducting band gap has been investigated for both K_3C_{60} and Rb_3C_{60} (Zhang *et al.*, 1991). The results show a good fit for the temperature dependence of the superconducting band gap 2Δ by BCS theory (see Fig. 14), although the zero-temperature band-gap value $[(2\Delta(0)/kT_c)]$ was found to be 5.3 for K_3C_{60} and 5.2 for Rb_3C_{60}, well above 3.5 for the case of a BCS superconductor. These results imply that the M_3C_{60} compounds are strong-coupling superconductors (Zhang *et al.*, 1991), indicating that the paired electrons are more strongly attracted to each other.

There have been several measurements of the isotope effect in superconducting M_3C_{60} to provide insight into whether or not the electron pairing mechanism responsible for superconductivity in the doped fullerenes involves the coupling between electrons and phonons as in BCS superconductors. In the experiments reported to date, the isotopic enrichment has involved ^{13}C. The experiments all suggest that $T_c \propto M^{-\alpha}$, consistent with phonon-mediated electron pairing, where the observed α values are compared with the BCS prediction of $\alpha = 0.5$. The experimental values of α for superconducting fullerenes at present differ from one group to another, though all groups suggest that intramolecular C_{60} vibrations are involved in the pairing mechanism for superconductivity and that the electron–phonon coupling constant is quite large.

Of interest also is the dependence of the superconducting parameters on pressure and magnetic field. Closely related to the high compressibility of C_{60} and M_3C_{60} (M=K,Rb) is the large linear decrease in T_c with pressure observed in K_3C_{60} and Rb_3C_{60} (see Table 4) (Sparn *et al.*, 1992). By attributing the smaller size of the K^+ ion relative to Rb^+ (0.186 Å) to an "effective chemical pressure" of 1.06 GPa, the pressure dependence of T_c for both K_3C_{60}

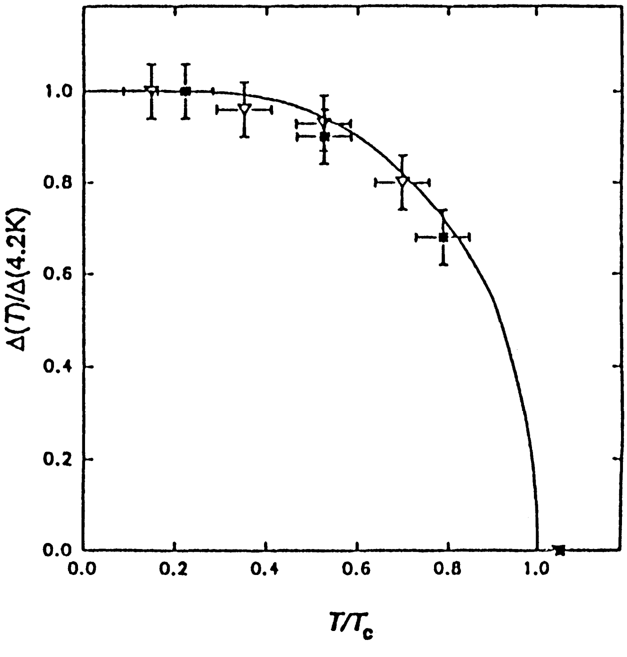

FIG. 14. Summary of the temperature-dependent superconducting energy gap results for K_3C_{60} (dark squares) and Rb_3C_{60} (open triangles). For comparison the values of the gap 2Δ have been normalized by the respective low-temperature (4.2 K) values and the temperature has been scaled by T_c. The solid line corresponds to the temperature dependence of $\Delta(T)/\Delta(0)$ calculated by the BCS theory (from Zhang *et al.*, 1991).

and Rb_3C_{60} can be explained. Listed in Table 4 are values for the characteristic superconducting parameters relevant to their magnetic field behavior, including estimates of the upper critical field (in tesla) at $T=0$, $H_{c2}(0)$, the lower critical field $H_{c1}(0)$, the coherence length ζ_0 at $T=0$, and the London penetration depth ξ_L. The large values of $\kappa_s=\xi_L/\zeta_0$ listed in Table 4 confirm that the M_3C_{60} compounds are strongly type-II superconductors.

10. C_{60}-RELATED TUBULES

In addition to ball-like fullerene molecules, it is possible to synthesize tubular fullerenes with very high aspect ratios (length/diameter). In analogy to the C_{60} ball, we can define C_{60}-derived tubules by bisecting a C_{60} molecule at the equator and joining the two resulting hemispheres with a cylindrical tube of carbon atoms in a honeycomb lattice one monolayer thick, and with the same diameter as C_{60}. If the C_{60} is bisected normal to a fivefold axis, the armchair tubule shown in Fig. 15(a) is formed, and if the C_{60} is bisected normal to a threefold axis, the zigzag tubule in Fig. 15(b) is formed (Dresselhaus *et al.*, 1992b).

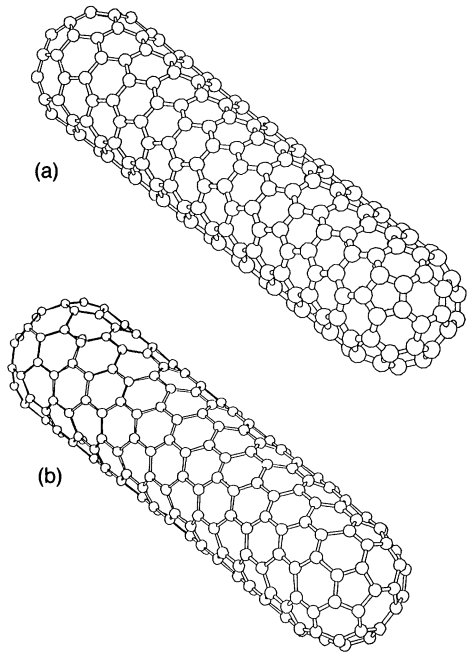

FIG. 15. By rolling up a graphene sheet (a single layer from a 3D graphite crystal) as a cylinder and capping each end of the cylinder with half of a C_{60} molecule, a "C_{60}-related tubule" one layer in thickness is formed. Shown here is a schematic model for a tubule arising from (a) an armchair cap with a fivefold axis, and (b) a zigzag cap with a threefold axis (from Dresselhaus *et al.*, 1992b).

Two reports have been made on the observation of carbon fibers of very small (nanometer) diameters (Iijima, 1991; Endo *et al.*, 1991, 1992) based on high-resolution transmission electron microscopy (TEM) measurements (see Fig. 16). These images suggest the existence of micron-long tubules that have cross sections consisting of several concentric coaxial tubes and a hollow core [see Fig. 16(a)]. In Fig. 16(b), we see one fiber with only two concentric tubules, and another in Fig. 16(c) with an inner diameter of only 23 Å, about three times larger than the diameter of C_{60} (Iijima, 1991). Such carbon tubules have been nucleated on vapor-grown carbon fibers (Endo *et al.*, 1991, 1992) or on the surface of the negative carbon electrode in a dc arc discharge (Iijima, 1991). These fullerene tubules differ in a fundamental way from the scroll-like graphite whiskers synthesized by Bacon many years ago in a dc carbon-arc discharge at much higher pressures of the rare gas than are used to synthesize fullerene tubules (Bacon, 1960). Highly elongated fullerenes with shapes between the traditional icosahedral fullerenes and the graphene tubules have also been observed by high-resolution transmission electron microscopy (Wang and Buseck, 1991).

The growth mechanism for cylindrical fullerene-related tubules is especially interesting. According to one model, the nucleation of a C_{60} tubule instead of a C_{60} ball is believed to be stabilized by a defect in the cap region. In the growth process, the pentagonal faces in the cap region act like catalytic particles to promote tubule growth (Endo and Kroto, 1992). Saito *et al.* (1992a) have suggested a series of steps that incorporate a C_2 unit through the motion of two pentagonal faces on a hemispherical fullerene-derived cap and promote tubule growth.

Iijima (1991) reports that the majority of the carbon tubules that he has observed by high-resolution TEM have screw axes and chirality. Using Fig. 17, we can specify the chirality and the tubule diameter of any graphene tubule in terms of the chiral vector

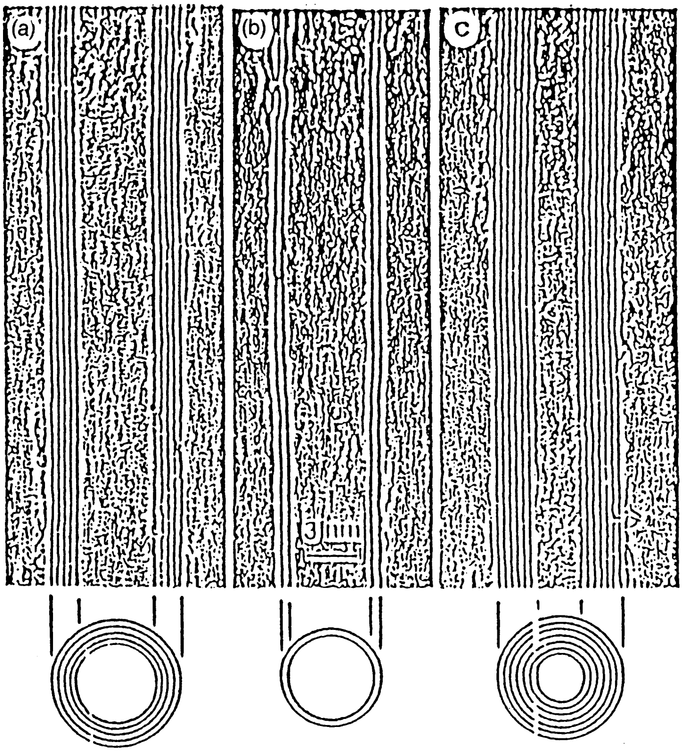

FIG. 16. The observation of N concentric carbon tubules with various inner diameters d_i and outer diameters d_0 was reported using TEM (from Iijima, 1991). (a) $N=5$, $d_0=67$ Å, (b) $N=2$, $d_0=55$ Å, and (c) $N=7$, $d_i=23$ Å, $d_0=65$ Å.

$\mathbf{c}_h=n\hat{\mathbf{a}}_1+m\hat{\mathbf{a}}_2$ that connects two crystallographically equivalent sites on a two-dimensional (2D) graphene sheet [Fig. 17(a)] (Dresselhaus *et al.*, 1992b), where a graphene sheet denotes a single layer of the 3D graphite lattice. The construction in Fig. 17 shows the chiral angle θ with respect to the zigzag direction ($\theta=0°$) and the unit vectors $\hat{\mathbf{a}}_1$ and $\hat{\mathbf{a}}_2$ of the hexagonal honeycomb lattice. The armchair tubule [Fig. 15(a)] corresponds to $\theta=30°$ on this construction. An ensemble of possible vectors specified by pairs of integers (n,m) denoting the vector $\mathbf{c}_h=n\hat{\mathbf{a}}_1+m\hat{\mathbf{a}}_2$ is given by Fig. 17(b) (Saito *et al.*, 1992b).

The cylinder connecting the two hemispherical caps is formed by superimposing the two ends of the vector $\mathbf{c}_h$, and the cylinder joint is made along the two lightly dotted lines in Fig. 17, which are perpendicular to the vector $\mathbf{c}_h$ at each end (Dresselhaus *et al.*, 1992b). The chiral tube thus generated has no distortion of bond angles other than distortions caused by the cylindrical curvature of the tubule. Differences in chiral angle θ and in the tubule diameter d give rise to differences in the properties of the various graphene tubules, as discussed below. In the (n,m) notation for $\mathbf{c}_h=n\hat{\mathbf{a}}_1+m\hat{\mathbf{a}}_2$, the vectors $(n,0)$ denote zigzag tubules and the vectors (n,n) denote armchair tubules. All other vectors (n,m) correspond to chiral tubules where the tubule axis has the symmetry properties of a screw axis (Saito *et al.*, 1992b). Of course, both right- and left-handed chiralities are possible for chiral tubules. Therefore, it is expected that chiral tubules are optically active to either right- or left-circularly polarized light, depending on their chirality. In terms of the integers (n,m), the tubule diameter d is given by

$$d=\sqrt{3}a_{\text{C-C}}(m^2+mn+n^2)^{1/2}/\pi, \tag{5}$$

where $a_{\text{C-C}}$ is the nearest-neighbor carbon–carbon distance and the chiral angle θ is given by

$$\theta=\tan^{-1}[\sqrt{3}n/(2m+n)]. \tag{6}$$

For example, a zigzag tubule ($\theta=0°$) with $(m,0)=(9,0)$ has a tubule diameter of 7.05 Å, while an armchair tubule (5,5) has $d=6.83$ Å, which exactly matches the diameter of 6.83 Å for a C_{60} ball.

Because of the special atomic arrangement of the carbon atoms in a C_{60} tubule, substitutional impurities other than boron are inhibited by the small size of the carbon atoms.

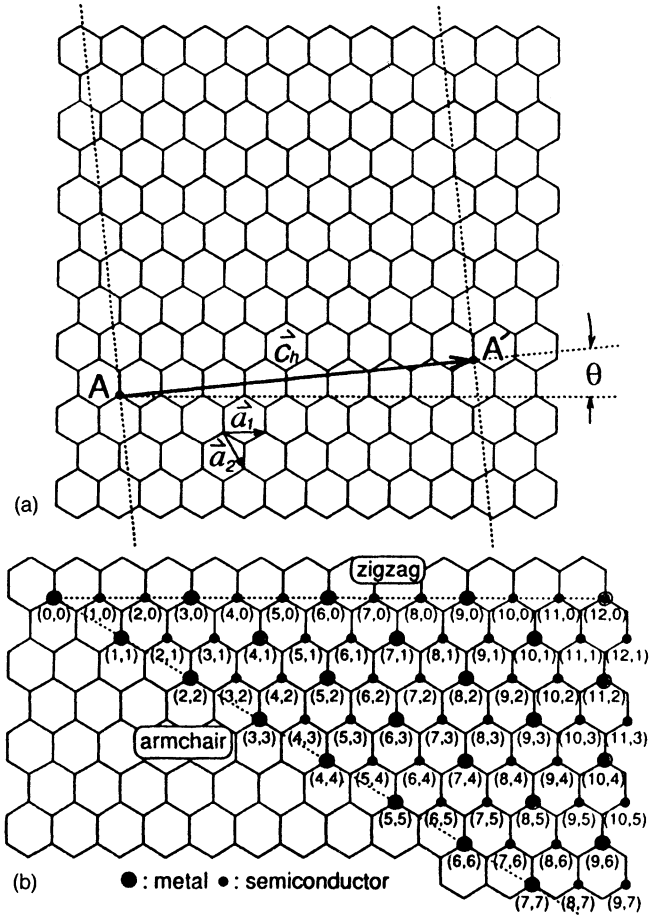

FIG. 17. (a) The vector $\overrightarrow{AA'}$ or $\mathbf{c}_h = n\hat{\mathbf{a}}_1 + m\hat{\mathbf{a}}_2$ on the honeycomb lattice defined by unit vectors $\hat{\mathbf{a}}_1$ and $\hat{\mathbf{a}}_2$ and the chiral angle θ with respect to the zigzag axis. (b) Possible vectors for general tubules, including zigzag, armchair, and chiral tubules. The large dots and small dots respectively denote metallic and semiconducting behavior for each of the possible tubules (from Dresselhaus *et al.*, 1992b).

Furthermore, the screw-axis dislocation, the most common defect found in bulk graphite, is inhibited by the monolayer structure of the C_{60} tubule. The special geometry of the C_{60}-related tubules should make these tubules relatively incompressible along the tubule axis, when compared to other materials (Overney *et al.*, 1992).

From a theoretical standpoint, fullerene tubules are interesting as examples of a one-dimensional periodic structure along the tubule axis. Geometrical confinement in the radial direction is provided by the monolayer thickness of the tubule. In the circumferential direction, periodic boundary conditions apply to the electronic and vibrational states associated with the enlarged unit cell that is formed in coordinate space and the subsequent zone folding that occurs for these states in reciprocal space. We can then expect to observe one-dimensional (1D) dispersion relations for electrons and phonons in C_{60}-derived tubules.

A number of methods have been used to calculate the 1D electronic bands for fullerene tubules, and these energy bands are closely related to the 2D graphene sheet used to form the tubule. Their results for the 1D electronic energy bands show that for small-diameter graphene tubules, about $\frac{1}{3}$ of the tubules are metallic and $\frac{2}{3}$ are semiconducting, depending on the tubule diameter d and chiral angle θ. Metallic conduction in a fullerene tubule is achieved when (Saito *et al.*, 1992c)

$$2n+m=3q, \tag{7}$$

where n and m are integers specifying the tubule diameter and chiral angle and q is an integer. Tubules satisfying Eq. (7) are indicated in Fig. 17(b) as large dots, and these are the metallic tubules. The small dots in this figure correspond to semiconducting tubules. Figure 17(b) shows that all armchair tubules are metallic, but only $\frac{1}{3}$ of the possible zigzag tubules are metallic (Saito *et al.*, 1992b). This effect is illustrated in the density of states for metallic and semiconducting tubules, shown in Fig. 18 for the (9,0) and (10,0) tubules, respectively (Saito *et al.*, 1992b). Here we see a finite density of states at the Fermi level for the (9,0) tubules, and a vanishing density of states for the (10,0) tubules, consistent with the metallic nature of the (9,0) tubules and the semiconducting nature of the (10,0) zigzag tubules. It is surprising that the calculated electronic structure can be either metallic or semiconducting, depending on the choice of (n,m), although there is no difference in the local chemical bonding between the carbon atoms in the tubules, and no doping impurities are present (Saito *et al.*, 1992b). These surprising results can be understood on the basis of the electronic structure of 2D graphite, which is a zero-gap semiconductor (Painter and Ellis, 1970) with bonding and antibonding π bands degenerate at the K point (zone corner) of the hexagonal Brillouin zone. The periodic boundary conditions permit only a few wave vectors to exist in the circumferential direction. If one of these wave vectors along the tubule axis direction passes through the K point in the graphite Brillouin zone (satisfying Eq. 7), then metallic conduction results.

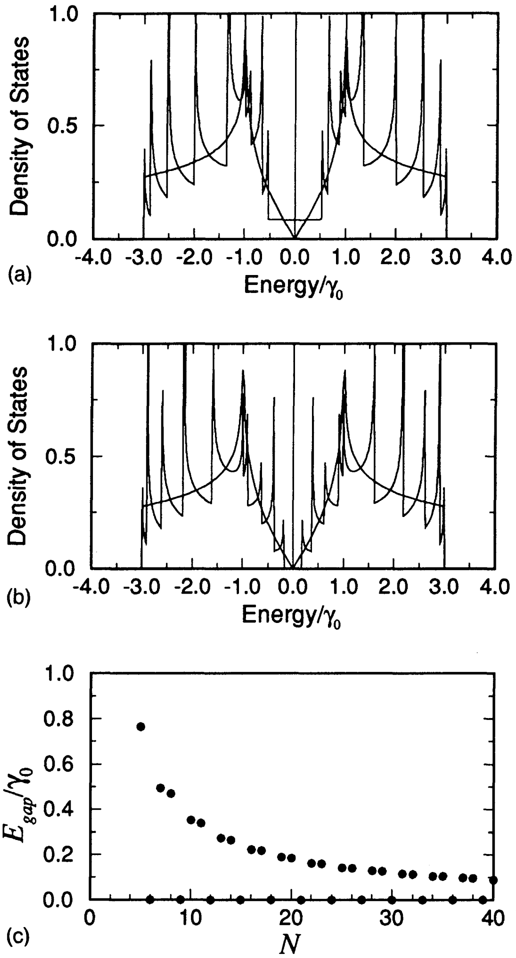

FIG. 18. Electronic 1D density of states for two (n,0) zigzag tubules: (a) the (10,0) tubule, which has semiconducting behavior, and (b) the (9,0) tubule, which has metallic behavior (from Saito *et al.*, 1992b). The zero of energy is chosen to coincide with the Fermi level. (c) Plot of the semiconducting gap E_{gap} normalized to the nearest-neighbor C–C overlap energy γ_0 for graphite vs the number of carbon atoms in the zigzag ring.

Metallic 1D energy bands are generally unstable under a Peierls distortion. However, the Peierls energy gap obtained for the metallic tubules is found to be greatly suppressed by increasing the tubule diameter, so that the Peierls gap quickly approaches the zero-energy gap of 2D graphite. Thus if we consider finite temperatures or fluctuation effects, such a small Peierls gap can be neglected. It is also of interest to note that as the tubule diameter increases, more wave vectors become allowed for the circumferential direction, the tubules become more two dimensional, and the semiconducting band gap disappears, as is illustrated in Fig. 18(c), which shows the diameter dependence of the semiconducting band gap for graphene tubules. Calculation of the electronic structure for two concentric tubules shows that pairs of concentric metal–semiconductor or semiconductor–metal tubules are stable.

From these results one could imagine designing a minimum-size conductive wire consisting of two concentric graphene tubules with a metallic inner tubule covered by a semiconducting (or insulating) outer tubule. This concept could be extended to the design of tubular metal–semiconductor devices without introducing any doping impurities (Saito *et al.*, 1992b). There are many possibilities for arranging arrays of metallic and semiconducting graphene tubules from a conceptual standpoint. It will be interesting to see what kinds of tubules and tubule arrays can be synthesized from a practical standpoint.

The elastic properties of fullerene tubules have also been considered by carrying out lattice-mode calculations of long fullerene tubules based on 30-carbon-atom hemispherical caps from C_{60} and consisting of 100, 200, and 400 carbon atoms (Overney *et al.*, 1992). These calculations show that the lowest bending vibrational mode frequency decreases as the length of the fullerene tube increases, saturating at a cluster size of about 200 carbon atoms. The theoretical magnitude of the beam rigidity of these tubules is found to exceed that of presently available materials (Overney *et al.*, 1992), so that graphene tubules are expected to offer outstanding mechanical properties.

11. APPLICATIONS

Because graphite is a material of extreme properties (modulus, strength, thermal conductivity, anisotropy, melting point, etc.), and because of the similarities between the bonding in graphite and C_{60}, we might also expect fullerenes to exhibit extreme properties. As in graphite where the planes are weakly van der Waals bonded, solid C_{60} has weak intermolecular bonding and strong intramolecular bonds. Although research on solid C_{60} and related materials is still at an early stage, these materials are already beginning to show many exceptional properties, some of which may lead to practical applications.

One possible application for C_{60} is as an optical limiter. Optical limiters are used to protect materials from damage by high light intensities via a rapid saturation of the transmitted light intensity with increasing incident intensity. Outstanding performance for C_{60} relative to presently used optical limiting materials has been observed at an optical wavelength of 5320 Å for 8-ns pulses using solutions of C_{60} in toluene and in CH_3Cl (Tutt and Kost, 1992). Although C_{70} in similar solutions also showed optical limiting action, the performance of C_{60} was superior. The proposed mechanism for the optical limiting is that C_{60} and C_{70} are more absorptive once the triplet excited state is populated. The initial absorption of a photon leads to electronic excitation to an excitonic state, with a subsequent intersystem crossing to a triplet state, followed by further stronger absorption of photons as excitations from the triplet state to higher-lying triplet states take place (see Sec. 7) (Tutt and Kost, 1992).

The possible use of C_{60} for the fabrication of industrial diamonds offers another area for possible applications. It is found that when rapid nonhydrostatic pressures (in the range of 20 GPa) are applied at room temperature to C_{60}, the material is transformed instantaneously into bulk polycrystalline diamond at high efficiency (Nuñez-Regueiro *et al.*, 1992). It is believed that the presence of pentagons in the C_{60} structure promotes the formation of sp^3 bonds during the application of high anisotropic stress. Enhanced nucleation of a high density of diamond crystallites on a Si substrate has been achieved by Meilunas *et al.* (1991) through the initial deposition of a $\sim$1000-Å C_{70} film, followed by positive-ion bombardment, and then by chemical vapor deposition growth of diamond in a microwave plasma reactor. A base layer of ion-activated C_{70} was found to be more effective in promoting sp^3 bonding (Meilunas *et al.*, 1991) than a similarly treated C_{60} buffer layer. Normally, for diamond films to grow from a mixture of gaseous CH_4 and H_2, the substrate surface (usually Si) must be pretreated with diamond grit polish or must contain small diamond seeds.

A photoconducting device can be fabricated using fullerene-doped polymers. Polyvinylcarbazole (PVK) doped with a mixture of C_{60} and C_{70} has been reported to exhibit exceptionally good photoconductive properties (Wang, 1992), which may lead to the development of future polymeric photoconductive materials. The effects of the fullerenes ($\sim$2.7% by weight) on the charge generation and transport still need to be understood.

Ever since C_{60} was discovered (Kroto *et al.*, 1985), the possibility of using fluorinated derivatives such as $C_{60}F_{60}$ as lubricants was considered. It was recently shown that highly fluorinated C_{60} is unstable in the presence of trace amounts of H_2O (Taylor *et al.*, 1992) and therefore is probably unsuitable for application as a lubricant.

As further research on these materials is carried out, it is expected, because of the extreme properties of carbon-based materials generally, that other interesting physics and chemistry will be discovered, and promising applications will be found for fullerenes and fullerene-related materials.

GLOSSARY

Antibonding States: Electronic states for which the electron charge distribution is decreased through interactions with neighboring atoms.

Armchair Tubule: Graphene tubule with orientation such that a cut normal to the tubule axis gives an up-up-down-down edge for the carbon-atom locations.

Bonding States: Electronic states where the energy is lowered by the excess charge distribution coupling to adjacent atoms.

Dopant: Foreign atom or molecule intentionally added to a host material.

Doping: The addition of foreign atoms or molecules to the host material.

Endohedral Doping: Placement of a foreign atom inside the fullerene cage.

Exohedral Doping: Placement of a foreign atom outside the fullerene cage.

Fullerene: An abbreviation of "buckminsterfullerene," the name given to a closed-cage polyhedral molecule of carbon atoms.

Functional Groups: A chemical group serving a particular purpose in the synthesis or in the end product of a reaction.

Glassy Carbon: A highly disordered, weakly conducting form of carbon containing graphitic ribbons, having high porosity and good mechanical properties.

Graphene Sheet: An isolated single layer of hexagonally arranged carbon atoms such as that found in graphite.

HOMO: Highest occupied molecular orbital.

Hybridization: The coupling and admixing of two electronic orbitals.

Icosahedron: A regular polyhedron having 20 faces and 12 vertices.

Infrared-Active Modes: Vibrational modes that are excited by infrared radiation.

Intercalation: The insertion of guest species in layers or in specially designated sites of the host material.

Kekulé Structure: A chemical structure where carbon atoms in benzene or analogous rings show alternating single and double bonds.

LUMO: Lowest unoccupied molecular orbital.

Octahedral Site: A lattice site with nearest neighbors at the centers of the faces of a cube.

Peierls Distortion: A lattice distortion resulting in a lowering of the total energy and of the symmetry.

Peierls Gap: A gap in the electronic density of states found at the Fermi surface as a result of the Peierls distortion.

π Electron: An electron whose wave function extends normal to the plane where the nuclei are located.

Pristine Fullerene: An undoped fullerene.

Raman-Active Modes: Vibrational modes that are symmetry allowed to participate in the inelastic (Raman) scattering of light.

Regular Truncated Icosahedron: A polyhedron formed by truncating each vertex of an icosahedron so that all of the 90 edges are of equal lengths.

Screw Axis: Symmetry axis that requires both a rotation and a translation.

Soot: A very fine (submicron) powder of carbon or carbonaceous material.

Soxhlet Extraction: A method for continuous extraction of a solute from a solid in a solvent near its boiling point.

sp^2 Trigonal Bonding: Three planar bonds derived from one s and two p atomic carbon orbitals making angles of 120° with each other.

sp^3 Tetrahedral Bonding: Four bonds derived from one s and three p atomic carbon orbitals making tetrahedral angles.

Tetrahedral Site: A lattice site with near neighbors located at the corners of a regular tetrahedron.

Two-Zone Furnace: An oven with two different constant-temperature zones. Vapor transport of the reactant (colder zone) and subsequent intercalation of the reactant into the host crystal or film takes place in the hotter zone.

van der Waals Bond: Weak dipolar bond between neutral atoms or molecules.

van der Waals Charge Cloud: An electron charge distribution that weakly binds near-neighbor atoms or molecules.

Vibronic Coupling: Coupling between electrons and vibrations of a molecule that turns on a symmetry-forbidden optical transition between two molecular states.

Zigzag Tubule: Graphene tubule with orientation such that a cut normal to the tubule axis gives a zigzag edge (up-down) of carbon atoms.

INTRODUCTION

Inertial confinement fusion, frequently referred to as ICF, inertial fusion, or laser fusion, is a means of producing energy by imploding small pellets containing thermonuclear fusion fuel. Inertial fusion is the younger of the two principal approaches to the development of controlled nuclear fusion for energy production; the other approach, magnetic fusion, is described more fully under FUSION, MAGNETIC CONFINEMENT. Inertial fusion also has defense applications in addition to energy production.

The inertial fusion concept is simple: A small hollow pellet containing fusionable fuel material is crushed so rapidly and forcefully that it is compressed into a small, dense, hot core that undergoes rapid, explosivelike, nuclear fusion reactions before it flies apart. Figure 1 illustrates this process. Powerful beams of energy, such as light from a laser or particles from an accelerator, are directed at the surface of the pellet with enough intensity to ablate surface material at high speed. The outward-going material acts like a powerful rocket exhaust and accelerates the remaining shell and fuel inward. The fuel is compressed to over 1000 times liquid density by the implosion. If this is done properly, a small region in the center of the compressed fuel becomes hot enough to initiate rapid thermonuclear fusion reactions. Fusion energy is

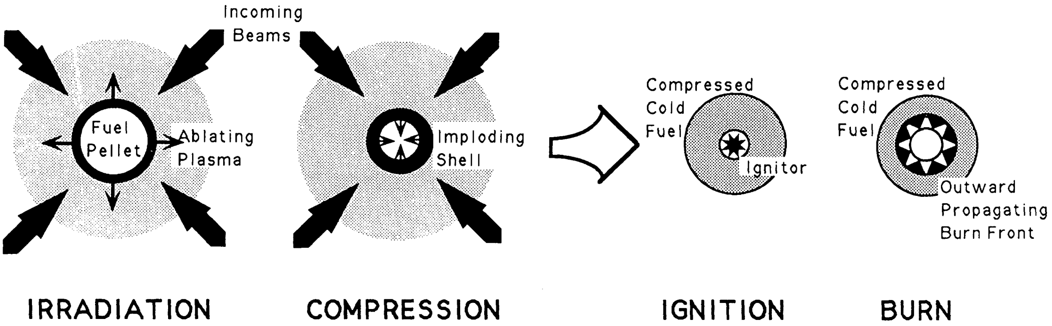

FIG. 1. Inertial confinement fusion concept. The four basic phases of an inertial fusion pellet implosion are (1) *irradiation* of the pellet surface and formation of a plasma with an intense energy beam, such as a laser; (2) *compression* of the pellet and fuel driven by the rocketlike blowoff of the surface material; (3) *ignition* of a central fuel core to about 1000–10 000 times liquid D-T density and 100 000 000 °C; (4) *burn* of the remaining compressed fuel while it is "inertially" confined.

produced when the fuel nuclei collide and bind (fuse) into heavier species, as depicted in Fig. 2 for the two heavy-hydrogen isotopes, deuterium (D) and tritium (T). Fusion energy is the result of the final mass being less than that of the sum of the lighter fuel components; mass is converted to energy. "Thermonuclear ignition" occurs when the energy released from the fusion reactions supplies enough heat to initiate fusion in the surrounding cold compressed fuel. This forms a thermonuclear "burn front" that rapidly propagates outward throughout the remaining fuel. In a small fraction of a nanosecond, before the pellet has time to disassemble, much of the pellet fuel undergoes fusion releasing a large energy burst, a small explosion, with an energy yield over 100 times higher than was initially applied to the pellet. In most applications, this process is repeated over and over again.

Although the ICF concept is simple, the execution has proved to be difficult because of the extreme conditions that need to be satisfied. The driver beams must be very powerful, between 100 and 1000 TW. For reference, the total world's instantaneous electric generation capacity is about 1 TW. At these intensities pressures over 1000 times that of the space shuttle's boosters are applied to the ICF shell. The shell undergoes several trillion *g*'s acceleration to speeds over 350 km/s (about 1000 times faster than a supersonic transport plane) in just a few tenths of billionths of a second. The compressed pellet core will reach about one trillion atmospheres pressure. As incredible as these numbers seem, many have been attained already and others are within sight.

If inertial fusion is perfected, then it may provide a virtually limitless source of energy in the mid-21st century. Energy from the fusion microexplosions is converted into heat for electric power and process heat production in a power plant reactor. Energetic fusion neutrons can break chemical bonds for synthetic fuel production as well as being used to breed tritium fusion fuel, fissile fuel, and radioisotopes. ICF has important defense applications to test hardness of equipment. Some people have even suggested that ICF could someday be used for space-craft propulsion. Spinoff applications and scientific advances have already emerged in such diverse fields as

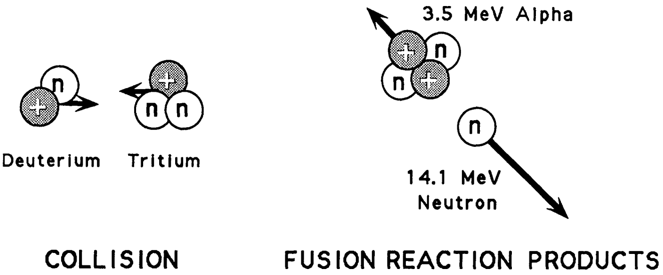

FIG. 2. Fusion reaction of deuterium and tritium. The 17.6-MeV energy release in the D-T fusion reaction is split between an alpha particle (helium nucleus) and a neutron.

x-ray lasers, x-ray lithography, astrophysics, space physics, innovative particle accelerator concepts, materials research, atomic physics, and ultrahigh-speed diagnostic instrumentation.

Controlled fusion is an attractive option for electric power production for a multitude of reasons. First, one of the best thermonuclear fuels, deuterium, is a plentiful constituent of ordinary water. Although common water is predominantly H_2O, the natural isotopic abundance of deuterium to hydrogen is 1 part in 6700. There is enough deuterium fuel in sea water to last several million years. Second, the energy concentration of thermonuclear fuel is high (about 3.45×10^{11} joules per gram for D-D reactions). There is no need for vast arrays of fuel storage tanks. A gallon of water contains about 1/8 gram of deuterium, the equivalent energy of about 300 gallons of gasoline. The total annual fuel for a 1000-MWe power plant, about 15 000 kg, could be carried in one truck. Third, fusion, being a nuclear process, emits no carbon dioxide to contribute to global warming or atmospheric pollutants. Fourth, universally available fuel reduces the impact of flukes of geographic fuel deposits on world politics and economics and acts as a stabilizing effect. Fifth, fusion is relatively safe. Even though fusion is a nuclear process and uses radioactive materials, its waste and accident hazard potential are much lower than those of fission plants.

Any future energy source must be economically competitive to be adopted. Economic analyses of fusion plant designs indicate that power costs are comparable to conventional and fission sources. Capital costs for fusion plants are likely to be higher, because of the complexity of fusion systems, but fuel and environmental costs should be lower. Much of the "hidden costs" of energy, such as distributed environmental effects (e.g., acid rain and CO_2 accumulation), individual health costs (e.g., cancers from radon and other emissions from coal burning), and other energy use costs ignored in the usual accounting, estimated to be about $\$500 \times 10^9$ a year (Hubbard, 1991), would be eliminated with fusion.

If fusion is so wonderful, why do we not have any operating fusion plants yet? The answer, unfortunately, is that the scientific and technical challenges encountered in the quest for controlled fusion have turned out to be among the most difficult undertaken by mankind, and it will be several decades before fusion can be commercialized.

Two vastly different approaches are currently being pursued to harness fusion for power production: magnetic fusion energy (MFE) and inertial confinement fusion (ICF). MFE, the older approach, began in the 1950s. In the MFE approach, a low-density thermonuclear fuel is contained and heated to thermonuclear temperatures in large magnetic "bottles" for long periods of time. The ICF approach was conceived in the 1960s. In contrast to MFE, ICF attempts to fuse very dense fuel during brief periods.

1. HISTORY

Fusion research began with the realization that it was the process that generated the sun's energy. Before this, there was a long standing dilemma: If the solar energy flux is produced by chemical reactions, such as combustion, then the sun could produce energy for only a few thousand years; thus, a much more efficient process had to be responsible. In the 1920s, Arthur Eddington conjectured that mass was being converted into energy, probably by a fusion process. This was not accepted initially because the solar interior was thought to have too low a temperature for sufficient nuclear fusion reactions to occur. Then, in 1928, George Gamow realized that nuclei can "tunnel through" the potential barrier caused by their mutual electrostatic repulsion at low temperatures. In 1931 Hans Bethe worked out the complex cycle of fusion reactions of the inertially (gravitationally) held material in stellar interiors. Solar "inertial" fusion is the Earth's oldest and most benign source of energy. We only intercept a minute fraction of the sun's huge fusion energy production (3.9×10^{26} Watts, from a consumption rate of 6.2×10^{11} kg/s of hydrogen) on Earth. Even so, sunlight, one way or another, generates all the Earth's renewable energy reserves: it drives the wind and the ocean currents, and fosters the growth of plants and trees that, in turn, are burned directly or in the form of petroleum and coal. However, it is difficult to replicate solar inertial fusion conditions on earth, since we do not have the advantage of having the sun's huge gravitational pull to contain the hot thermonuclear fuel indefinitely.

Man has succeeded in producing substantial fusion energy in only one way to date, by the explosion of a thermonuclear (hydrogen) bomb. A key principle of an H-bomb's operation is the use of the inertia of the device's mass to contain the thermonuclear material and delay it from flying apart before the bulk of it can undergo fusion. This is a formidable task since the bomb's thermonuclear fuel must be simultaneously heated to thermonuclear temperature (above a few kilovolts) and compressed to high density (well above that of normal solids). The inertia must resist pressures comparable to those found in stellar cores. The energy source used to drive the hydrogen bomb's fuel to thermonuclear conditions is an atomic (fission) bomb. The ICF concept also relies on inertially held fuel, similar to a thermonuclear bomb, but on a much smaller scale, without the use of a fission driver, and in a safe, controlled manner.

Research in controlled inertial fusion began in earnest in the early 1960s, shortly after the invention of the laser. Researchers (Nuckolls *et al.*, 1972) realized in about 1961 that immense pressures could be applied by using intense laser light to compress small pellets containing thermonuclear fuel analogously to a fusion bomb. Nuckolls introduced the idea of temporally shaping the laser pulse to drive implosions ablatively to densities over 1000 times liquid density. The ICF program was totally classified at this time because of its connection with the fusion bomb program and, perhaps, because achievement seemed imminent. These calculations led to a classified experimental laser fusion program at Lawrence Livermore National Laboratory (LLNL) in 1963. There were also a number of independent theory and experimental programs that sprang up throughout the world in the mid to late 1960s that were on a similar track. Readers interested in a more complete history should see the references.

Although ICF has similarities to its larger weapon cousin, it differs in important regards. ICF pellet explosions must be small enough to be contained safely in a reactor chamber; one milligram of D-T fuel burned completely yields fusion energy with about 340 MJ, the equivalent of 160 pounds of high explosive. The practical limit confinable in a power reactor is a 500–1000 MJ yield. It turns out that achieving fusion yield on a miniaturized scale is much more difficult a task than making a nuclear bomb, and the two are not as closely related as initially thought. The first major declassification of the program occurred in 1972 with the paper of Nuckolls *et al.*

However, impressive progress is being made and scientists are optimistic about achieving ICF. The remainder of this article will describe these current research trends.

2. PRINCIPLES OF CONTROLLED FUSION

2.1 Nuclear Fusion Process

Nuclear fusion is the result of the collision and binding of two or more lighter nuclei. The D-T fusion process, illustrated in Fig. 2, is exothermic because the final total mass is less than that of the original deuterium and tritium, even though a heavier alpha particle is formed in the process. The energy released, E_r, is related to the lost mass Δm and the speed of light by Einstein's well-known relation $E_r = \Delta mc^2$. The 17.59-MeV excess energy from the D-T mass loss appears as kinetic energy of the products, a 3.5-MeV alpha particle and a 14.1-MeV neutron. Fusion can be thought of as the inverse of the more familiar nuclear fission process, which is the *splitting* of a heavy nucleus into two or more lighter parts. Fusion is exothermic for light elements; fission releases energy when heavy elements, such as uranium, split. The colliding nuclei must be very energetic to overcome the "Coulomb barrier" between them, caused by their mutual electrostatic repulsion, to get close enough for their nuclear forces to act and make them fuse. Singly charged hydrogen isotopes require about 200-keV directed energy to overcome the Coulomb barrier; more highly charged species require even greater directed energy. Overcoming the Coulomb barrier is a very stiff requirement. The good news is that a deuterium-tritium fuel thermal temperature of only $(50\text{–}100)\times 10^6$ °C (i.e., 5–10 keV) has a sufficient fraction of nuclei in the high-energy tail of its distribution function to be useful for fusion energy production. The adjective "thermonuclear" modifying fusion refers to the use of such a "thermal" fuel distribution. The bad news, of course, is that these temperatures are still exceedingly high and no material can contain them. At the temperatures required for thermonuclear fusion, all matter is in the plasma state, that is, ionized. Plasmas are made up of charged particles and respond in a complex manner to electric and magnetic fields in addition to the usual hydrodynamic forces. In fact, a large fraction of the obstacles to perfecting fusion power lies in the difficulty of controlling the response of the plasma fuel to the strong long-range collective electrical forces introduced by its own charged-particle nature.

2.2 Fusion Fuels: Temperature Requirement

D-T is the most frequently considered fuel mixture for controlled fusion energy production because it has the lowest temperature threshold requirement, high fusion reaction rate, and high Q value, the energy yield per reaction. The D-T fusion cross section has a resonance near zero energy and a peak of about 5 barns (5×10^{-24} cm^2) at 125 keV. Although tritium is not naturally plentiful, since it is unstable with about a 13-year half-life, it can be bred in the lithium thermal blanket of a fusion reactor. Other fusion reactions require higher temperatures and have lower reaction rates. Table 1 lists several fusion reactions that are candidates for energy production. Doubtless, the first fusion reactors will operate on D-T fuel, but so-called advanced fuels, such as the ones using deuterium (D-D and D-^{3}He) and proton reactions, have reactor advantages. D-D reactions do not require tritium breeding. The proton-fusion reaction products are neutronless. D-^{3}He is attractive because there are no radioactive reaction products and the specific yield is high. Unfortunately, the supply of ^{3}He on earth may be extremely small. However, ^{3}He is plentiful on the moon's surface, where it might be mined, and recently it was found in high concentration in the sea water near Pacific Ocean bottom thermal vents.

2.3 The Lawson Criterion: Fuel Density-Confinement Requirement

Even when the plasma fuel is hot enough to overcome the Coulomb barrier, the probability of two nuclei being on a collision path is quite small. The fuel must therefore be held together long enough for most of it to fuse. The containment requirement is given by Lawson's criterion, which for equal mixtures of D-T fuel above 10 keV temperature is

$$n\tau \geqslant 10^{20}\ \mathrm{s\,m}^{-3}. \tag{1}$$

The fuel number-density confinement-time product $n\tau$ must exceed the value of the right-hand side of Eq. (1), the Lawson number; this is basically a trade-off between density and confinement time. MFE and ICF attempt to satisfy Lawson's criterion in diametrically opposite ways. Namely, for MFE, low-density fuel ($n > 10^{20}$ m^{-3}, about 10^{-5} of atmospheric density) is heated and contained for long periods ($\tau > 1$ s) in magnetic bottles;

Table 1. Thermonuclear reactions considered for controlled fusion. D-T will be the fusion fuel in the earliest reactors since it has the lowest threshold temperature and ρR requirements, and high energy release Q. In general, "advanced fuels" have stringent requirements and lower yield, although they offer other advantages. ^{11}B-p fusion is non-neutronic, and has no radioactive byproducts, and it is conceivable that electricity could be generated directly from its charged reaction products without a thermal conversion stage. D-^{3}He offers similar advantages to ^{11}B-p, and has a lower threshold and high Q, but ^{3}He has a high temperature threshold for fusion and may be extremely rare on Earth. The energy released to each product from the fusion reactions shown in column 2 is in parentheses in MeV; n stands for neutron, p stands for proton, and notation ^{A}He refers to the isotope of He with atomic number A.

Fuel	Fusion reaction	Q (MeV)	T (keV)	ρR (g/cm^2)
D, T	^{4}He(3.5)+n(14.1)	17.6	5–10	2–5
D, D	^{3}He(0.82)+n(2.45) T(1.01)+p(3.02)	3.65	20–50	10–20
^{11}B, p	3 ^{4}He(8.68) ^{4}He+Be(8.59)	8.68	100–400	50–500
D, ^{3}He	^{4}He(3.6)+p(14.7)	18.3	~50	

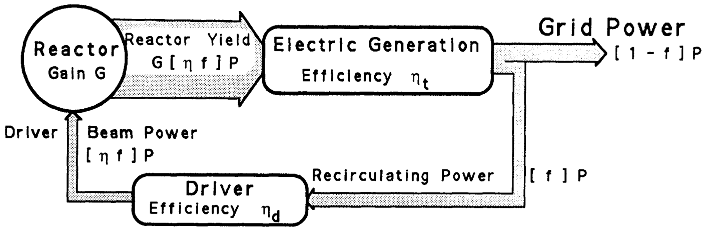

FIG. 3. Power flow in an ICF power station. Power supplied to the grid is the reactor output less the portion wasted in the thermal portion of the power plant, heat exchanges, turbines, generators, etc. (typically 30%–40%) and the fraction *f* needed to run the driver and other power station systems (<25%).

for ICF, high-density fuel ($n > 10^{31}$ m^{-3}) is produced for ultrashort "inertial" times ($\tau < 10^{-10}$ s).

The Lawson criterion has a more convenient form for the inertial fusion case, i.e., in terms of the fuel mass-density radius product, ρR; it is

$$\rho R > 3 \text{ g/cm}^2. \qquad (1')$$

Equation (1′) follows from Eq. (1) by noting that number and mass density are related by $n = \rho / m_{\text{ion}}$ and that the dissembly time of a sphere of radius R, the equivalent confinement time for ICF, is $\tau \approx R/4c_s$, where c_s is the speed of sound in the fuel. Actually, the requirement for ICF, Eqs. (1′) and (1), is about an order of magnitude higher than the MFE equivalent because a much higher fraction (~30%) of the available fuel needs to be burned in a pellet explosion compared to a marginal MFE reactor. The ρR criterion dictates that the D-T fuel must be compressed to over 1000 times its normal liquid density of $\rho_{\text{DT}} = 0.2$ gm/cc. This requirement will be discussed in more detail later.

2.4 Power-Reactor System Requirements

For a fusion power plant to be economically practical, its output must exceed all of its own operating needs, including inefficiencies, by a large margin. The recirculating power fraction needed to run the plant should remain below 25% for economic viability. Figure 3 shows a block diagram of the power flow in an ICF power reactor. Assuming the power plant has 35% thermal efficiency, it is easy to estimate the minimum required pellet gain, G, i.e., pellet energy yield divided by its absorbed driver energy. In terms of the driver efficiency (η_d) of converting its operating power into a useful beam, the criterion is

$$\eta_d G > 10. \qquad (2)$$

Equation (2) dictates a pellet gain requirement, for example, of $G > 100$ for a 10% efficient driver. Laser drivers under consideration have efficiencies of <10% and would require gains over 100, whereas ion-beam accelerators with projected efficiencies of 25%–35% could get by with pellet gains as low as 40 or 30. A great deal of current ICF research effort focuses on determining whether this gain-efficiency product can be met, and what driver-pellet combination is best. It should be pointed out that most other ICF applications have less stringent requirements than power production.

3. ELEMENTARY DESCRIPTION OF ICF PHYSICS

A good description of the basic physics involved in inertial fusion can be made from elementary considerations. We go through the basic ICF principles below.

3.1 The Need for High Pellet Compression

As noted earlier, limiting the maximum yield of the pellet explosion to 500–1000 MJ or so tells us that we are dealing with at most milligrams of D-T and pellets of millimeter dimensions. A millimeter-radius pellet has an initial D-T fuel $\rho_0 R_0$ of about 0.02 gm/cm^2 assuming, for simplicity, that it is a uniform drop at liquid density ($\rho_{\text{DT}} = 0.2$ gm/cc). The fuel must reach $\rho R > 3$ to satisfy the Lawson criterion, Eq. (1′), a factor of 150 higher than its initial state. Fuel compression is the only solution. An estimate of the final compressed fuel radius needed is made by noting that

$$\frac{\rho R}{\rho_0 R_0} \approx \frac{[m/\frac{4}{3}\pi R^3]R}{[m/\frac{4}{3}\pi R_0^3]R_0} \approx \left(\frac{R_0}{R}\right)^2 \sim 150 \Rightarrow \frac{R_0}{R} \sim 12.$$

Since $\rho/\rho_0 \sim (R_0/R)^3$, a convergence ratio of $R_0/R \sim 12$ corresponds to a final compressed fuel density of order 2000. Detailed computer calculations call for compression between 1000 and 10 000. It is advantageous to strive for compression levels above the minimum. The higher the fuel density, the lower the required driver energy; the higher the fraction of fuel that undergoes fusion reaction, the higher the pellet gain.

3.1.1 Difficulty of Attaining High Pellet Compression. Anyone who has attempted to squeeze and compress solid- or liquid-phase material knows that it requires tremendous pressures because of its lack of compressibility. The minimum specific energy needed to compress cold D-T is approximately the same as for a Fermi-degenerate electron gas, $\mathscr{E}_{\text{Fermi}}$, assuming that the implosion is isentropic, i.e., the fuel is heated only by compressive work. If excess heat, termed "preheat," gets into the fuel during the implosion process then more driver energy is needed. Preheat is caused by energetic particles, radiation, or shock-wave deposition from the driver-pellet interaction. Compression energy $\mathscr{E}_c$ more than a factor of two over the minimum $\mathscr{E}_{\text{Fermi}}$ level begins to be problematic. We can estimate the energy needed to compress an ICF pellet by referring to Table 2. A minimum energy of about 11 kJ per milligram D-T (10^{-3} gm $\times\, \mathscr{E}_{\text{Fermi}}$) is needed to compress the fuel to 1000 times liquid density. Thus, the minimum beam pulse energy is over 100 kJ since less than 10% of the driver energy gets converted into compressive energy. The maximum acceptable driver output is in the range of 5–10 MJ, assuming a pellet gain of 100 and a reactive explosive yield limit of 500—1000 MJ.

Other phenomena can ruin pellet implosion besides preheat. Fuel can squirt out of the fuel core before reaching high density if nonuniformities or pressure imbalances are present, just as Jell-O will ooze between your fingers if squeezed. It is critical that the pressure driving the implosion be applied very symmetrically and uniformly. Any latent nonuniformities are exacerbated by inevitable hydrodynamic instabilities that occur during pellet compression. One particularly troublesome hydrodynamic instability, Rayleigh–Taylor (RT), occurs when high-density fuel is pushed (accelerated) by a much lower density ablation plasma. Uniformity requirements put stringent constraints on the driver, geometry, and implosion approach and will be discussed further later.

3.2 Pellet Gain

Pellet gain G is the ratio of thermonuclear energy yield to the driver energy incident on the pellet assembly (also known as the target capsule), i.e.,

$$G=\frac{E_{\text{out}}}{E_d}=\eta\phi\left(\frac{\mathscr{E}_b}{\mathscr{E}_c+(m_h/m)\mathscr{E}_h}\right). \qquad (3)$$

The expression on the right-hand side of Eq. (3) results from recognizing that the energy yield is a product of the total fuel mass m, the thermonuclear energy released per unit mass $\mathscr{E}_b$, and the fraction of the fuel that undergoes fusion ϕ, i.e., $E_{\text{out}}=\phi m\mathscr{E}_b$. Only a small fraction η of the driver energy couples usefully to the fuel to compress it and to heat a small mass m_h in the ignitor region to thermonuclear burn temperature, i.e., $\eta E_d=m\mathscr{E}_c+m_h\mathscr{E}_h$. The beam-pellet coupling efficiency η includes both reflective beam losses and inefficiency in the rocket ablation process; as mentioned earlier, η is typically about 0.1. It is difficult to achieve a fuel burn-up fraction ϕ greater than 0.3, which limits the coefficient in front of the bracket to only about 0.03. To obtain gains of about 100 then requires fuel gain [the quantity in parentheses in Eq. (3)] over 3000.

The tabulation of $\mathscr{E}_b$, $\mathscr{E}_h$, and $\mathscr{E}_c$ for D-T in Table 2 allows us to estimate the maximum gain expected from an ICF pellet. If *all* the D-T fuel in the pellet is uniformly heated to 5 keV, the best fuel gain that can be expected is less than 600, resulting in an overall pellet gain of only about 20, which is far too small for power plant use. The critical trick, therefore, is to heat only a central core, the ignitor region. The ignitor region should contain the least amount of fuel that can initiate a prop-

Table 2. Characteristic energy densities involved in pellet fusion using D-T fuel.

Burning D-T yield	$\mathscr{E}_b=3.4\times10^{11}$ J/g
Heat to burn-temperature	$\mathscr{E}_h=5.8\times10^{8}$ J/g (@ 5 keV)
Energy to compress fuel	$\mathscr{E}_c>\mathscr{E}_{\text{Fermi}}=1.1\times10^{7}$ J/g (@$1000\times n_{\text{liq}}$) (note $\mathscr{E}_{\text{Fermi}}\propto n^{2/3}$).

agating fusion burn throughout the remaining cold fuel. This technique of heating only a fuel core to ignition is called "hot-spot ignition."

3.3 Ignition

Ignition occurs when the hot-core (ignitor) radius R_c is greater than an α-particle mean free path R_α, where R_α is given by

$$\rho R_\alpha \approx 0.3 \text{ g/cm}^2 \quad \text{for} \quad T_c = 10 \text{ keV}. \qquad (4)$$

About 20% of the ignitor fusion yield is in α particles that, in turn, can heat about six times the original ignitor mass of cold fuel up to fusion temperature. This process cascades and a nuclear fusion "burn front" propagates outward into the dense cold fuel. The ρR Lawson criterion, Eq. (1′), for the ignitor is an order of magnitude smaller than for the pellet as a whole. There is a great premium on achieving as high an ignitor density as feasible because its mass, and hence energy requirement, decreases dramatically, viz., $m_h = \rho R_\alpha^3 \sim (\rho R_\alpha)^3/\rho^2$. The upper limit fuel gain of 30 000 ($\sim \mathcal{E}_b/\mathcal{E}_{\text{Fermi}}$), corresponding to an overall simple pellet-gain limit of 1000, is not really attainable. This is because fuel is heated in the ignitor, the ignitor region will be larger than the theoretical minimum because of asymmetries and mixing of cold and hot fuel at its boundary, and the actual energy required to compress the fuel, $\mathcal{E}_c$, is higher than the minimum Fermi-degenerate level, $\mathcal{E}_{\text{Fermi}}$.

The pellet gain needed for power production lies between 30 and 1000. The lower limit assumes the driver has a high efficiency ($\sim$30%), such as might be attainable from an ion-beam accelerator; the upper limit is near the theoretical limit for a simple ICF pellet. A gain of 100–150 would be sufficient with a 10% efficient driver and is the generally accepted program goal. Success is not assured even though the pellet gain needed is below the ideal by an order of magnitude. The pellet implosion process is extraordinarily complex because of the extremes of density and temperature conditions created and highly nonlinear interactions of the driver beam with the pellet. Close attention must be paid to optimizing the driver coupling efficiency and implosion physics compatibility. Although this is a very challenging task, steady and impressive progress is being made.

Figure 4 shows a generic ICF gain curve. For driver energies below that required for hot-spot ignition, the yield is from volumetric fusion of fuel nuclei in the tail of the thermal distribution. A driver energy in the ignition region satisfies Eq. (4) and propagating burn begins; the thermonuclear yield rapidly increases forming an "ignition cliff." Finally, for driver energies above the minimum ignition level, the gain increase becomes proportional to the additional fuel mass (and driver energy). Energy application requires a driver-efficiency–gain product $\eta_d G$ over 10 to overcome the inefficiencies of the implosion process and power-plant thermal cycle, as noted earlier; this requirement is shown as a hatched area on the diagram. In addition, 500–1000 MJ is the maximum yield that can be reasonably confined in a reactor; hence, the practical driver pulse limit is between 5 and 10 MJ.

4. APPROACHES TO ACHIEVEMENT OF INERTIAL FUSION

Two approaches to achieve high-gain implosions are being pursued, namely,

1. direct drive, in which the driver beam strikes the pellet surface directly, and
2. indirect drive (also known as the "classified approach" or x-ray drive), in which the beam energy is first converted to x rays in a *Hohlraum*; it is the x rays that then strike and implode the pellet.

The direct-drive and indirect-drive ideas are sketched in Fig. 5.

Each approach has advantages and limitations, and neither has been proven as yet to be suitable (or unsuitable) for achieving high-gain controlled fusion. Direct drive has advantages of simplicity and potentially higher efficiency, but has stringent driver illumination symmetry requirements. Driver-beam uniformity requirements are reduced in the indirect-drive approach, but its efficiency is likely to be lower as a result of the extra x-ray conversion step. Excellent progress is being made in developing both approaches and it is premature to choose one over the other at this time. Both approaches must ultimately achieve similar pellet conditions.

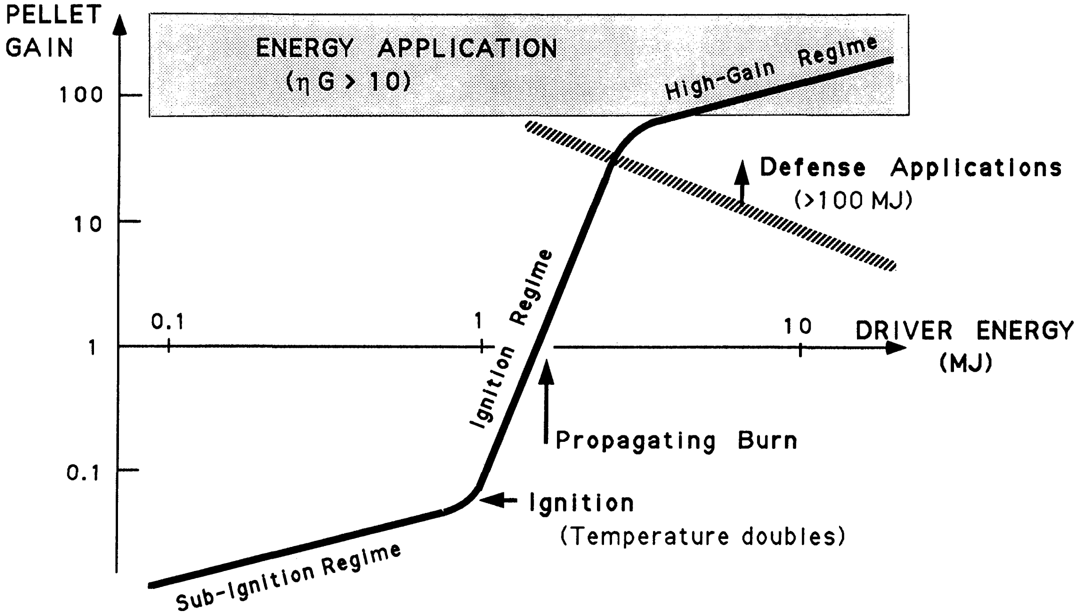

FIG. 4. Gain curve for an ICF pellet. Fusion yield gradually increases with driver energy until ignition conditions are met in the central core. Above ignition, fusion products from the core ignite surrounding fuel and the gain rapidly increased; this is the ignition "cliff." At still higher driver energy, the gain increases in proportion to the additional fuel mass.

4.1 Critical Issues of High-Gain Inertial Fusion

High-gain pellet requirements for energy production are listed in Table 3. The same basic conditions apply to both direct and indirect drives, but sometimes in different manifestations. The first three requirements are common to defense and energy implementations, while the last two requirements are mainly energy application concerns. Each requirement is briefly discussed in turn.

4.1.1 Good Driver-Target Interaction Physics. Good driver-beam absorption in the plasma formed outside the pellet surface is important. The size (and therefore cost) of these sophisticated drivers increases rapidly with energy. Recall that the driver efficiency needed to meet the $\eta_d G > 10$ criterion is about 10%, and so there is little leeway for additional losses. Additionally, beam energy must be absorbed properly to generate the high ablation pressures needed to implode the pellet efficiently. Ablation plasma with a thermal energy distribution is the best. Energetic (also called "fast" or "suprathermal") electrons generated in some beam-target interaction processes can penetrate and deposit energy into the dense fuel. If too many suprathermal electrons are present they can heat the fuel

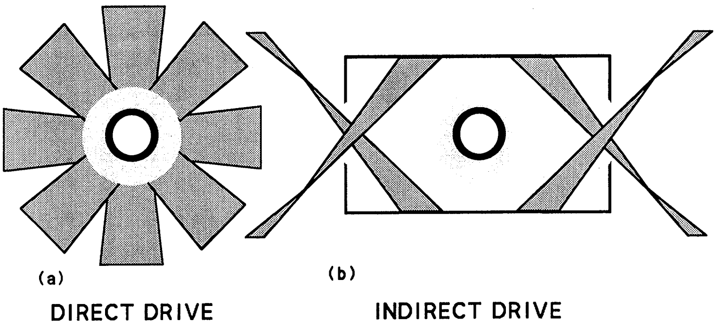

FIG. 5. Comparison of direct- and indirect-drive ICF approaches. (a) In the direct-drive method, the drive beams focus onto the pellet surface to drive the implosion. (b) In contrast, in the indirect-drive approach, the driver beams create x rays in a *Hohlraum* which, in turn, strike the pellet surface to drive the implosion.

Table 3. Critical issues of inertial fusion: approximate conditions that need to be satisfied for successful inertial-fusion energy production.

Good driver-target interaction physics	
High deposition of driver energy onto the pellet	$75\% < \eta_d < 100\%$
Minimal preheating of the cold thermonuclear fuel	$E_{\text{preheat}} < 1\%\ E_d$
High ablation pressure and hydrodynamic efficiency	$P > 10$ Mbar; $\eta > 10\%$
High symmetry of driver-beam illumination	
Uniform pressure for pellet implosion	$\Delta P/P < 1\%$
Hydrodynamic Implosion Stability	
Achieve high pellet compression (densities)	$n_c > 1000 n_{\text{liquid}}$
Minimal mix of hot and cold fuel or ablator	$m_{\text{mix}} < (\text{few } \%)\ m_h$
Robust pellet design	
Low driver energy for ignition and gain	$E_d < 10$ MJ
High-gain potential	$G \geqslant 100$
Reactor compatible system	
Efficient driver	$\eta_d > 10\%$–50%
Repeatable driver	$f_{\text{rep}} \sim 5$–10 Hz
Reliable and reactor compatible driver	Millions of shots
Economically competitive	cents/kWh

prematurely (preheat). The higher back pressures caused by preheated fuel prevent the high compression needed for high-gain explosion. Just a percent or so of the driver energy in suprathermal electrons can spoil the process. Energetic ions can be accelerated in the absorption process, too; these are undesirable because they transmit momentum to the pellet poorly (lower the pressure) and they waste driver energy.

Virtually all ICF pellet implosion research in the past, and in the foreseeable future, uses laser drivers. This is because they alone can presently generate the high irradiances needed for pellet implosion.

Laser light cannot penetrate beyond the so-called critical density, n_c, in the plasma surrounding the pellet shell, as illustrated in Fig. 6(a). The critical density is well below solid density; light is absorbed in this "underdense" ablation plasma by inverse bremsstrahlung and other processes. The critical density is the density at which the incoming light frequency equals the local plasma frequency. The plasma frequency is the natural oscillation rate of electron waves in a plasma and is given numerically by $f_{\text{pe}} = 9 \times 10^3 n_e^{1/2}$ Hz, where n_e is the electron density in electrons/cm^3. For 1-μm wavelength laser light the critical density is 10^{21} electrons/cm^3. The critical density scales with light wavelength like λ^{-2}; hence, the shorter the laser wavelength, the higher the density to which light can penetrate. Energy absorbed in the underdense plasma flows up the density profile through heat conduction to the pellet surface, where it ablates shell material that in turn applies pressure to drive the shell inward. The closer the absorption region is to the ablation surface, the higher the hydrodynamic efficiency, the fraction of the absorbed energy converted into kinetic energy of the imploding shell and fuel.

Poor laser absorption and suprathermal particle generation have been major problem until recently. Normally, light travels up the plasma density gradient towards the target, where it is absorbed by a process called inverse bremsstrahlung. In the inverse bremsstrahlung process, electrons absorb photons as they are jiggled by the light wave's electric field near ions; the energy taken up by the electrons collisionally couples to the ions. It is the inverse process to ordinary bremsstrahlung, photon generation due to electrons scattering from ions. The higher the critical density (shorter wavelength light), the more efficient is the absorption process. Unabsorbed light at the critical density reflects back towards the laser.

At the very high light intensities needed for ICF, the interaction of the light with the target plasma can also exhibit some fascinating, but usually deleterious, processes. For laser irra-

FIG. 6. Interaction and absorption of laser light. (a) Regions in which laser light interaction processes occur in the underdense ablation plasma. The underdense plasma extends up to the critical density, n_c (10^{21} electrons/cm^3 for 1.06-μm Nd-laser light), about a factor of 50 times less dense than solid D-T. (b) Mechanism responsible for the stimulated Brillouin scatter (SBS) instability. SBS is capable of reflecting almost all the incident light before it is absorbed, a fascinating but very undesirable effect.

diance-(wavelength)^2 products $I\lambda^2$ above a few times 10^{13} W μm^2/cm^2, the light can modify the plasma density profile by pushing plasma out of its high-intensity electric field regions through a process called ponderomotive force. Ponderomotive force in a plasma is analogous to vacuum radiation pressure, but is much stronger for a given wave intensity. There are hosts of plasma instabilities that are driven by ponderomotive-force–induced density changes. Ponderomotive force effects tend to be self-aggravating and to grow to large amplitudes, and can become very disruptive. For instance, a fascinating process known as stimulated Brillouin scatter (SBS) can reflect over 80% of the incident 1-μm (Nd-laser) light before it even reaches the absorption layer!

Stimulated Brillouin scatter instability is in a class of nonlinear phenomena called parametric instabilities. Parametric processes involve the interaction of a large-amplitude wave, often called the pump, with two or more other waves in the system. Typically, density ripples form in the plasma from the interference of the incident and reflected waves, as illustrated in Fig. 6(b). It is the ponderomotive force that pushes plasma away at the peaks of the interference pattern to create the ripple. The density ripple acts much like a Bragg reflection grating with just the right periodicity (half the incident laser wavelength) to backscatter more of the incident wave; this in turn further deepens the density ripple, causing more scatter, and so on. The three waves involved are the incident (i), the reflected (r), and the wave caused by the density ripple, commonly called the beat (b) wave. The three waves must have frequency and wave numbers that conserve energy and momentum; this is equivalent to satisfying the following relations:

$\omega_i = \omega_r + \omega_b$, energy conservation

$k_i = k_r + k_b$, momentum conservation.

The parametric processes are particularly strong when all three waves are normal modes (resonant, natural waves) of the plasma. Since plasma can support many types of waves, there are several possible parametric instabilities. Parametric processes generally require the incident intensity to be above some "threshold" value to become unstable. The threshold intensity occurs at the point where the parametric growth of the secondary waves just exceeds their natural damping rates; for 1-μm light, threshold values are in the same range as intensities needed for pellet implosion.

Underdense parametric instabilities important in the laser fusion context include the stimulated Brillouin scatter instability (SBS), in which the incident and reflected electromagnetic waves interfere to form a plasma ion acoustic (sound) wave; the stimulated Raman instability (SRS), in which the beat wave is an electron plasma wave; and the two-plasmon decay (TPD) instability, in which incident light decays into two plasma electron waves at one quarter of the critical density. These underdense instabilities tend to reflect the light and generate very energetic, "suprathermal," electrons.

Light not reflected in the underdense plasma can still cause trouble. Intense laser light reaching the critical density region can steepen it by the same ponderomotive force phenomena. The critical-surface steepening in turn suppresses inverse bremsstrahlung and promotes undesirable absorption processes, such as resonant absorption and parametric-decay instability. Resonant absorption and parametric-decay absorption are less efficient than inverse bremsstrahlung and generate undesirable suprathermal populations of electrons and ions. Figure 6(a) schematically indicates where many of these processes occur in the density profile leading up to the target surface. Most parametric phenomena get worse in larger (more reactorlike) plasmas. Since laser irradiance above 10^{14} W/cm^2 is needed to implode pellets, parametric instabilities could be very strong and disruptive for the multimillimeter-sized plasmas characteristic of ICF reactor pellets.

The laser-light interaction and absorption problems discussed above are now largely resolved as a result of extensive theoretical and experimental investigation by the laser fusion community. One way to alleviate problems is to avoid pellet designs that require highly shaped pulses with intense peaks ($>10^{16}$ W/cm^2) that were prevalent in the early phases of the ICF program. However, it is now clear that the best solution is to use short-wavelength laser light. Figure 7, a plot of absorption fraction versus laser irradiance for 1-μm laser light and its second, third, and fourth harmonics, shows the benefits of short-wavelength light clearly. This finding rules out the use of CO_2 lasers ($\lambda \approx 10$ μm), HF or DF lasers ($\lambda \approx 2$–3 μm), and iodine lasers ($\lambda \approx 1.3$ μm), which were once candidate drivers. It also rules out using the fundamental wavelength of Nd-glass lasers ($\lambda \approx 1$ μm) and probably even its second harmonic ($\lambda \approx 0.5$

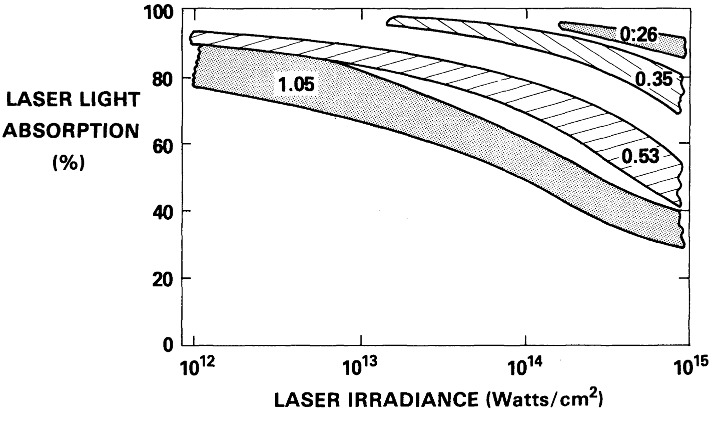

FIG. 7. Light absorption decreases with increasing laser intensity. Low absorption is due, in large part, to parametric instabilities. Note that absorption gets better with shorter-wavelength (higher-frequency) laser light.

μm), which have been the most common research drivers through the 1980s. Fortunately, Nd-laser light can be converted to its third or even fourth harmonic efficiently ($\sim$70%). Short-wavelength light is used almost exclusively in most current research programs. The KrF gas laser, which operates at $\lambda \approx 0.25$ μm and has both a favorable wavelength and the potential of reasonable efficiency ($\sim$10%), is currently being developed for ICF. Finally, even though it appears that the major laser-target interaction issues are settled, researchers have, more frequently than not, been confronted with unexpected results whenever new parameter regimes are explored. Therefore, laser interaction issues could well resurface when the next generation of experiments produce more reactorlike conditions.

Absorption processes for light- and heavy-ion beams are thought to be more straightforward and inherently benign compared to those of laser light. Initial experiments on stopping distances of ions in solids and plasma support this expectation. However, no particle-beam experiments have been performed at parameters even close to those required for ICF. One open question is whether particle beams are compatible with the direct-drive approach. This is because particle beams tend to deposit energy deeper into solid-density target material than laser ablation fronts and it is not yet clear whether high-gain direct-drive targets can accommodate this.

4.1.2 High Symmetry of Driver-Beam Illumination. Pellets need to implode to about $\frac{1}{15}$ of their initial radius to compress their fuel to several thousand times liquid density. Before irradiation, most pellet shell designs have wall thicknesses, ΔR_0, between about $\frac{1}{10}$ and $\frac{1}{50}$ of their radius R_0; i.e., have "initial aspect ratios," $R_0/\Delta R_0$, between 10 and 50. The shells become several times thinner than their initial values when they are subjected to the pressure and ablation of the intense driver irradiation. This "in-flight aspect ratio," $R/\Delta R$, which is typically in the range of 30–100, is the relevant quantity for determining implosion uniformity requirements and Rayleigh–Taylor instability susceptibility. During implosion, the shells must traverse distances of about 100 times their own thickness uniformly without breaking. Simple kinematics dictates that pressure nonuniformities over the pellet surface be no worse than about 1%. This exceptional pressure uniformity requirement translates into almost the same degree of uniformity for the incident-beam irradiance. This is especially true in the direct-drive approach with short-wavelength lasers where absorption occurs close to the ablation surface. Transmittal of beam nonuniformities to the pellet is the one disadvantage of short-wavelength light. Typical high-powered lasers tend to be rather nonuniform because of the very high amplification they undergo, even if multiple beams overlap on the target. Fortunately, there has been spectacular progress made in solving the driver uniformity problems. A variety of beam smoothing and balancing techniques were developed which can give pellet illuminations of the required quality. Smoothing methods are described later in this article in Sec. 5.1.

Breakthroughs in beam smoothing have largely removed the principal disadvantage of the direct-drive compared to the indirect-drive approach. Since the driver beams do not strike the pellet surface directly in the indirect approach, but rather their generated x rays, beam uniformity requirements are reduced and more driver flexibility is allowed.

4.1.3 Hydrodynamic Implosion Stability. Hydrodynamic stability of the pellet during implosion is closely related to the beam-symmetry issue discussed above. Both phenomena affect the ability to maintain a spherical pellet implosion. As discussed above, the beam needs to have about 1% or better uniformity. However, even with perfectly smooth illumination small unavoidable imperfections in the pellet itself will grow in amplitude through hydrodynamic instability.

Hydrodynamic instability, specifically the Rayleigh–Taylor (RT) instability, occurs because of a system's tendency to go to its minimum energy state. For instance, if a glass of water is turned upside down and the water-air surface is *perfectly* smooth, the 14-lb/in.^{2} air pressure is sufficient to hold the water in the glass. However, the slightest ripple on the water surface grows exponentially through Rayleigh–Taylor instability and the water sloshes out onto the floor, the lower-energy state. Rayleigh–Taylor instability can occur when a low-density fluid supports or accelerates a higher-density fluid.

Pellet implosions have two regions where hydrodynamic instability is important. Pressure from the low-density ablation plasma accelerates the dense pellet shell and fuel inwards and, hence, this interface is unstable. Hydrodynamic instability occurring near the ablation surface can ruin the implosion by breaking up the pellet shell before achievement of maximum compression. The pellet implosion is also susceptible to RT instability at the interface between the hot ignitor and the surrounding cold denser fuel towards the end of the compression process. The amplitude of RT growth during the linear phase is

$$A(t)=A_0 \exp(\gamma_{\mathrm{RT}} t), \qquad (5)$$

where the Rayleigh–Taylor growth rate, γ_{RT}, is

$$\gamma_{\mathrm{RT}}=\alpha(k_p g)^{1/2} \qquad (6)$$

for two fluids separated by a sharp interface undergoing an acceleration of magnitude g. The wave number of the perturbation, k_p, is related to the perturbation wavelength λ_p by $k_p=2\pi/\lambda_p$. The Attwood number α is unity for a large density jump between these two fluids.

The most dangerous RT wavelength for ICF pellet implosion near the ablation surface is $\lambda_p \sim \Delta R$, the thickness of the pellet shell. The acceleration g is approximated by using $R=gt^2/2$, and, hence, the number of growth e-foldings of this most dangerous mode, $N_{m\mathrm{RT}} = \gamma_{\mathrm{RT}} t$, is approximately

$$N_{m\mathrm{RT}} \approx (2\pi R/\Delta R)^{1/2}. \qquad (7)$$

Rayleigh–Taylor instability is a very serious problem, as can be seen by noting, for example, that ripples on a shell with an in-flight aspect ratio $R/\Delta R$ of 100 will grow 25 e-folds (or 7.7×10^{10} times) in amplitude, clearly unacceptably large.

The pellet design must keep RT growth at an acceptable level. This is a difficult, but not impossible, task. Fortunately, there are clever ways to reduce the instability growth—for instance, use of thicker shells to increase ΔR, accelerating the shell for the first half of its implosion phase and letting it coast the rest of the way to cut R in half, shaping the beam pulse power in time, or reducing the steepness of the ablation region, as well as other techniques. Most ICF researchers think that by careful design $N_{m\mathrm{RT}}$ can be kept below 7 or 8; this is an acceptable level provided that pellet surface imperfections are 100 Å or less. Mass producing pellets with close to perfect smoothness is a challenge, but current state of the art is close to achieving this. Understanding hydrodynamic growth in ICF targets and devising techniques to reduce it to acceptable levels are, perhaps, the most challenging topics in current ICF research.

The interface between the hot fuel ignitor core and the surrounding dense cold fuel is also susceptible to Rayleigh–Taylor instability because the hot ignitor core is typically less dense than the cold fuel. A deleterious effect that can result is that some of the cold fuel gets mixed into the hot ignitor region, thereby cooling it below threshold for efficient thermonuclear burn. If this happens then a much bigger and more expensive driver is required to heat the ignitor and the gain of the pellet decreases.

Researchers think that there are high-gain pellet designs that overcome the hydrodynamic instabilities described here. But the uncertainties are large enough that the Rayleigh–Taylor physics underpinnings and pellet designs need thorough testing. The next major ICF experimental facility will explore these ignition-regime physics issues.

4.1.4 Robust Pellet Design. Pellets for an ICF commercial power plant must have gain of order 100. In addition, they must work with driver pulses below 10-MJ energy, and they need to be robust so that they work under less than ideal conditions. Pellets must work one after another, several times each second, millions of times per year even though being injected several meters into position in a reactor chamber, where the reactor environment is harsh, where there is some variance of driver performance from shot to shot, and where alignment may not be perfect.

4.1.5 Reactor-Compatible System. Finally, for power generation, the driver and pellet design need to be compatible with the reactor. As noted earlier, the driver must be efficient ($\geqslant$10%) and be capable of sustaining a high repetition rate (several Hz) for sustained periods between mean failures. Beam entry and focusing needs to be consistent with the reactor geometry and environment. The first wall of the reactor needs to survive millions of microexplosions and have facilities to purge the system of pellet debris. This latter requirement tends to favor the simple minimal-mass direct-drive approach. Last, but not least, whatever system eventually satisfies all the physical requirements must also be economically viable. Pellet capsules have to be mass produced at low per-unit cost and the driver and reactor capital and operational costs must be competitive. The capital cost of a fusion power plant can be higher than other alternatives, but its lower fuel, environmental-impact, and hidden costs must compensate.

Most of the ICF critical issues discussed above are under active investigation. They are being addressed through computer simulation and laboratory experiments. In addition, it is noted that important aspects of the feasibility of high-gain inertial fusion are claimed to have been demonstrated at the Nevada test site in an underground nuclear explosion program called Halite/Centurion.

5. ICF DRIVERS

The driver is intimately connected with the implosion physics requirements. All joules are not created equal. First, the driver must satisfy all the critical pellet-coupling requirements, have adjustable pulse shape, and be efficient enough for a power reactor or be affordable for a defense facility. For energy application, the driver must also be capable of high pulse-repetition rate, be reliable, and be reactor compatible.

Two lasers that potentially satisfy these requirements, at least for the less demanding defense need, are the solid-state neodymium (Nd) glass laser and the krypton-fluoride (KrF) gas excimer laser. Other laser systems were considered in the course of the ICF program but were discarded, primarily because of failure to meet the ICF-pellet physics requirements; their wavelengths were too long.

Particle-beam accelerators are attractive ICF driver contenders because of their high intrinsic efficiency (~30%) and repetitive pulse capability. Two ion-beam approaches are under investigation, i.e., low-energy light ions at very high currents and high-energy heavy ions at low current. In either case, the resulting ion beams need to be focusable to power densities above 10^{14} W/cm^2 and to have suitable stopping ranges. The light-ion approach, also called pulsed power because of the type of accelerator technology involved, is attractive because of its relatively low cost and compactness. But pulse power has major technological hurdles to overcome in focusing its beams to intensities sufficient for ICF and in demonstrating reactor compatibility. The heavy-ion approach, on the other hand, uses extensions of conventional high-energy accelerator technology. The heavy-ion approach is thought by many researchers capable of satisfying all requirements; but there is only a small program developing this option at present.

It should be pointed out that there is no clear consensus as to which, if any, of these drivers is the most suitable for inertial fusion applications. Driver development is a very expensive and long-term enterprise. Technology is advancing rapidly. Breakthroughs occur occasionally that transform a seemingly dead-end approach into a contender; there is no reason not to expect more to come. In addition, all the driver-beam/target interaction issues have not been resolved. Many critical interaction issues need actual fusion reactor conditions to be settled. Some drivers are more compatible with direct drive than indirect drive, and vice versa. Finally, the ultimate economics of drivers is very uncertain; a prohibitively expensive technology today may be inexpensive in the 21st century, when fusion commercialization would occur. For these reasons a multipronged driver approach is favored.

5.1 Lasers

5.1.1 Nd-Glass Lasers. The development of high-power lasers in 1961 was the stimulus that spurred serious contemplation of controlled inertial fusion. The glass laser in particular was the first laboratory device able to concentrate energy to large enough intensities to develop the tremendous pressures needed to implode ICF pellets. A few percent of neodymium ions embedded in optical glass or crystal host, when pumped using flashlamp light, produces strong lasing action near 1 μm (~1060 nm) wavelength, which is in the near infrared. Energy can be stored in the inverted population over a long time interval (360 μs) and then stimulated to lase in less than 1 ns. The large ratio of storage to lasing times allows tremendous power concentration.

Even though the glass laser is presently too inefficient (less than 1%) for an energy reactor driver, it is the driver of choice for most inertial fusion research. This is because the glass laser can develop the needed power densities, is adaptable, and can test a wide range of ideas. Since inception, glass lasers have grown over a million-fold in energy output. Figure 8 shows photographs of three glass lasers used in ICF research. The Pharos III laser, located in the Space Plasma Branch of the Naval Research Laboratory (NRL), is typical of about a half-dozen medium-sized lasers in the world that have been used to elucidate much of the ICF-relevant laser-target interaction physics. The next Nd-glass laser shown is the 24-beam Omega laser located at the Laboratory for Laser Energetics of the University of Rochester that, along with the twelve-beam Gekko XXII facility at Osaka University in Japan, are the principal direct-drive implosion facilities. Finally, the large ten-beam Nova laser located at the Lawrence Livermore National Laboratory (LLNL) is the most powerful laser in the world; Nova primarily tests indirect-drive issues. Nova may soon be upgraded from about 100-kJ pulse level to the 1- to 2-MJ range to explore critical pellet ignition issues around the turn of the century.

Glass lasers used in the ICF program have undergone considerable evolution over the years. They are very flexible in beam pulse length and wavelength capability. Second-, third-, and fourth-harmonic conversion of the fundamental 1-μm wavelength into green, blue, and ultraviolet light with efficiencies of 70%–80% is routinely achieved by passing the light through optically active crystals, such as potassium di-hydrogen phosphate (KDP). It is fortunate that Nd-glass laser beams can operate at short wavelengths because that is what the great preponderance of research data has indicated is required for ICF.

Pressure applied to the pellet surface needs to be ultra-uniform ($\sim$1%), yet even good-quality high-power glass lasers have focal intensity variations more than an order-of-magnitude larger. Laser beam uniformity requirements are somewhat relaxed for the indirect-drive approach, but even so there are deleterious consequences of nonuniform beams. Fortunately, beam uniformity problems are largely solved. The group at Osaka University, Japan, introduced the idea of breaking the beam up into a multitude of beamlets with a random phase distribution. This has the effect of averaging nonuniformities by roughly a factor of $N^{1/2}$, where N is the number of overlapped beamlets in the focal region, and transforming long-wavelength distortions into shorter-wavelength interference patterns. Pressure nonuniformities over small distances tend to be smoothed by thermal diffusion between the absorption and ablation regions of the target. A further significant development was the invention of the induced spatial incoherence (ISI) method at NRL (Lehmberg and Obenschain, 1983). ISI accomplishes simultaneous spatial and temporal smoothing of the beam's focus by breaking up the beam into N beamlets, like the Osaka approach, and introducing a time delay into each beamlet path greater than the coherence time of the laser beam. Thus, interference patterns from all the overlapped beams move rapidly around and average, because of the statistically independent nature of the ISI beamlets. Nonuniformities are not "frozen" into the focal distribution, as would be the case for very coherent lasers. The coherence length of laser light is shortened from meters to less than a millimeter by introducing bandwidth, a slight frequency spread, onto the beam. Beam patterns that are uniform within the 1% level required for direct-drive were demonstrated using ISI with both 1-μm Nd-glass lasers and doubled (0.5-μm) Nd-glass lasers. A side benefit of using a uniform beam is that there are no high-intensity spikes to exceed threshold and to excite problematic parametric instabilities and filamentation, as discussed earlier. Beam-smoothing advances are still being made. The Laboratory for Laser Energetics, at the University of Rochester, has invented a variant of ISI that works with a frequency-tripled Nd-glass beam, which, by itself, does not have enough inherent bandwidth available. NRL is testing an "echelon-free" version of ISI for use in a developmental krypton-fluoride laser, Nike.

The poor (< 1%) efficiency of glass lasers and their high cost (> \$1000/J at present) are not suitable for an energy reactor. Nonetheless, a glass laser is the leading driver candidate for the first defense application facility, where high efficiency is not essential. In addition, there are active programs to develop higher efficiency, less expensive, and high-repetition-rate solid-state lasers. One approach is to use arrays of solid-state laser diodes instead of flash lamps to pump Nd-glass in a

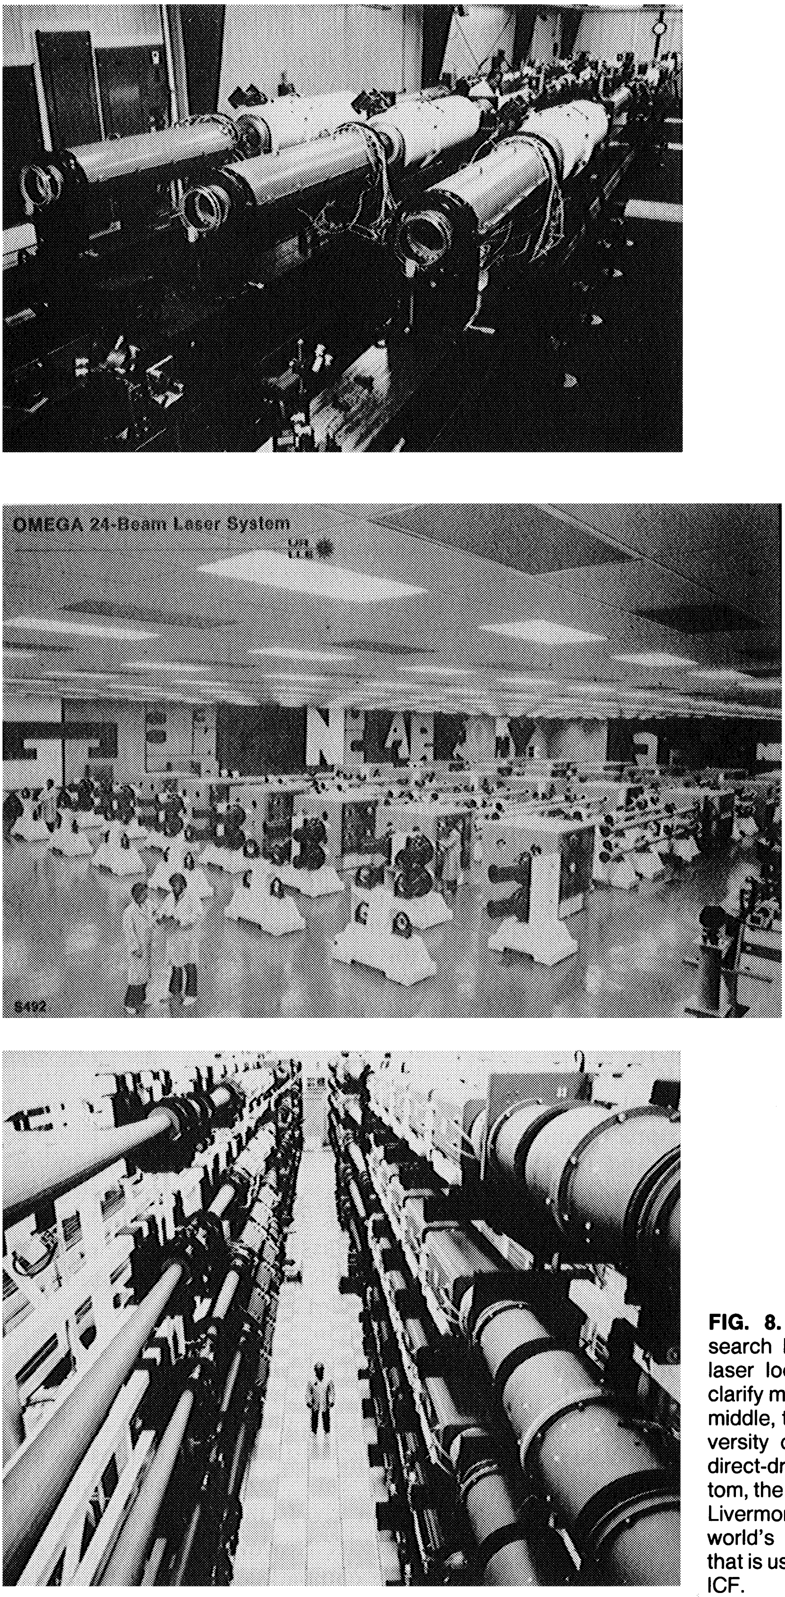

FIG. 8. Three Nd-glass ICF research lasers. Top, the Pharos III laser located at NRL that helped clarify many ICF physics processes; middle, the Omega laser at the University of Rochester used to test direct-drive pellet implosions; bottom, the Nova laser at the Lawrence Livermore National Laboratory, the world's most powerful glass laser, that is used to develop indirect-drive ICF.

narrow, efficient, frequency interval. Diode pumping works on a small scale but it is an open question whether the scheme scales economically to the MJ level. Most research lasers have used the master oscillator/power amplifier (MOPA) architecture. The laser pulse starts in an oscillator and is amplified by many mirrorless amplifiers staged in a long linear chain. New laser configurations are now emerging, such as the LLNL Athena design, which may lead to lower per-joule cost in large systems.

5.1.2 KrF Lasers. The most attractive alternative laser driver to the glass lasers for ICF is the krypton-fluoride (KrF) laser, which lases at about 249-nm wavelength. An excimer is a bound molecule formed with the ground state of a rare-gas atom, such as Kr, and an excited state of another component, fluorine in this case, i.e., KrF*. Excitation is usually accomplished by shooting energetic electron beams through the laser gas. The KrF laser is an ICF candidate because it has both short wavelength, for desirable target coupling, and, perhaps, sufficient (~10%) intrinsic efficiency. Gas lasers can also be designed to operate at high repetition rates and beam-smoothing techniques can be employed. Thus, KrF could satisfy all the requirements for a defense-facility driver and perhaps even an energy-plant driver. However, KrF proponents have many technical obstacles to overcome before it becomes the driver of choice.

KrF laser development is about one decade behind Nd-glass lasers. Development has been slow and fraught with technical problems. The first KrF system designed for ICF was the 2-kJ Aurora laser at the Los Alamos National Laboratory. KrF lasers do not store pump energy over relatively long times and then dump it into a short intensified laser pulse as do glass lasers. Rather, KrF lasers need to be continuously pumped throughout the laser pulse. To get the high intensities and efficiencies needed for ICF, a compression scheme is used to concentrate the energy of a half-microsecond or so pulse into about 10 ns. There are two pulse compression methods, optical multiplexing and Raman compression. Each technique has its own set of advantages and drawbacks. Optical multiplexing, the current method of choice, works by starting with an oscillator pulse with the correct pulse duration, splitting it into multiple beamlets, and delaying each beamlet sequentially in time so that they enter the KrF laser amplifiers in a long train of pulses that match the laser pump duration. After amplification the beamlets are recombined, one on top of another, before focusing onto the target. It remains to be seen if such a complex system, with hundreds of mirrors, can be made robust and efficient enough for practical use.

5.1.3 Laser-Driver Summary. All lasers have a reactor compatibility problem. Each beam has some optical element, a mirror or a lens, exposed to the harsh reactor interior environment. These components must tolerate large pressure impulses, radiation, neutrons, debris, and other reaction products from the pellet explosion. While this is not a big problem for low repetition rates, such as for a defense system, it is of serious concern for energy reactors that operate at 5–10 microexplosions each second, day after day, month after month. This is not necessarily a fatal flaw, because the last optical elements could be placed far away, may be protected with coatings or gas flows, or may be easily replaceable. Drivers in energy plants need to be reliable and put out millions of pulses between mean failures. Laser systems need to undergo significant engineering advances to meet this reliability requirement.

In the near term, however, there is no driver better than the Nd-glass laser for sorting out the myriad of physics issues to demonstrate the scientific feasibility of ICF for either defense or energy application. These physics investigations, carried out in many laboratories throughout the world, can test the viability of pellet designs and uncover and help overcome technical obstacles and determine whether the direct-drive or indirect-drive approach is best. The current strategy is to do just that. The proposed 1–2-MJ Nova-Upgrade Nd-glass laser at LLNL is designed to explore the pellet ignition regime and to test high-gain system designs.

5.2 Ion-Beam Accelerators

Particle beams can drive pellet implosions as long as they satisfy all the implosion physics requirements. Particle beams, like laser drivers, can work in either the direct or indirect mode. However, indirect drive appears more compatible with known ion stop ping distances than direct drive. In many respects, particle beams are preferable to laser beams. Ion energy deposition in targets seems more straight forward and benign than that with lasers. Particle accelerators have high efficiency, typically between 25% and 50% from wall plug to beam. Particle accelerators do not have delicate optics exposed to the reactor. Accelerators are amenable to reliable high-repetition-rate operation. Three particle-beam approaches have been considered for ICF: electron beams, light-ion beams, and heavy-ion beams. The U.S., Russia, and others pursued the electron-beam approach until the 1980s when it was demonstrated that electrons do not couple properly to pellets. Electrons cause excessive target preheat due to their long range. Ion beams are still candidates.

ICF target designs require ion deposition ranges between 40 and 200 mg/cm^2. The deposition mechanism for ions passing through cold material is primarily excitation and ionization of bound electrons the ions, described by the Bethe formula. The range of ions in cold material scales approximately as E^2/Z^2A, where E is the energy, Z is the effective charge, and A is the atomic number of the projectile ion. Thus, low-energy light ions (low atomic number A) and high-energy heavy ions can have similar ranges. Figure 9 lists a comparison of light- and heavy-ion ranges in cold aluminum. For example, a 100-MeV lithium ion ($A=7$) has about the same range as a 10-GeV lead ion ($A=207$). Of course, more low-energy ions are required than high-energy ions for the same deposited energy density in the target. As ICF targets become heated and ionized by the beam, stopping ranges decrease, an advantage for the ICF application.

Two completely different accelerator technologies produce light-ion and heavy-ion beams, viz., pulsed-power devices and high-energy accelerators. The former efficiently accelerates high currents (tens of MA) of light ions to moderate energies (< 100 MeV) and the latter accelerates low currents (tens of kA) of heavy ions to high energy (~ 10 GeV). Each approach has its own strengths and weaknesses.

5.2.1 Heavy-Ion Accelerators. Heavy-ion drivers are the leading contenders for use in ICF energy production plants. The technology is well adapted for high efficiency, high repetition rate, high reliability, and good target energy deposition. Heavy-ion accelerators are extensions of conventional linear accelerators (linacs) used for high-energy physics research (see ACCELERATORS, LINEAR). Ions from a source are injected into a long train of linac acceleration modules. The accelerating electric fields in the linac are applied by using rf fields in cavities or by using induction coils. The former is an rf linac, the latter an induction linac. Both approaches are being pursued, rf in Germany and induction in the U.S. Figure 10 shows schematics of rf and induction heavy-ion accelerators.

Heavy-ion accelerators differ from conventional accelerators in important respects. They accelerate heavy ions ($A > 200$) rather than the protons or electrons usually used in most elementary-particle research accelerators. They need to accelerate higher beam currents in highly compressed pulses to get the very high energy densities needed for ICF. Significant engineering hurdles need to be overcome to build a suitable heavy-ion driver.

There has been progress in developing heavy-ion driver technology. In the U.S., the

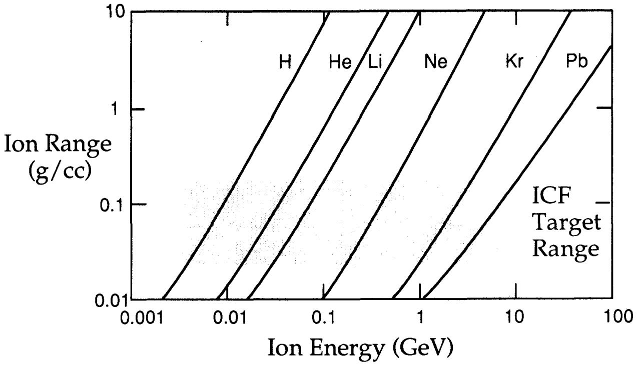

FIG. 9. Ion stopping ranges in solid material as a function of ion kinetic energy. Low-energy light ions and high-energy heavy ions have stopping ranges suitable for imploding ICF pellets.

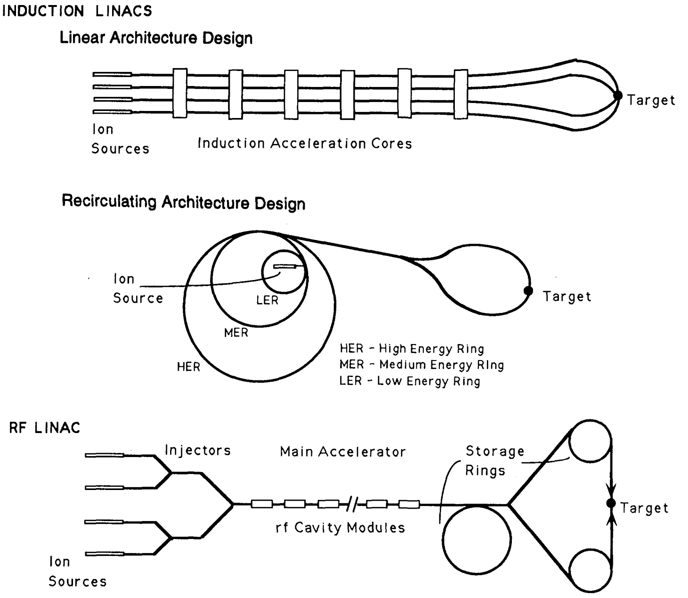

FIG. 10. Schematics of a rf linac (German approach) and two induction (U.S. approach) heavy-ion accelerators for ICF.

Lawrence Berkeley Laboratory (LBL) has built a small test module under its Heavy Ion Fusion Accelerator Research (HIFAR) program. Multiple ion sources, multiple beam transport, and pulse length compression were successfully demonstrated using the HIFAR four-beam accelerator. The next step, currently in its formative phase, is the Induction Linac Systems Experiment (ILSE) project. ILSE is, in many ways, a one-tenth scale model of a full heavy-ion system. ILSE will test beam-combining techniques, space-charge effects, emittance growth, and other beam-transport issues of a full-sized driver. A rf-linac heavy-ion accelerator program called SIS/ESR at GSI, Darmstadt, Germany, intends to study space effects in storage rings, bunching techniques, and ion ranges in hot matter (to study range shortening in plasma). The next step planned for the Darmstadt program is to build a heavy-ion fusion (HIF) demonstration accelerator, first at 1 GeV, 100 kJ, to be upgraded later to 1 MJ energy content per pulse.

Heavy-ion accelerators are not without potential problems. These machines need excellent beam quality (low-emittance beams) so that they can focus to high irradiance onto small ICF capsules in a fusion energy reactor. At the high currents needed, the beam's space-charge fields introduce emittance growth during acceleration that aberrates the beam. Additionally, a disruptive longitudinal resistive instability can develop between the beam and the accelerator structure that limits the maximum current in the induction-linac approach. There is little experience with accelerators in this regime and these issues need to be resolved. Nonetheless, the consensus is that heavy-ion beam drivers are suitable for ICF.

The current strategy is to develop heavy-ion technology in increasingly larger modules at the same time that high-gain ICF implosion physics is tested with glass lasers. There is an implicit assumption, yet untested, that a high-gain system that works with a laser driver will be compatible with a heavy-ion driver. Heavy-ion drivers presently appear best matched to the indirect-drive approach. One reason for this is that it may be difficult to irradiate a pellet uniformly directly with a small number of ion beams. Another reason indirect-drive is more compatible with particle beams is that ion ranges are too long for the most efficient rocket ablation. You may ask why ICF pellet physics cannot be done entirely with heavy-ion drivers instead of lasers. The answer is that it could, but most interaction and implosion experiments require a heavy-ion system capable of depositing the high energy densities needed for ICF. The entry fee for such a system is over 10^9 dollars and is at least a decade away.

5.2.2 Light-Ion Accelerators. Pulsed-power devices accelerate high-current, light-

Table 4. Driver requirements summary for defense and energy applications.

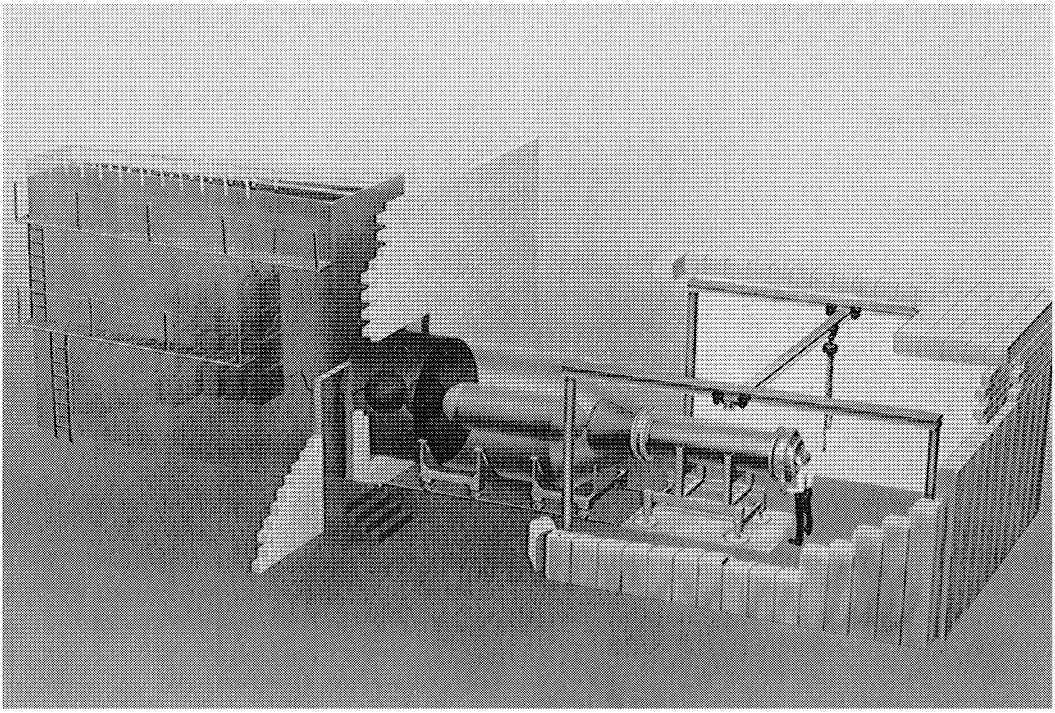
Requirement	Defense	Energy
Driver efficiency	Any (Yield >100 MJ)	$\eta_d G>10$ (e.g., $G>100$, $\eta_d>10\%$)
Pulse repetition rate	Single shot	5–10 Hz
Driver size	Cost limited	$E_d<10$ MJ (reactor limit)
Other	Experimental access	Reliable, economic, reactor compatible,...

ion beams. Their operation is very different from conventional and heavy-ion particle accelerators. Pulsed-power electron accelerators arose in the 1960s, primarily as an intense x-ray source. Pulse power works by arranging a series of electrical energy transfer stages, using capacitors and transmission lines, with successively shorter pulse duration. The temporal pulse compression progressively bunches the stored energy to higher and higher instantaneous powers, i.e., eventually into the multiterawatt regime. For example, a capacitor bank charges up over several minutes in the first stage, the stored energy is switched into a capacitive storage line in several hundred microseconds, and then transferred to a pulse-forming network in about 100 ns, and, finally, bunched and applied across the beam-emitting diode in about 10 ns. In the light-ion mode of operation, the polarity of the diode is arranged so that ions emitted from the anode can leave the machine. Figure 11(a) is a photograph of a research pulse-power machine at NRL called Gamble II, where much pulse-power technology was pioneered. Diode operation is complicated and the preponderance of pulse-power research is devoted to engineering diodes to produce the desired beam. For example, the ideal diode must optimize the ion emission fraction, produce a beam with acceptable emittance, focus the beams to small (pellet) dimensions, produce the ion species desired, and suppress prepulses, among other properties. An advantage of pulse-power accelerators is that they may be relatively inexpensive and compact compared to other drivers.

A large light-ion accelerator designed for the ICF program, the Particle Beam Fusion Accelerator II (PBFA-II) device at Sandia National Laboratories (SNL), is shown in Fig. 11(b). The goal of PBFA II is to deliver a 10-ns pulse of 1 MJ of lithium ions onto a 3-mm radius target at 100 TW/cm^2. PBFA II has cylindrical geometry to cover a pellet surface better. If this can be done, then PBFA II may meet the minimum requirements for ignition and some defense applications. The maximum focused lithium beam power from PBFA-II was about 7 TW/cm^2 in 1990. The light-ion–beam research thrust is to develop diodes that emit much higher quality (more focusable) beams needed to reach the required 100-TW/cm^2 level. Unfortunately, as with heavy ions, it is difficult to do pellet implosions until high intensities are in hand. Nonetheless, relevant experiments have been done with pulse power. Absorption of light ions in cold material and plasma as well as concepts to transport a focused beam along a long (e.g., 2 m) channel have been demonstrated at NRL and Sandia. NRL also pioneered the plasma opening switch and inductive storage developments, which makes possible suppression of prepulse energy and higher power compression, and makes for a more compact driver. Sandia has developed a modular inductive-based accelerator called HERMES and is testing high-repetition-rate accelerators that may ultimately satisfy all the requirements of an energy reactor driver. However, light-ion drivers are far from meeting reactor requirements and considerable development is needed to test their viability.

5.3 Comparison of ICF Drivers

The only driver technology that can currently test the pellet-implosion critical issues of high-gain ICF is the Nd-glass laser. The largest existing glass laser, Nova, which currently delivers about 100 kJ per pulse, may be upgraded in the late 1990s to deliver blue (third-harmonic) pulses in the 1–2-MJ range to test pellet ignition processes. Experiments with such a laser can explore the pellet ignition regime and provide the information needed to design a pellet/driver system for a defense facility. Further, if the ignition experiments go favorably, then most of the information will be in hand to establish the driver requirements and limitations of a high-gain



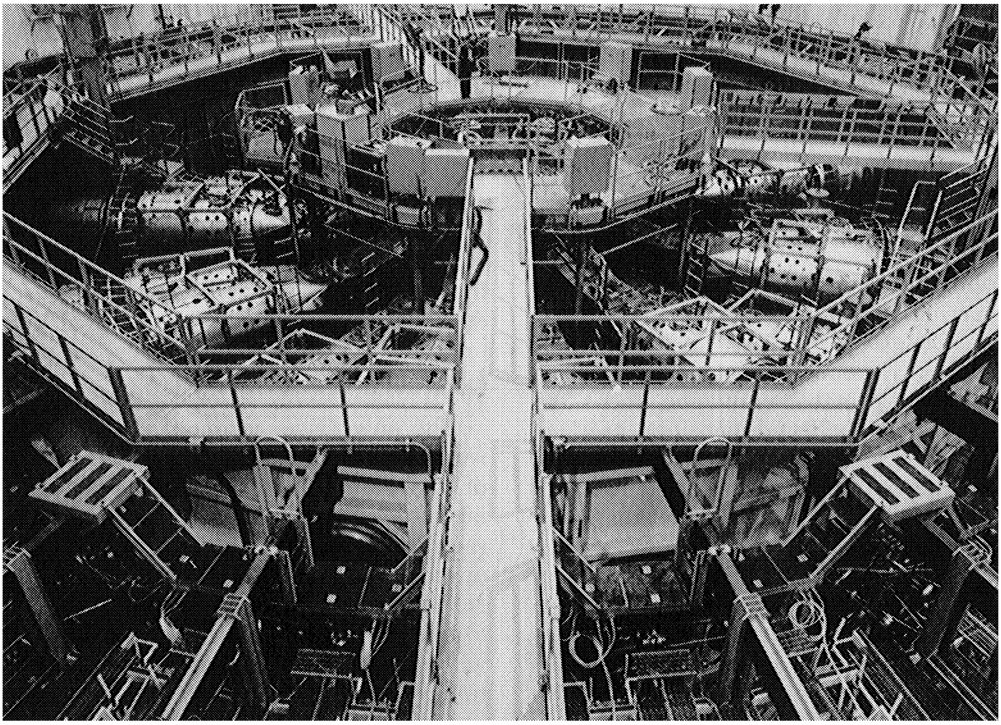


FIG. 11. Two light-ion pulse-power accelerators used in ICF research. (Top) A drawing of the Gamble II pulse-power research accelerator located at NRL. (Bottom) Particle-beam fusion accelerator (PBFA) II located at Sandia National Laboratory that can deliver almost 1 MJ of light-ion beam energy in a single pulse.

pellet system for power production. But, as noted before, it is unlikely that glass lasers are suitable for a power reactor. A comparison of driver requirements for power production and military applications is indicated in Table 4. Of all the driver candidates for energy application, heavy-ion accelerators have the most promise, but are also the least mature technology.

6. ICF POWER REACTORS

An ICF power plant consists of the driver, reactor and associated turbine, generators, and support systems. The reactor is the chamber in which the pellet microexplosions occur and the released fusion energy is converted into the heat used to drive the turbines and generators. ICF reactors will be very different from fission reactors and share the same desirable radiological-hazard and environmental benefits of the magnetic fusion reactors. The reactor will have a first wall to protect and contain the "blanket." The blanket converts the fusion products, primarily neutrons, into heat and provides for breeding of tritium. Breeding is needed to replenish the used-up tritium fuel. A distinct advantage of ICF is that its reactor can be simpler and more innovative than those envisioned for a MFE plant. This is because the driver, the most complex and costly portion of the system, is located outside the reactor area; only the beams enter the reactor itself. This separation of driver from reactor vastly simplifies dealing with such practical concerns as maintenance and reliability.

On the other hand, an ICF reactor has some unique demanding requirements, not the least of which is standing up to several million microexplosions per year (each releasing the energy equivalent of several hundred pounds of TNT) for several years at a time. Protection of the first surface in the reactor and any beam-steering or -focusing elements in the line of sight exposed to the bursts and debris is a challenging engineering feat. Additionally, the beam must propagate through the reactor to the target while maintaining adequate focus and minimal losses. Each driver type has its own unique set of constraints connected with beam transport. Means must be provided to inject target capsules (ICF pellets including any associated *Hohlraum* structures) into proper position in the center of the reactor several times each second. Target capsules have to be insensitive to errors in alignment or beam irradiation parameters. They also must be inexpensive. The reactor and power plant should also have provisions for dealing with the target-capsule debris accumulation. Although each burst contributes a small amount of debris, accumulations over millions of shots can be appreciable, particularly for targets involving *Hohlräume*. Direct-drive–based systems have reduced target debris accumulation since they use only bare pellets, and these can be made up largely from their own cryogenic D-T fuel. On the other hand, direct drive requires extraordinary pellet illumination symmetry of the incoming beams, which can complicate the reactor geometry.

There are not yet any ICF reactor designs with enough engineering detail actually to build a prototype. Several reactor concepts appear compatible with drivers and may be economically viable. Figure 12 shows sketches of several ICF reactor ideas. The first wall protects the thermal blanket and frequently maintains vacuum integrity of the reactor. As such it bears the brunt of the energy, radiation, and debris from each microexplosion. It must have a reasonable service life since it is located deep inside the reactor and is not easily repaired or replaced. The first wall also must efficiently transmit the raw fusion energy, mostly in the form of neutrons, to heat the surrounding thermal blanket and to breed additional tritium fuel. Reactors fall into three types characterized by the kind of first-wall material they incorporate, viz., dry wall, wet wall, and gas filled.

Dry walls are solid material barriers. Low-atomic-number materials are preferred, such as graphite, silicon carbide, etc., to reduce activation levels and radiation damage. Most metals, like steel, are unacceptable since they typically have long-lived activation and would require an enormous reactor diameter (> 100 m) to limit radiation damage to acceptable levels. Some dry-wall concepts are quite innovative. For instance, one idea is deliberately to use a material in which a thin (few-micron) layer of the first wall ablates away on each pulse as it absorbs the brunt of the explosion products; eventually, a fresh wall would have to be installed. Another dry-wall concept called

FIG. 12. Three ICF power reactor concepts. (Top) Liquid first-wall reactor called LIBRE. (Middle) Dry first-wall reactor consisting of lithium ceramic granules, called CASCADE. (Bottom) Buffer-gas first-wall reactor design called SOLASE.

CASCADE would use a thick flowing layer of small lithium-ceramic granules as both the blanket material and the first wall; heat and contaminants can be removed from the granules outside the reactor chamber.

Wet-wall reactors employ a layer of flowing liquid metal, such as lithium, as the first surface. Structural damage to liquids is self-healing and contaminant extraction occurs outside the reactor cavity. The liquid lithium may be just a wet layer flowing over the surface of a dry wall, or, innovatively, a thick flowing "waterfall," such as in the HYLIFE concept, which acts as a combined blanket and first wall. One property of wet walls that needs further attention is whether their vapors cause interference to the incoming driver beams.

If incoming beams can tolerate ambient pressures in the mTorr range, then deliberate introduction of gas into the reactor vessel can be protective. Gas "first walls," such as incorporated in University of Wisconsin's SOLASE reactor, work by absorbing the prompt x rays and target debris before they reach the first solid surface. This buffers the blanket wall from much of the prompt impact of the explosions. However, SOLASE requires gas pressures in the reactor chamber that can interfere with the transport of some types of incoming beams. Also, a shock wave is set up in the buffer gas that eventually does strike the wall.

It is likely that the ICF reactor that eventually ends up in a power plant will look quite different from present versions since serious development can only take place when a specific driver and pellet implosion is selected, and a prototype plant is within sight.

7. RECENT PROGRESS IN THE ICF PROGRAM

There has been steady progress in the worldwide inertial fusion effort since its inception. The United States has by far the largest ICF programs and driver facilities in the world. The program has been reviewed numerous times since its inception and has consistently been found to be of high quality and has made steady progress on all fronts. Groups in Europe, Japan, Russia, Canada, China, and elsewhere have all made important contributions. Table 5 lists the major ICF experimental facilities in the world as of 1992. There are many smaller experiments and theory efforts worldwide in addition to those listed in Table 5. Most of the physics phenomena that affect the interaction of beam energy with the target and the pellet response are now known and understood well enough to design a large driver facility to test pellet ignition and gain.

Among the non-U.S. efforts, the Japanese program at Osaka University is particularly broad and vigorous. Collaborations among ICF researchers cross many national boundaries, even though the U.S. indirect-drive classification policy through 1992 has been inhibiting.

Road blocks have been met from time to time while trying to resolve inertial-fusion critical issues. But most of these have been overcome through the interplay of good experiments, theory, computer simulation, and inventiveness. Some significant ICF advances include the following:

1. Interaction physics has been largely solved and is no longer the dominant critical issue.
2. Rayleigh–Taylor instability and mix understanding and control has made strides.
3. Effective laser-beam smoothing and balancing methods are invented.
4. Agreement of calculations with experiments is now quite good.
5. Advances have been made in laser and ion-beam driver technologies.
6. Fabrication of high-surface-quality and cryogenic targets has been demonstrated.
7. Low-ignition-threshold indirect-drive concept was invented.
8. Lastly, Halite/Centurion underground nuclear tests have "...excellent performance, putting to rest fundamental questions about basic feasibility to achieve high gain."

Progress is also evident in the march toward satisfying the Lawson criterion, Eq. (1′). The $Tn\tau$ plot shown in Fig. 13 shows a steady advance towards ignition, break-even, and high gain. The next major step to be taken in the program is the demonstration of pellet ignition. Although the indirect-drive approach is the largest component of the ICF program, it is important to note that the smaller programs have made major progress in solving

Table 5. Major ICF research facilities (1992). Laboratory is usually denoted by its acronym: LLNL is Lawrence Livermore National Laboratory; SIOFM is the Shanghai Institute Of Fine Mechanics; CEA is Commissariat à l'Energie Atomique; AWE is Atomic Weapons Establishment; UR-LLE is University of Rochester—Laboratory for Laser Electronics; RAL is Rutherford-Appleton Laboratory; LANL is Los Alamos National Laboratory; SNL is Sandia National Laboratory; LBL is Lawrence Berkeley Laboratory; and GSI is Gesellschaft für Schwerionenforschung. Beam energy and wavelengths or particle types are typical of pulses useful for ICF research. The primary ICF research area is denoted by I-D (indirect drive), D-D (direct drive), Driver dev. (driver technology), and ICF feasibility, which refers to classified experiments done to establish the feasibility of some ICF issues in underground nuclear explosion tests (UGT) in the late 1980's.

the beam symmetry and smoothness requirements and the beam-target interaction issues, which are critical for both direct drive and x-ray drive. The significant improvements in beam quality and balance demonstrated at the University of Rochester and beam-smoothing techniques from NRL have substantially met the requirements for ICF. Some of these beam improvements are incorporated in the LLNL Nova system (called "Precision-Nova"). At this juncture, neither the direct- nor indirect-drive approach is assured of either success or failure. However, the positive claims of the classified Halite/Centurion program together with the laboratory results have been very encouraging.

There is steady progress in driver development, too. LLNL's Nova laser is working well, University of Rochester's Omega laser has demonstrated impressive beam-quality improvement at short wavelength, and Osaka's Gekko XII system has demonstrated good reliability and versatility, as noted above. KrF laser development at NRL includes the incorporation of a form of the induced spatial incoherence beam-smoothing technique. Sandia has made progress meeting its near-term lithium-beam milestones in the PBFA II light ion program. There has also been progress in the HIFAR heavy-ion accelerator program, located at Lawrence Berkeley Laboratory (LBL), as well as the European heavy-ion efforts at Darmstadt, despite low funding levels. At present, the glass laser is the only driver technology advanced enough to perform a laboratory ignition demonstration in the near

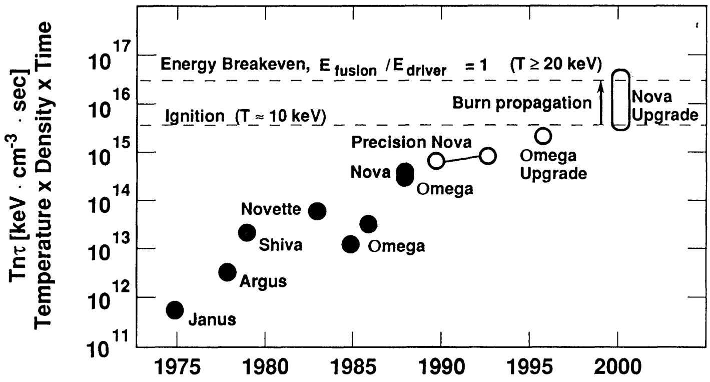

FIG. 13. ICF progress on the Lawson $Tn\tau$ diagram. The temperature–density–confinement-time product has progressively increased over the years to within a factor of ten of scientific feasibility. The next generation research facility, Nova-Upgrade, should achieve ICF ignition. (From the FPAC Final Report).

term. Barring a technology breakthrough, glass lasers are ruled out as an energy driver because of their low efficiency (< 1%). However, other driver technologies have the potential of yielding an inertial energy driver. No driver yet meets the repeatability, efficiency, and reliability requirements and high-gain target compatibility ultimately needed.

8. PROGNOSIS AND CONCLUSION

There were two major reviews of the U.S. fusion program in 1990. The U.S. Department of Energy formed the Fusion Policy Advisory Committee (FPAC) to recommend a broad plan to bring fusion energy to commercialization for both the magnetic and inertial fusion programs. Europe has decided not to establish a major ICF program at this time, but rather is watching the U.S. effort. A schematic of the FPAC plan for inertial fusion development is shown in Fig. 14. The U.S. National Academy of Sciences (NAS) also completed an in-depth review of the inertial fusion program, primarily for defense application. These studies noted the immense difficulty and long lead times involved in fusion research and recommended that research efforts be immediately accelerated so that commercialization could begin in the early 21st century. Both reviews concluded that inertial-fusion defense applications were important and likely to be successful. They also concluded that prospects for the more stringent energy-production goal were encouraging. In particular, FPAC recommended that both the ICF and MFE programs proceed with experiments to explore burning fusion conditions, so-called "ignition" facilities. These fusion facilities would form the basis required to build an ICF engineering test reactor. An ignition facility would also lead to the Laboratory Microfusion Facility (LMF) for defense applications.

The next major step in the ICF program will be the construction of an ignition facility. The ignition facility envisioned consists of a major upgrade of the present 10-beam, 100-kJ Nova facility at LLNL to a 20-beam Nd-glass laser that delivers 1–2 MJ of third-harmonic (blue) light pulses onto ICF targets. The plan calls for this "Nova-Upgrade" to reach the conditions necessary to explore pellet ignition in about the year 2000. The Japanese program at Osaka is also discussing the possibility of a large facility of its own. If these ignition-level experiments are successful, then fusion researchers would have most of the information

needed to build a high-yield ICF implosion facility. As noted earlier, commercialization of ICF for energy production requires more than successful high-yield pellet implosions. Energy production also requires a highly reliable repetitively pulsed system, driver and reactor, with sufficient efficiency and economic viability to be competitive. FPAC urged the Department of Energy to undertake a program specifically to examine prospects for achieving these additional requirements and to pursue the most attractive path. For this reason, the development of a heavy-ion driver has high priority.

The next decade will be an exciting period in ICF development. If all goes well, the feasibility of high-yield pellet explosions will be verified, a selection of a driver approach compatible with power reactors made, and an engineering test facility initiated leading to commercialization in the next century. The development of fusion for power production is a formidable task, taking much more time, resources, and ingenuity than initially envisioned. Commercialization is far from being assured, even now after three decades of development. But, if it is ultimately successful, then the payoff economically, environmentally, and geopolitically will be immense.

GLOSSARY

Ablation: The process of removing material from the surface of a pellet as a result of intense radiation from the driver beam.

Aspect Ratio: Ratio of the radius of a pellet to the thickness of its shell wall.

Break-Even: The point at which the amount of fusion energy produced is equal to the energy used in a fusion device.

Burn Front: A self-sustaining thermonuclear fusion reaction region that propagates outward throughout the remaining fuel.

Capsule: The target of ICF driver beams. In the direct-drive approach the capsule is the pellet. In the indirect approach the capsule is the pellet-*Hohlraum* combination.

Critical Density: The density at which the incoming light frequency equals the local plasmas frequency.

Deuterium (D): The heavy isotope of hydrogen with one neutron; it is a component of fusion fuel that is abundantly found in natural water.

Direct-Drive Approach: The ICF method in which the driver beams directly irradiate the pellet surface.

Driver: The device that produces the intense beams that are focused on the target to implode the pellet. Drivers include lasers and particle beams.

Fusion Policy Advisory Committee (FPAC): The committee set up in 1990 by the U.S. Department of Energy that laid out magnetic and inertial fusion energy development plans through commercialization.

Gain: The ratio of the fusion yield of an ICF pellet to the input driver energy.

Heavy-Ion Accelerator: Instrument for accelerating high–atomic-number particle beams for ICF.

HIFAR: Heavy-ion fusion accelerator research program located at Lawrence Berkeley Laboratory which is exploring heavy-ion driver technology.

Hohlraum: An enclosure in which driver-beam energy is converted into x rays; these x rays are contained in the *Hohlraum* and irradiate the pellet surface.

Hot-Spot Ignition: Ignition of small amount of thermonuclear fuel in the center of the bulk of the cold compressed fuel.

Hydrogen Bomb: Also called H bomb, an explosive that derives its energy release from thermonuclear fusion.

Ignition: The process in which the fusion energy released supplies enough heat to propagate a self-sustaining fusion burn front into the surrounding thermonuclear fuel.

Indirect-Drive Approach: Also known as the "classified approach," the ICF method in which the beam energy is first converted into x rays in a *Hohlraum*; the x rays then irradiate and implode the pellet.

Induced Spatial Incoherence (ISI): A method to produce an ultrasmooth laser beam profile.

Inertial Confinement Fusion (ICF): Also frequently referred to as inertial fusion, inertial-fusion energy (IFE), or laser fusion, a means of producing bursts of fusion energy by imploding small pellets containing thermonuclear fuel. IFE refers specifically to the civilian energy-production application.

Isentropic Compression: Heating of a material by compressive work.

Lawson Number: The minimum product of density and confinement time ($\sim 10^{20}$ s m^3) of a fusion fuel plasma needed to produce net energy in a fusion reactor.

Magnetic Fusion Energy (MFE): An approach toward controlled thermonuclear fusion in which low-density thermonuclear fuel is contained and heated to thermonuclear temperatures in large magnetic "bottles" for long periods of time.

Nova: The largest neodymium-glass laser in the world, located at Lawrence Livermore National Laboratory; it is used primarily for indirect-drive ICF research. Upgrades to Nova include "Precision Nova," which improved the laser's beam uniformity and balance, and the proposed "Nova Upgrade" which, if approved, will increase the current 100-kJ beam energy up to 1–2 MJ.

Omega: A large neodymium-glass laser located at the University of Rochester that is used for direct-drive ICF research.

Parametric Instabilities: Parametric processes involve the interaction of a large-amplitude wave, often called the pump, with two or more other waves in the system. These processes are often unstable, grow to large amplitude, and cause interesting, but deleterious, effects for ICF applications.

PBFA II: A large light-ion accelerator at Sandia National Laboratory being tested as an ICF driver.

Pellet: A spherical shell containing the fusion fuel in the ICF approach.

Plasma: Ionized matter that responds to electric and magnetic forces as well as mechanical forces. Plasma is often called the fourth state of matter.

Plasma Frequency: A natural oscillation frequency of electron waves in a plasma.

Ponderomotive Force: A force caused by intense electromagnetic wave gradients that is important in many laser plasma interaction processes.

Preheat: Excess heating of the fuel before final compression.

Pulse Power: Type of driver used to accelerate intense light-ion (low atomic number) beams for ICF.

Rayleigh–Taylor Instability: An instability caused when a dense fluid is accelerated by a less dense fluid. This instability occurs during the pellet implosion and can break up the pellet before maximum compression.

Thermonuclear Fuel: Low-atomic-number nuclei that can undergo fusion reaction and give off net energy. Deuterium and tritium are the thermonuclear fuels most considered for controlled fusion applications.

Tritium (T): The unstable heavy isotope of hydrogen with two neutrons; it is a fusion fuel component that would be bred in the blanket of a fusion reactor to replenish supplies.

Underground Tests (UGT): Experiments performed in underground nuclear detonation tests at the DOE nuclear test site in Nevada.

INTRODUCTION

Nuclear fusion is the combining of light nuclei to form more massive ones with the conversion of nuclear binding energy to kinetic energy. This energy conversion process is the source of heat in the stars and in the Sun. If this reaction can be replicated on Earth in a controlled manner, there would exist an energy source to supply mankind in perpetuity.

In order to achieve the fusion reaction, charged nuclei have to approach to within distances of 10^{-14} m of each other for nuclear transitions to occur. However, this close approach is impeded by the Coulomb repulsive force of the positively charged nuclei. Only if particles have enough kinetic energy, so that they can penetrate this Coulomb barrier, can the fusion reaction take place. Hence, to achieve fusion it is necessary to heat the fuel to a sufficiently high temperature that particles can penetrate close to each other's nuclear core. Then a nuclear fusion environment can be created where the kinetic energy released by the fusion reaction products maintains the temperature of the fuel.

The fusion environment is at a temperature even greater than that found in the Sun. In order to achieve this environment technologically, special conditions are required to establish insulation of the fuel from the surrounding "cold" Earth temperature. Otherwise the energy losses to the neighboring environment will exceed the energy produced by the fusion reaction. The task of producing adequate heat confinement is the crucial aspect of the controlled-fusion program. As will be described here, great progress has occurred since the program's initiation in the 1950s, yet much more is needed in order to achieve one of the great challenges to mankind: Earth-based energy from controlled fusion.

1. ENERGY FROM THE FUSION REACTION

Only a few fusion reactions have sufficiently high rates and energy gain to be exploitable in a practical fusion reactor. As a result the issue of what fuels are available for use on Earth when controlled fusion is feasible is significant and is discussed in this section.

1.1 Fusion Reactions

The three most important fusion reactions for energy applications are

$$d+d\rightarrow\begin{cases}{}^3\mathrm{He}+n+3.3\ \mathrm{MeV}\\ t+p+4.0\ \mathrm{MeV}\end{cases},$$

$$d+t\rightarrow{}^4\mathrm{He}+n+17.6\ \mathrm{MeV},$$

$$d+{}^3\mathrm{He}\rightarrow{}^4\mathrm{He}+p+18.3\ \mathrm{MeV}.$$

Figure 1 shows the cross sections and reaction rates of these three reactions. These curves show that the energy dependence of the rate of fusion reactions decreases rapidly below the energy of maximum reactivity, a manifestation that the Coulomb barrier can quench the fusion reaction. A fusion environment must achieve temperatures in excess of the ideal ignition temperature, T_{ideal}, which is the lowest temperature for which a self-sustaining fusion reaction can be achieved when energy losses due only to bremsstrahlung radiation are accounted for. For the *d-t* reaction T_{ideal} is 5×10^7 K, or, in units more commonly used by research workers, 4 kiloelectronvolts (keV). For the *d-d* and *d*-^{3}He

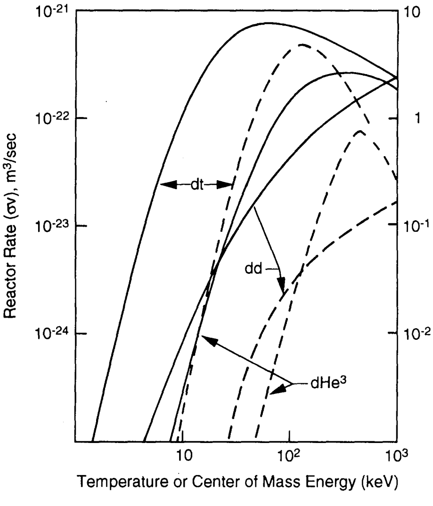

FIG. 1. Solid curves: reaction rates averaged over a Maxwellian distribution as functions of temperature (in keV units); dashed curves: cross sections as functions of center-of-mass energy for the *d-d*, *d-t*, and *d*-^{3}He fusion reactions.

reactions the ideal temperatures are 40 and 30 keV, respectively.

1.2 Fuel Availability

One of the principal motivations for using controlled fusion for energy is the availability of fuel reserves. Among the reactions listed in Fig. 1, the *d-d* reaction clearly is a fuel resource with virtually inexhaustible supply. Deuterium is a stable isotope of hydrogen, which is stored in sea water with a natural abundance of 1 part in 6500. The energy content of 1 L of water from the *d-d* reaction (2×10^9 joules) is equivalent to the energy content of about 50 L of oil. The effective energy content can even be raised substantially if the tritium and ^{3}He products produce further fusion reactions. With deuterium extracted from sea water, if energy is consumed at a rate of 10^{21} J/y, the *d-d* reaction can provide an energy source for $\sim 10^9$ y.

The main drawback of the *d-d* reaction is a relatively low reaction rate and yield, which makes its implementation more difficult as compared to the *d-t* and *d*-^{3}He reactions. Of the two, *d-t* has a clear advantage in achieving a fusion environment, as the ignition temperature is appreciably lower and reaction rates are higher than for the *d*-^{3}He reaction. For this reason the first planned demonstration of controlled fusion conditions is based on the *d-t* reaction.

As a long-term energy source, the *d-t* reaction is feasible, although not as directly as with the *d-d* reaction. Tritium is an unstable element with a half-life of 12 years. Hence tritium must be constantly bred during reactor operation. Breeding is possible via the nuclear reactions

$$n+{}^6\mathrm{Li}\rightarrow t+{}^4\mathrm{He}+4.8\ \mathrm{MeV},$$
$$n+{}^7\mathrm{Li}\rightarrow t+{}^4\mathrm{He}+n-2.5\ \mathrm{MeV}.$$

Both reactions can be used to produce tritium. The *n*-^{6}Li reaction is exothermic, and if the released energy is exploited, the effective yield per *d-t* reaction would be 22 MeV. Though the ^{7}Li reaction is endothermic, it does not appreciably degrade the energy output of the entire *d-t* cycle. ^{6}Li has a natural abundance of 7.5% while ^{7}Li has a natural abundance of 92.5%. Thus as tritium will ultimately be bred from lithium, it is the availability of lithium that governs the energy potential of the *d-t* reaction. The officially estimated "economically" extractable lithium reserves are equivalent to about one thousand years of energy supply. In addition the lithium found in sea water, if economically extractable, would imply an energy reserve on the scale of millions of years.

Despite its long-term potential, the implementation of fusion energy based on *d-t* has several difficulties. The need to breed tritium complicates reactor design; and, since it is radioactive, there will be siting restrictions. There is controversy about whether the hazards associated with the long-lived radioactive material generated from the neutrons produced by the *d-t* reaction are a significant environmental concern (though it is generally agreed that such problems are far less severe than with fission reactors). Perhaps the most significant problem is whether the long-term integrity of containment vessels can be maintained under the continuous flux of 14-MeV neutrons (advanced materials research is needed to demonstrate that walls can be fabricated from material that anneals with minimum deterioration from defects caused by neutron bombardment).

These concerns give impetus to the desire to exploit the *d*-^{3}He fusion reaction, which by itself produces only charged fusion products (though some neutrons are produced from the *d-d* side reaction). Another potential benefit of the *d*-^{3}He reaction is the possibility of directly converting charged fusion products to electrical energy with an efficiency of $\sim 80\%$, whereas energy derived from energetic neutrons needs first to be converted to heat, so that the ultimate conversion to electricity is limited to a thermodynamic energy efficiency of $\lesssim 40\%$.

Unfortunately, there is a crucial uncertainty in the *d*-^{3}He cycle, that of fuel availability. Though ^{3}He is a stable element, it is light enough to escape the Earth's gravitational field. Hence only trace amounts of ^{3}He are found on Earth. Paradoxically, ^{3}He is present on the moon (Wittenberg *et al.*, 1986). The ^{3}He, which originates in the flux of the solar wind, is embedded in lunar rock. It has been estimated that this ^{3}He source can supply mankind with energy for hundreds of years. On a longer time scale, one can envision space travel to the larger planets, Jupiter and Saturn, where the gravitational field is strong enough to retain ^{3}He. An alternative scenario is that Earth-based sources of ^{3}He can come from other fusion reactors operating on *d-d* or *d-t* reactions. Neutron-producing reactors could be sited in remote areas and supply ^{3}He for electricity-producing ^{3}He reactors close to populated areas.

The above discussion indicates that with appropriate technological progress, the fusion reaction from several fuels can provide civilization with a long-term energy source. The choice of fuel cycle will depend on the quality of the energy confinement scheme that is devised, the environmental standards that are deemed acceptable, and the technologies that are developed in the future.

1.3 Magnetic Confinement

Still, the first major step remains to be proved; i.e., can a controlled-fusion Earth-based environment be established? There has been considerable progress toward answering this question, but much more information is needed from future research. This article is devoted to explaining the principles of magnetic confinement, where an ionized gas (commonly called a plasma) is isolated from the surrounding "cold" environment by magnetic pressure. For an alternative approach, see FUSION, INERTIAL CONFINEMENT.

In the subsequent sections we present the following material: In Sec. 2 we discuss the confinement parameters that must be achieved if the energy produced from the fusion reaction is to exceed the energy required to produce the hot plasma conditions necessary for copious fusion reactions to occur. In addition we will present an overview of the principal energy-loss mechanisms associated with a confined hot plasma. In Sec. 3 we discuss magnetically confined equilibrium and give examples of several confinement schemes. In Sec. 4 we examine in more detail the mechanisms for particle confinement and transport for two of the most important confinement concepts, the mirror machine and the tokamak. The viability of a plasma confinement concept usually depends on the stability of the configuration. An overview of stability considerations is given in Sec. 5. Finally, in Sec. 6, past progress and the present state of magnetic confinement research is discussed.

2. INTRINSIC ENERGY-LOSS MECHANISMS

2.1 Lawson Criterion

All fusion confinement schemes rely on heating a plasma in a configuration that is sufficiently well insulated from its surroundings. The Lawson criterion, the product of the particle density n and energy lifetime τ arising from all possible loss mechanisms, is a measure of how close a given configuration is to creating a fusion environment. It is obtained by observing that a plasma (with, say, equal numbers of electrons and hydrogenic ions) with a temperature T (throughout Sec. 2 we assume that electron and ion temperatures are equal), electron density n, and lifetime τ loses power density at a rate $P_l = 3nkT/\tau$. In order to have a self-sustaining fusion reaction, this power loss must be compensated by the energy produced by the fusion reaction. It is envisioned that charged fusion products will be contained in the system with their kinetic energy being absorbed by the background plasma, while fusion-produced neutrons escape from the plasma region. A self-sustaining reaction (a burn) occurs when the power production of the charged-particle fusion products compensates the thermal energy losses of the plasma. Thus the criterion for a fusion burn is

$$3nkT/\tau \lesssim \gamma n^2 \langle \sigma v \rangle W_F \,, \qquad (1)$$

where $\langle \sigma v \rangle$ is the fusion reaction rate averaged over the background ion distribution functions (σ is the fusion cross section, v $\equiv$ relative ion velocities), γ is a numerical factor that depends on the fuel mixture (for *d-d*, $\gamma = \frac{1}{2}$, for *d-t*, $\gamma = n_d n_t / n^2 \leqslant \frac{1}{4}$, etc.; the subscripts d and t refer to deuterium and tritium), and W_F is the energy of the charged fusion products. From Eq. (1) the Lawson criterion follows:

$$n\tau > \frac{3kT}{\gamma \langle \sigma v \rangle W_F} \equiv (n\tau)_{\mathrm{L}} \,, \qquad (2)$$

where the right-hand side depends on temperature and fuel mix. Figures of $n\tau$ versus temperature, for the optimum fuel mix, are given in Fig. 2. One observes that $n\tau$ values in excess of 10^{20} m^{-3} s are needed to achieve self-sustaining fusion.

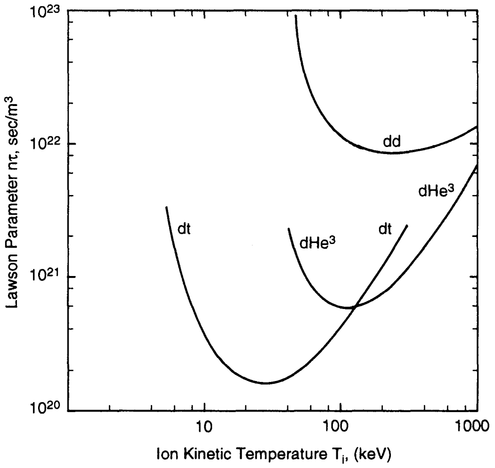

FIG. 2. Lawson diagram for sustaining fusion burn for the *d-d*, *d-t*, and *d*-^{3}He reactions.

A less stringent, modified Lawson criterion applies to the condition for obtaining net energy when energetic neutrons are produced. For the *d-t* fuel cycle with ^{6}Li used for the breeding of tritium, 22 MeV per reaction is released, with only 3.5 MeV going into charged products inside the plasma. With a 40% heat conversion efficiency, the critical $n\tau$ that is needed to achieve fusion energy is reduced by a factor of 3. However, external power must then be continuously supplied to this so-called "wet-wood burner" mode of operation.

2.2 Loss Mechanisms

The feasibility of attaining fusion energy depends on devising thermal insulation so that Eq. (2) can be satisfied. There are several intrinsic power-loss mechanisms that place upper bounds on $n\tau$, including radiation, diffusive losses due to collisions, and diffusion due to small-scale turbulence. The composite loss rate can be written as $1/\tau = \Sigma_i 1/\tau_i$, with τ_i^{-1} the effective energy-loss rate per electron-ion pair for each individual mechanism.

2.2.1 Bremsstrahlung. Radiation due to bremsstrahlung is a basic loss mechanism and is due to the radiation emitted by electrons colliding with each other and with ions. The power radiated P_{brem} is given by

$$P_{\text{brem}} = 3nkT/\tau_{\text{brem}} \tag{3}$$

with $n\tau_{\text{brem}} = 2.8\times10^{21} T_{10k}^{1/2}/Z_{\text{eff}}$ m^{-3} s, where T_{10k} is the plasma temperature in units of 10 keV, and $Z_{\text{eff}} = \Sigma_i Z_i^2 n_i/n_e$ with Z_i the atomic number of species i. The subscript e refers to electrons (we note that the $n\tau$ curves in Fig. 2 take into account the bremsstrahlung power loss as well as the fusion power gain). As bremsstrahlung is not significantly reabsorbed by the plasma in configurations appropriate to controlled fusion, the losses are not readily "recycled" back into the system (except perhaps with some thermodynamic efficiency ~35%–40%). Impurities sputtered from the wall can accumulate in plasmas and can cause significant increase in the bremsstrahlung loss rates even if the hydrogen component is not significantly diminished. Hence the suppression of impurity accumulation is critical in plasma containment. Because of bremsstrahlung losses many possible neutron-free fusion reactions cannot be used for fusion power production. Examples include $p + {}^{11}B \rightarrow 3\alpha + 8.7$ MeV, $p + {}^6\text{Li} \rightarrow {}^4\text{He} + {}^3\text{He} + 4$ MeV, etc.

2.2.2 Synchrotron Radiation. The other important radiation process with significant energy loss is synchrotron radiation. This is single-particle radiated power due to cyclotron motion of electrons in a magnetic field, which is given by

$$P_{\text{sync}} = 3nT/\tau_{\text{sync}} \tag{4}$$

with

$$n\tau_{\text{sync}} = 1.9\times10^{21}\beta/T_{10k} \text{ m}^{-3}\text{ s}$$

with $\beta = 4\mu_0 kT/B^2$ the ratio of kinetic pressure to magnetic pressure, a fundamental plasma parameter in magnetic fusion. If the radiated power were to propagate without further absorption, this parasitic loss mechanism would severely affect the viability of nearly every magnetic fusion concept. Fortunately, most of the radiation is reabsorbed by the plasma, and even escaping radiation can be reflected by external conducting walls and reabsorbed by the plasma. Calculations show that synchrotron losses do not constitute a constraining loss mechanism in a *d-t* reactor, whereas they do constrain *d-d* or *d*-^{3}He reactors to operate at moderately high β values (typically $\beta \gtrsim 15\%$).

2.2.3 Diffusion. The other important mechanism that determines plasma lifetime is particle diffusion. In subsequent sections we shall describe magnetic containment configurations in which the particle orbits are isolated from the surrounding walls. However, binary collisions and fluctuating fields cause particles to deviate from their orbits, and eventually these particles diffuse to the walls. Energy losses due to binary collisions can be reliably calculated. Such losses, together with radiation, establish the intrinsic containment properties of a given configuration. In toroidally shaped devices collisional losses are generally compatible with reactor operation. In open-ended devices, these losses are a significant constraint for power production.

2.2.4 Turbulence Losses. Losses due to fluctuations from instabilities appear to govern the lifetime of almost every magnetic fusion experiment that has been developed. Roughly, these losses can be categorized in two forms: those due to macroinstability and those due to microinstability. In macroinstability, the unstable mode affects the entire plasma column and the loss of integrity of the confinement scheme. In such cases the losses are usually incompatible with achieving energy production. However, in some cases macroinstability is localized to the plasma interior, and the integrity of the thermal insulation can still be maintained.

In microinstability the instability structure is on a scale small compared to the plasma size. These fluctuations cause stochastic motion of particles, much like that produced by collisional diffusion. Typically it is this diffusive process that appears to determine thermal containment time of even the best-contained plasmas. The detailed mechanisms for such losses are not fully understood, and the theoretical and empirical descriptions of these losses are still being established (Callen, 1992).

The control of these self-induced fluctuations is a key to obtaining the plasma parameters needed to fulfill the Lawson condition. Such fluctuations can have a beneficial effect. For example they can prevent the buildup of unwarranted impurity in the plasma center, or they can allow dynamo action to maintain steadily the magnetic structure of a configuration that would not be possible to sustain in absence of fluctuations. It now appears that, at least in tokamak experiments, the natural fluctuation level is compatible with the achievement of controlled fusion conditions.

3. MAGNETICALLY CONFINED EQUILIBRIUM

In order to prevent heat from escaping from a confined hot plasma to the cold surroundings, a means of providing both confinement forces and thermal insulation is needed. Magnetic fields can in principle provide both properties.

Many different magnetic field configurations have been proposed. Roughly the proposals can be divided into two classes, toroidal and open ended. In the former case the trajectories of magnetic field lines lie on a surface of a torus, as shown in the spiral lines in Fig. 3. Charged particles, which constitute the plasma, move nearly parallel to these field lines, and as a result under many conditions the particles remain inside the torus. In open-ended machines the trajectories of magnetic field lines inside the plasma reach the surrounding wall as shown in the two configurations of Fig. 4. However, particles are inhibited from reaching the wall if the magnetic field strength increases toward the wall.

In this section we will discuss some basic ideas in magnetic plasma containment and show how they have been specifically applied to various containment concepts.

3.1 Magnetohydrodynamic Equilibrium Equations

To understand containment one can examine solutions of the magnetohydrodynamic (MHD) equilibrium equations (see MAGNETOHYDRODYNAMICS), which take the form

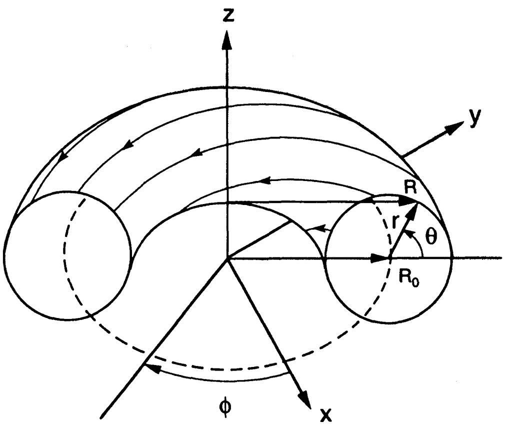

FIG. 3. Typical toroidal configuration showing coordinates (Z,R,ϕ) and (r,θ,ϕ).

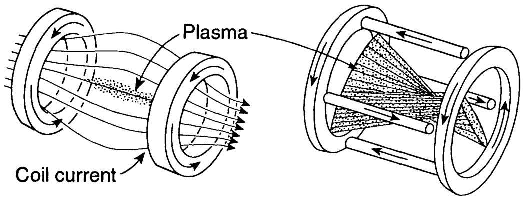


(a) Simple mirror with Helmholtz Coils

(b) Min-B mirror with quadrupole coils

FIG. 4. Two mirror configurations which are examples of open-ended machines. The symmetric mirror (a) tends to be MHD unstable. With a quadrupole field, shown in (b), stabilizing concave-shaped field lines are produced.

$$\mathbf{j}\times\mathbf{B}=\nabla\cdot\mathbf{P},\qquad \nabla\times\mathbf{B}=\mu_0\mathbf{J}, \tag{5}$$

where $\mathbf{B}$ is the magnetic field, $\mathbf{j}$ the current density, and $\mathbf{P}$ the generalized momentum flux tensor. It is frequently appropriate to take $\mathbf{P}$ as isotropic, whereupon $\mathbf{P} = p\mathbf{I}$ with p the scalar pressure and $\mathbf{I}$ the unit dyadic (pressure isotropy is established if the particle lifetime is longer than the collisional relaxation time to a Maxwellian distribution). These equations can be written in stress conservation form,

$$\nabla\cdot\mathbf{\Pi}=0, \tag{6}$$

with the stress tensor given by $\mathbf{\Pi}=\mathbf{BB}/\mu_0-(B^2/2\mu_0)\mathbf{I}-\mathbf{P}$. One can show from the virial theorem that Eq. (5) only allows solutions if on a surface S bounding the containment volume, the "force" $\int\mathbf{\Pi}\cdot\mathbf{n}\,dS$ is nonzero, with $\mathbf{n}$ the unit normal vector to the bounding surface S. This means that in order to obtain equilibrium one must supply an external anchor. One type would simply be plasma leaning against external solid material walls. This method is not generally satisfactory since thermal heat losses would usually be too large [nonetheless there are serious "wall containment" concepts, such as originally proposed by Budker, being developed that depend upon the relatively low heat conduction across magnetic fields to obtain the needed thermal insulation (Ryutov, 1975)]. The more standard technique is to have magnetic coils, which establish external magnetic fields that can isolate the plasma from wall contact. In turn these coils need to be anchored by external forces.

3.2 Two-Dimensional Pinch Solutions

To begin to understand the solutions of Eq. (5), it is informative to consider a system that is unbounded in the z direction, symmetric in the θ direction (where θ is the angle about the z axis), and contained radially in r. If we take the momentum flux tensor $\mathbf{P}$ as isotropic, $\mathbf{P}=p\mathbf{I}$ (note that p is the particle pressure) and the magnetic field of the form $\mathbf{B}=\hat{\mathbf{z}}B_z(r)+\hat{\theta}\,B_\theta(r)$, the general solution to Eq. (5) is

$$p(r)+\frac{B_z^2(r)}{2\mu_0}-\left\langle p+\frac{B_z^2}{2\mu_0}\right\rangle=-\frac{B_\theta^2(r)}{2\mu_0}, \tag{7}$$

where

$$\langle a(r)\rangle=2r^{-2}\int_0^r dr'r'a(r').$$

There are several issues that this form illustrates. First of all, at a wall $r = a$, the pressure $p(a)$ can vanish, and the averaged contained pressure is then

$$\langle p\rangle=[B_z^2(a)+B_\theta^2(a)-\langle B_z^2\rangle]/2\mu_0. \tag{8}$$

We see that the particle pressure can be expressed in terms of a containment parameter,

$$\langle\beta\rangle=2\mu_0\langle p\rangle/B_z^2(a), \tag{9}$$

where $B_z(a)$ is also the applied external magnetic field if there are no embedded external current carriers inside the plasma. Equation (7) then becomes

$$\langle\beta\rangle=1-\langle b_z^2\rangle+b_\theta^2(a) \tag{10}$$

with $b_j(r)=B_j(r)/B_z(a)$.

We now note that there is freedom in specifying b_z or b_θ. The case where $b_\theta=0$ is the "theta pinch" solution, where the nomenclature arises because in such a configuration the plasma current is in the θ direction. In this case one can show that $1>b_z^2(r)$, and hence $\langle\beta\rangle\leqslant 1$. This is why β is frequently used as a measure of effectiveness of stored plasma pressure with respect to an applied magnetic field.

In principle the greatest effectiveness in confining plasma is obtained with the z-pinch solution where plasma currents are in the z direction and $B_z=0$. This case does not require any external magnetic field to achieve radial containment (note that the θ pinch is unbounded in the z direction, which is why the virial theorem is not violated). Thus from just its equilibrium properties, the z pinch is extremely attractive for fusion application. Unfortunately, in its most basic form the z pinch is highly unstable, and drastic modification of the configuration is usually considered necessary to have a tractable concept. Nonetheless, interest in the pure z pinch continues today. Novel ideas for stabilization are being investigated by Lehnert in the ex-trap experiment (Drake *et al.*, 1989). There is also considerable interest by several groups in the high-density fast z pinch produced from thin fibers, e.g., Haines *et al.* (1991), where the time scale for producing fusion energy might be more rapid than the time scale for instability to develop.

The most direct way to stabilize a z pinch is to have simultaneously both $\hat{\mathbf{z}}$-directed and $\hat{\boldsymbol{\theta}}$-directed currents. In Eq. (7) the kinetic pressure and the magnetic pressure due to B_z are completely interchangeable. In the limit of zero kinetic pressure, the solution is a "force-free solution," where the plasma currents are parallel to the magnetic field so that the magnetic force $\mathbf{j}\times\mathbf{B}=0$. There is a class of solutions where the direction of B_z changes inside the discharge, and such solutions are characteristic of the reversed-field pinch (RFP), one of the important concepts in controlled fusion research.

Another prototype solution contained in the structure of Eq. (7) is one where B_z is nearly constant within the discharge and the plasma beta is low. Typically, $\beta_z=2\mu_0 p/B_z^2 \ll 1$ while $\beta_\theta=2\mu_0 p/B_\theta^2 \approx 1$. Such discharges are stable for a wide range of parameters and are the basis of the so-called tokamak, the lead concept for achieving fusion by magnetic containment. Many issues in tokamak containment will be discussed later.

Both these "low-β" solutions sacrifice high-β effectiveness in exchange for achieving stability. Beta values ~10% have been achieved in these concepts and the determination of the upper permissible beta is one of the important questions under investigation in controlled fusion.

3.3 End Stoppering

The magnetohydrodynamic (MHD) solutions presented thus far do not exhibit axial containment. For axial containment either we have to "stopper" the ends or we have to wrap the straight solutions into a torus. First we discuss end stoppering.

Axial stoppering can be achieved by varying the magnitude of the magnetic field along the z axis if the pressure tensor is anisotropic. As particle orbits in a magnetic field cause the pressure tensor to be symmetric about the magnetic field direction, while the parallel component is unaffected by the magnetic field, the pressure tensor $\mathbf{P}$ takes the form

$$\mathbf{P}=p_\perp(\mathbf{I}-\mathbf{bb})+p_\parallel\mathbf{bb}, \tag{11}$$

where $\mathbf{b}$ is in the direction of the magnetic field, $p_\perp$ is the perpendicular pressure, and $p_\parallel$ is the parallel pressure. The component of Eq. (11) along the magnetic field gives the relation

$$\frac{\partial p_\parallel}{\partial s}=\frac{-(p_\perp-p_\parallel)}{B}\frac{\partial B}{\partial s}, \tag{12}$$

where s is the distance along a field line. This equation shows that the pressure $p_\parallel$ can be confined along the magnetic field if B increases toward the ends. This axial containment is an example of the mirror principle. In Sec. 4 we will study in more detail how electric and magnetic forces act on particles to achieve containment.

3.4 Toroidal Configurations

The two-dimensional pinch solution is frequently considered as a mathematical limit of a large-aspect-ratio toroidal system. However, this "attachment" of ends of a nearly straight system onto itself brings in many new physical features, some of which are discussed in this section and others in Sec. 4.

3.4.1 General Considerations. To study containment in toroidal configurations, Eq. (5) has to be solved in three-dimensional geometry. A typical three-dimensional configuration is shown in Fig. 3. In such a configuration there is a toroidal axis of radius R_0 (the dashed curve in Fig. 3) on which a magnetic field closes on itself. Frequently R_0 is constant, but in principle R_0 can vary as it does in some concepts. The other field lines wrap around the toroidal axis as indicated by the lightly drawn spirals in Fig. 3. The winding number of a field line is the ratio of the number of times it wraps around poloidally (the short way around) to the number of times it wraps around toroidally (the long way around). The winding number is commonly called the rotational transform ι; its inverse, $1/\iota$, is denoted as q, the safety factor, which is a parameter closely related to plasma stability. A convenient set of coordinates, shown in Fig. 3, is the toroidal angle ϕ, the poloidal angle θ, and the radial distance to the magnetic axis r. For a toroidally symmetric configuration one can readily show that if the rotational transform is irrational, a single field line is constrained to lie on a surface. Such "magnetic flux" surfaces can also be attained in configurations that are not axisymmetric. This property leads to the stellarator concept, to be discussed below, where the flux structure can be formed directly from external magnetic coils, rather than the internal plasma current.

3.4.2 Vertical Field. In a toroidal pinch, there will be a toroidal plasma current $I_p\hat{\boldsymbol{\phi}}$ that produces B_θ fields. The average self-magnetic force, $\langle \mathbf{I}_p \times \mathbf{B}_s \rangle$ with $\mathbf{B}_s$ the magnetic field produced by $\mathbf{I}_p$, produces the so-called hoop force directed outward in the $\hat{\mathbf{R}}$ direction. This self-force tends to produce expansion of the current ring. To obtain confinement, this force must be compensated by an external vertical magnetic $\mathbf{B}_v$, directed such that $I_p\hat{\boldsymbol{\phi}} \times \mathbf{B}_v$ is in the $-\hat{\mathbf{R}}$ direction. For a torus of large aspect the magnitude of $\mathbf{B}_v$ is found to be

$$\mathbf{B}_v = \frac{aB_\theta(a)}{2R_0}\left(\ln\frac{8R_0}{a} - \frac{3}{2} + \frac{l_i}{2} + \langle \beta_\theta \rangle\right), \tag{13}$$

where $B_\theta(a)$ is the poloidal component of the magnetic field that is generated by the plasma current $I_p \approx 2\pi a B_\theta(a)/\mu_0$,

$$\langle \beta_\theta \rangle = 2\mu_0 \int_0^a dr\, rp(r)/a^2 B_\theta^2(a)$$

is the average beta with respect to the magnetic field, and l_i (the internal inductance) is a quantity of order unity that depends on the detailed current profile. The need of such an external vertical field can be viewed as a consequence of the virial theorem.

From Eq. (13) one infers that the intrinsic β value with respect to the vertical field is large, with $\beta \approx R/a$. Such high beta values can arise if the toroidal magnetic field B_ϕ is zero. However, stability considerations demand the presence of an external toroidal magnetic field B_ϕ, which considerably reduces the β that can be achieved. In the RFP the toroidal B_ϕ and poloidal B_θ magnetic fields are comparable in magnitude, while in the tokamak B_ϕ is considerably larger than B_θ—typically $B_\phi/B_\theta \approx R/a$.

We also note that toroidal magnetic fields are typically produced by magnetic field coils where the coils are wound through the hole in the plasma as shown schematically in Fig. 5(a). In Fig. 5(b) the plasma region and toroidal field coil are shown as they exist in the Text tokamak. The inner coil structure gives rise to complications that would be worth while to avoid if an alternative configuration proved suitable. This is a motivation for the study of compact toroids where there are no external coils through the plasma hole.

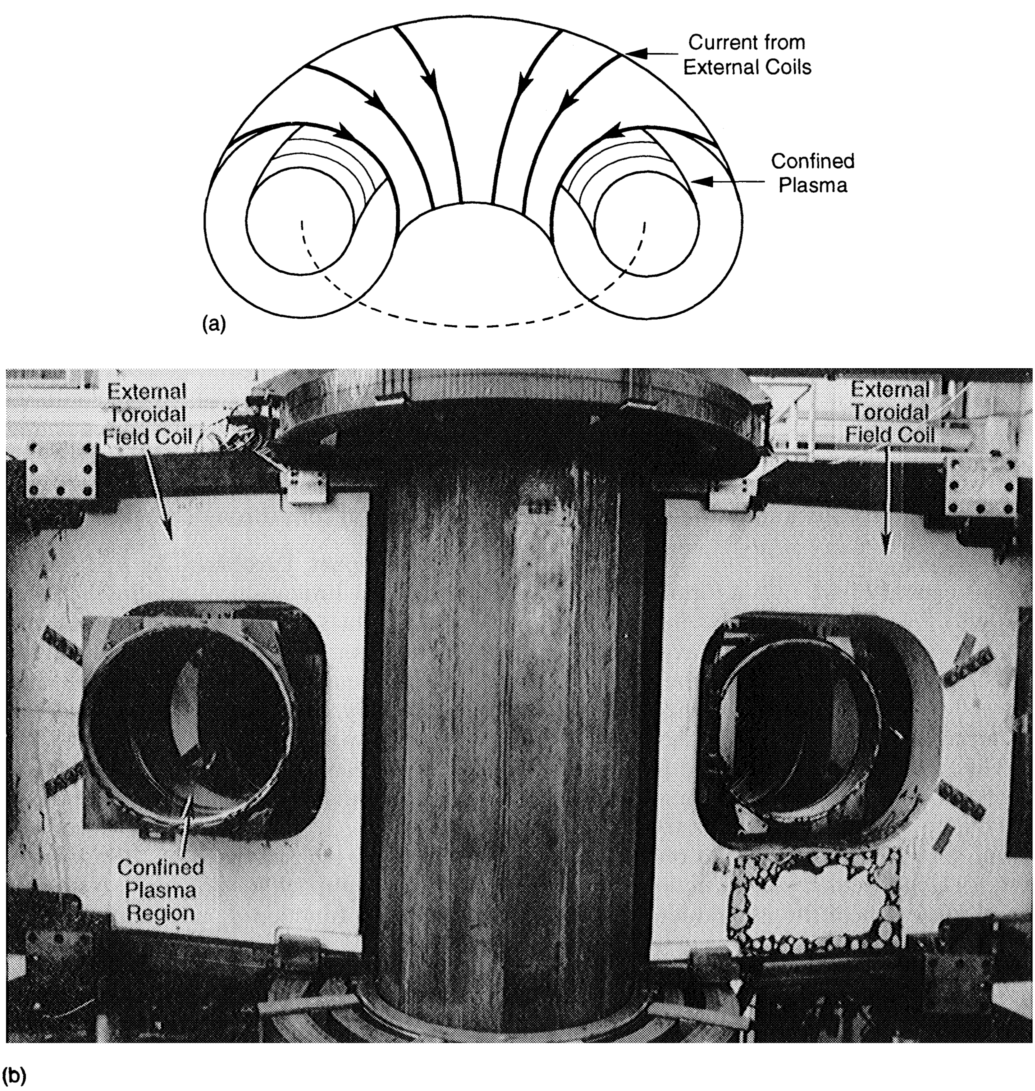
3.4.3 Compact Toroids. As $\beta \approx a/R$ appears to be a limitation of confinement, increased β values are achieved by increasing a/R. The extreme is to have $a/R \approx 1$. If in this case the external toroidal field coils are eliminated entirely, one need not have hardware through the inside of the torus. Instead, the plasma can reach the axis of the machine, and one has a configuration known as a compact toroid.

To discuss the structure of the magnetic fields in a compact toroid, we introduce a magnetic flux function ψ_p where

$$\mathbf{B}_\theta = \nabla\psi_p \times \hat{\boldsymbol{\phi}}/2\pi R.$$

The magnetic field then lies along contours of constant ψ_p. A schematic figure of the flux surface of a compact toroid is shown in Fig. 6. The z axis is an axis of revolution. The poloidal magnetic field is closed and reverses direction inside the separatrix (the separatrix is the curve that intersects at the points marked by $\times$, which separate the closed and open field lines). The closed field lines constitute the region of containment. Outside the separatrix the field lines are open, and the plasma that reaches these outer lines, as well as plasma reaching the z axis, flows toward the walls. By and large, the flux surfaces are produced by the toroidal plasma current. However, the hoop force still needs to be compensated for by an external vertical magnetic field, just as in the large–aspect-ratio case.

As an example, a prototype analytic solution for the flux ψ_p without toroidal field, which satisfies Eq. (5), is



Current from External Coils
Confined Plasma
(a)
External Toroidal Field Coil
External Toroidal Field Coil
Confined Plasma Region
(b)

FIG. 5. (a) In the usual toroidal configuration the plasma is surrounded by external toroidal field coils as indicated schematically by the heavy lines with arrows. (b) The plasma region and field coils are shown for the Text tokamak, at the University of Texas, Austin. The central region is the structural support as well as the magnetic flux column that is used as a transformer to drive plasma current.

$$\psi_p = 4\psi_{\max}(R^2/R_0^4)(R_0^2 - R^2 - \alpha^2 z^2), \qquad (14)$$

where

$$\frac{\psi_{\max}}{2\pi} = \frac{R_0^2}{4}\left(\frac{\mu_0 p_0}{2(1+\alpha^2/4)}\right)^{1/2},$$

$$p = p_0 \psi_p / \psi_{\max} .$$

R and z are radial and axial cylindrical coordinates indicated in Fig. 6, and R_0 is a constant. The plasma pressure is confined to the region $\psi_p > 0$, and the curve $\psi_p = 0$ defines the separatrix. For this solution the separatrix forms an ellipsoid of revolution with major axis R_0 in the radial direction, and R_0/α in the z direction. The required external magnetic field $\mathbf{B}_{\text{ext}}$ is directed in the z direction. The needed external field B_{ext} can be expressed in terms of a beta condition $\beta_0 = 2\mu_0 p_0 / B_{\text{ext}}^2$, with p_0 the pressure at the 0 point of Fig. 6 where the poloidal magnetic field vanishes. For a spherically shaped separatrix ($\alpha = 1$), $\beta_0 = \frac{45}{16}$, while for an axially elongated separatrix ($\alpha \to 0$), $\beta_0 = 1$.

Another type of compact toroid, known as the spheromak, is one where the plasma also

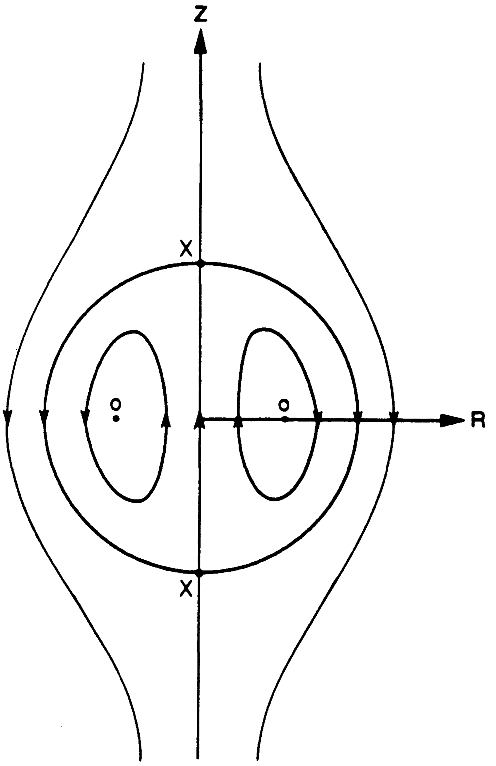


FIG. 6. Schematic flux surface of a compact toroid. The three-dimensional configuration is envisaged by revolving this plot around the z axis. Closed poloidal field lines are closed inside the separatrix curve passing through the points labeled ×. Outside the separatrix, field lines are open. The poloidal flux maximizes at the poloidal field null inside the toroid where $B_\theta=0$ and which is indicated by the points labeled 0. There are no external current carriers penetrating the torus. A toroidal field inside the toroid can arise from plasma currents flowing along poloidal field lines.

carries poloidal current, so that toroidal magnetic field exists inside the containment region, but not outside the separatrix. In these configurations the roles of kinetic pressure and magnetic field pressure from the toroidal field are nearly interchangeable. Now, both the kinetic pressure and toroidal magnetic field pressure maximize at the 0 point and vanish at the separatrix.

A third type of compact toroid is Astron (Christofilos, 1962). This is a configuration where current carriers are energetic particles. In this case the external magnetic field B_{ext} confines the energetic particles in orbits that are essentially the betatron orbits that appear in the theory of particle accelerators (see BETATRONS). The dominant momentum flux associated with the orbits of this configuration is

$$\mathbf{P}=m_b\langle n_b v_\theta^2\rangle\hat{\theta}\hat{\theta} \tag{15}$$

with m_b and n_b the mass and density of the energetic particles and v_θ the θ-directed velocity component. Now Eq. (5) needs to be solved using Eq. (15) for $\mathbf{P}$. If the current formed by this beam of energetic particles is intense enough, the shape of the poloidal magnetic fields is similar to that obtained with the other compact toroid solutions.

3.4.4 Inductive Voltage Drive. The diverse toroidal concepts discussed will last only a magnetic diffusion time unless magnetic flux is "pumped" into the configuration. The diffusive nature of the discharge can be inferred from combining Faraday's induction law, Ohm's law, and Ampère's law, which leads to a diffusionlike equation for the flux ψ_p that is essentially of the form

$$\frac{\partial\psi_p}{\partial t}=\frac{1}{\sigma\mu_0}\,\Delta\psi_p \tag{16}$$

with σ the electrical conductivity. Unless a source of flux is present, Eq. (16) predicts that the magnetic configuration decays with a characteristic time τ_M given by

$$\tau_M\approx\mu_0\sigma a^2/4\approx 4\times10^{-4}a^2T^{3/2}(\text{eV})/Z_{\text{eff}}\ \text{s},$$

where a is the minor radius in meters and T_e(eV) the electron temperature in electron volts, and the electrical conductivity is $\sigma = 1.3\times10^3T_e^{3/2}$ (eV)$/Z_{\text{eff}}$ siemens/m with Z_{eff} the mean atomic number of the discharge. Sample diffusion times are $\tau_M=6\times10^{-3}$ s for $a=0.2$ m, $T_e=50$ eV, which are typical of startup parameters; $\tau_M=1.0$ min for $a = 1.0$ m, $T_e=3$ keV, which are typical parameters for present-day tokamaks; and $\tau_M=0.8$ h for $a=2$ m, $T=15$ keV, which are typical of fusion reactor parameters. We observe that stronger magnetic flux pumping is required for small devices at low temperatures than for large devices at high temperatures.

The most obvious flux pump mechanism is to link magnetic flux, just as one does in a transformer, as shown in Fig. 7. The flux ψ_F in the solenoid core is $\psi_F = B_FA_F$, where B_F is the magnetic field in the solenoid and A_F the cross-sectional area of the solenoid. If B_F

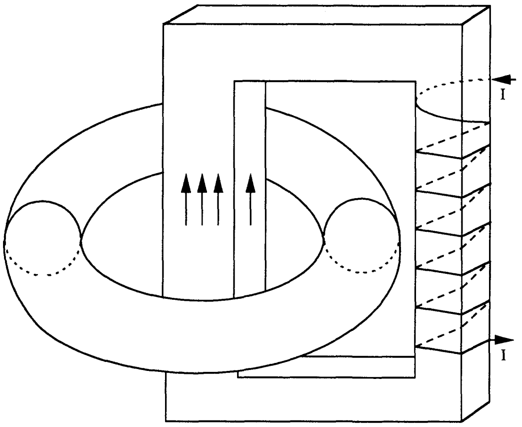

FIG. 7. Transformer link to a toroidal plasma. The change of magnetic flux inside the central transformer column supplies toroidal voltage to the plasma.

changes from B_{FM} to $-B_{FM}$, it follows from Faraday's law that a voltage V_F is imposed on the core plasma given by

$$V_F = \frac{-\partial\psi_F}{\partial t} = \frac{-\partial B_F}{\partial t} A_F .$$

In turn, the voltage is Ohmically dissipated by the plasma, so that $V_F = -A_F\, \partial B_F/\partial t = I_p\mathcal{R}$ with I_p the plasma current and $\mathcal{R}$ the plasma resistance ($\mathcal{R} \approx 2R/\sigma a^2$). Because the total flux that can be pumped is limited to $2A_F B_F$, then for a fixed current and resistance the solenoid can supply voltage for a time t_F given by $t_F = 2B_{FM}A_F/I_p\mathcal{R}$. This Ohmic method of magnetic flux pumping will allow a reactor to operate on the scale of hours. Though quite long by today's standards, Ohmic magnetic flux pumping implies periodic shut-down and start-up of the reactor, which is not desirable from several engineering considerations (one of the more significant reasons is that the many start-up phases lead to large changes in the wall temperature, which cause continual thermal stress that eventually causes wall fracture). Hence, alternative flux pumping techniques, frequently called current drive, are desirable (Fisch, 1987). For example, radio-frequency waves have been used to drive steady plasma currents through a variety of mechanisms. Though less efficient than Ohmic drive, they do offer the possibility of achieving truly steady-state operation in a toroidal machine where plasma current is needed to form nested flux surfaces.

3.4.5 Stellarators. A way to avoid the need for driving current in a toroidal plasma is to design a stellarator configuration where flux surfaces form solely from the current in the external coils. The demonstration that "vacuum magnetic fields" form flux surfaces can be inferred from the properties of a periodic stellarator with helical symmetry and arbitrarily large aspect ratio. Consider a cylindrical coordinate system (r,θ,z), with the system extended in z, and define a phase variable $\chi = \theta - \alpha z$ with α a constant. The vacuum magnetic field can be expressed as $\mathbf{B} = \nabla\Phi$, which, with $\nabla \cdot \mathbf{B} = 0$, requires Laplace's equation to be satisfied, $\Delta\Phi = 0$. A helical stellarator solution has the form

$$\Phi = B_0\, z + \frac{1}{\alpha} \sum_{n=1}^{\infty} b_l I_l(l\alpha r) \sin(l\chi), \tag{17}$$

where $I_l(x)$ is the Bessel function of imaginary argument. The field lines generated by these solutions lie tangent to a helical flux function ψ_H,

$$\psi_H = B_0 \frac{\alpha r^2}{2} - r \sum_{l=1}^{\infty} b_l I_l'(l\alpha r) \cos l\chi. \tag{18}$$

These solutions are the first approximations to the fields that can be generated in a torus with a large aspect ratio ($R_0/a \gg 1$, where R_0 and a are typical major and minor radii). Helical solutions are obtained by winding the external current carrier in a helix M/l times around poloidally for each toroidal turn, with M an integer and $\alpha = M/lR_0$. The pitch of the coil is M/l. Examples of the shapes of constant–helical-flux contours at fixed z generated from various coil configurations are given in Fig. 8(a). At a given poloidal cross section there are l current paths flowing in one direction [shown by the symbol ⊕ in Fig. 8(a)] and perhaps l current paths in the opposite direction (shown by the symbol ⊖). If the latter set of currents is absent the configuration is called a heliotron or torsatron; with a torsatron a single coil forms toroidal and helical fields. The magnetic field lines inside the torus wind around the magnetic axis with a rotational transform that is less than the pitch of the current loops. The rotational transform increases with increasing radial distance until a separatrix is reached (in these figures the separatrices are the contours that cross on themselves), where the

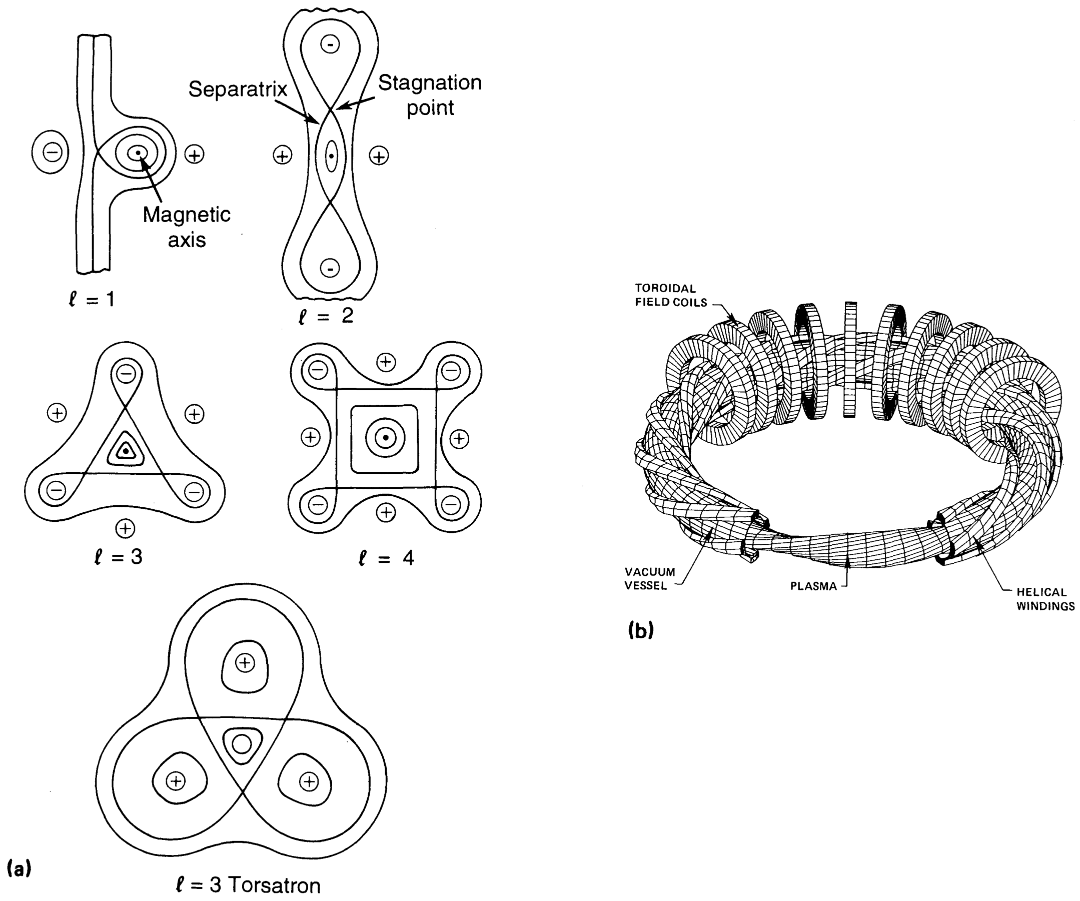

FIG. 8. (a) Magnetic surfaces showing separatrix points, and separatrices for $l=1$, 2, 3, and 4 stellarators and for the $l=3$ torsatron. (b) Three-dimensional view of coil set of an $l=2$ classical stellarator (Wendelstein VII-A) showing the twisting magnetic flux surface (from Carreras *et al.*, 1988).

rotational transform equals the pitch. At radii outside the separatrix, field lines are not contained but intersect the wall. Unlike in a typical tokamak, $q = 1/\iota$ decreases away from the magnetic axis.

In practice a straight system must be wrapped into a large–aspect-ratio torus as in Fig. 8(b). Observe that the magnetic flux surfaces twist to follow the external helical currents. However, strict helical symmetry is broken by the toroidal shape. With strict helical symmetry it follows from Eq. (18) that the magnetic fields inside the separatrix have nested flux surfaces. With helical symmetry broken (as it must be in a toroidal configuration), it is not at all obvious that a field line generates a magnetic flux surface rather than filling a volume of space. Fortunately, the flux surface property is retained over a large volume surrounding the magnetic axis. However, flux surfaces disappear near the separatrix (there field lines meander over a finite volume) and additional structure in the field lines (so-called magnetic islands) arises near surfaces with rational rotational transform. With proper coils, an acceptable volume of mostly nested magnetic surfaces can be designed. Within these good surfaces, plasmas can be retained to beta values comparable to what is possible with tokamaks.

Historically, the stellarator concept was one of the pioneering confinement concepts in controlled fusion. The three-dimensional aspect of the configuration made design and analysis difficult, and progress in the field (in part because of poor design choices) lagged behind tokamak research. In more recent years, as a result of clearer conceptual ideas of the stellarator concept, very promising experimental results have emerged in stellarator research. Today, the stellarator concept, with its multiple design options and its intrinsic truly steady-state nature, is a leading alternative to tokamaks as a means for achieving fusion-grade plasmas (Carreras *et al.*, 1988).

4. PARTICLE ORBITS AND CLASSICAL TRANSPORT IN MAGNETICALLY CONFINED PLASMAS

4.1 Particle Orbits in Magnetic and Electric Fields

Without magnetic and electric fields or collisions, a particle in an enclosed volume moves in a straight line until it hits the surrounding wall. Magnetic and electric fields can be designed to prevent the particles from hitting bounding surfaces. The orbits are determined from the equations of motion,

$$\mathbf{v}=\frac{d\mathbf{r}}{dt}, \quad M_j\frac{d\mathbf{v}}{dt}=e_j(\mathbf{v}\times\mathbf{B}+\mathbf{E}), \tag{19}$$

with M_j and e_j the mass and charge, respectively, of species j. When $\mathbf{B}$ is spatially uniform and $\mathbf{E}=0$, the particle motion perpendicular to the magnetic field is a circle with a radius $\rho_j=v_\perp/\omega_{cj}$ (known as the Larmor radius) about a point called the guiding center, where $v_\perp$ is the velocity component perpendicular to the magnetic field and $\omega_c = e_jB/M_j$ is the cyclotron frequency of species j. However, the parallel velocity, $v_\parallel\equiv\mathbf{v}\cdot\mathbf{B}/B$, remains constant and the particle moves without containment parallel to the magnetic field in a manner shown in Fig. 9(a). With a homogeneous static electric field present perpendicular to the magnetic field, a particle takes on an additional drift motion, $\mathbf{v}_E=\mathbf{E}\times\mathbf{B}/|B|^2$, giving rise to a motion shown in Fig. 9(b), with the motion of the guiding center being perpendicular to the direction of $\mathbf{E}$.

The motion we have described has not taken into account collisions between particles due to the binary Coulomb interaction. Because of the long-range nature of the Coulomb potential, the many small-angle deflections arising from collisions with relatively large impact parameters are more important than the large-angle deflections arising from collisions with small impact parameters. The small-angle deflections cause the particle pitch angle $\theta=\cos^{-1}(v_\parallel/|\mathbf{v}|)$ of species j to change by 90° in a characteristic scattering time τ_j, which is given by

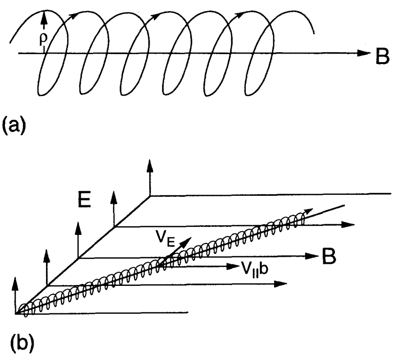

FIG. 9. (a) Motion of a charged particle in a uniform magnetic field. (b) Motion of a charged particle in uniform electric and magnetic fields that are perpendicular to each other. The particle guiding center moves in a plane perpendicular to **E**.

$$\begin{aligned} n_e\tau_i&\approx 1.5\times10^{10}A^{1/2}E_i^{3/2}(\text{keV})/Z^3,\\ n_e\tau_e&\approx 1.5\times10^{10}(M_e/M_i)^{1/2}E_e^{3/2}(\text{keV})/\\ &\quad(1+1.5Z), \end{aligned} \tag{20}$$

where E_j(keV) is the mean energy of species j in keV, $j\equiv i$ refers to ions, $j\equiv e$ refers to electrons, A and Z refer to the ions' atomic mass and number, respectively, and we assume only one ion species for simplicity.

As a particle scatters, the guiding center of a particle likewise deflects, and in a scattering time $t = \tau_j$, the guiding center is deflected by roughly one Larmor radius. For time scales much longer than τ_j the evolution across field lines is described by random walk theory. The diffusion coefficient D_j for species j is given by $D_j=\Delta x_j^2/\Delta t$, with Δx_j the random step that occurs after a time Δt. In our case, $\Delta x=\rho_j$ and $\Delta t=\tau_j$, which gives the "classical" diffusion coefficient of a particle in a straight magnetic field,

$$D_j\approx\rho_j^2/\tau_j. \tag{21}$$

When collisions are taken into account in fields where **E** and **B** are mutually perpendicular, particle diffusion across field lines gives rise to a thermal conduction coefficient $\chi\sim D_i$. As a result, for a slab model of a plasma, with the magnetic field in the z direction and an electric field in the x direction, and with the plasma confined in x within a characteristic spatial scale $L_p \gg \bar{\rho}_i$ ($\bar{\rho}_i = \sqrt{2T_i/m_i}$), the characteristic lifetime for energy confinement, τ_{th}, is

$$\tau_{\text{th}} \approx L_p^2/\chi_i \approx L_p^2 \bar{\tau}_i/\bar{\rho}_i^2 \, , \tag{22}$$

where for $\bar{\tau}_i$ we use Eq. (20) with $E_i = T_i$. As $L_p \gg \bar{\rho}_i$, the energy lifetime is many 90° deflection times.

In addition collisions prevent the unbounded acceleration of particles when a parallel electric field is present. With collisions the parallel equation of motion gives roughly

$$\frac{dv_\parallel}{dt} = e_j \frac{E_\parallel}{M_j} - \frac{v_\parallel}{\tau_j}$$

with a steady-state solution $v_\parallel = e_j E_\parallel \tau_j / M_j$ which produces a plasma current

$$j_\parallel = -en_e(v_{\parallel e} - v_{\parallel i}) \approx \tau_e n_e e^2 E_\parallel / M_j \equiv \sigma E_\parallel$$

with e the magnitude of the electron charge. Within a numerical coefficient this value of σ reproduces the electrical conductivity used in Eq. (16).

4.2 Spatially Varying Fields

By considering magnetic and electric fields that vary slowly in space compared to a Larmor radius, and slowly in time compared to a cyclotron period $\sim 1/\omega_c$, one can demonstrate particle containment along the magnetic field. Under these conditions the quantity $\mu \equiv m(\mathbf{v}_\perp - \mathbf{v}_E)^2/B$ is an adiabatic invariant, i.e., it remains conserved to high accuracy during a particle's motion. As a consequence of this invariance, the parallel velocity of the guiding center, $v_\parallel$, is given by

$$v_\parallel = \pm \{ (2/M_j) [\mathscr{E} - \mu B(s) - e_j \, \Phi(s)] \}^{1/2}, \tag{23}$$

where $-\nabla\Phi = \mathbf{E}$, $\mathscr{E} = \frac{1}{2}mv^2 + e_j \, \Phi$ is the total conserved particle energy, $B(s) = |\mathbf{B}|$, and Φ is the electrostatic potential. From Eq. (23) it is clear that if the magnetic field is increasing, a particle can be contained along the field line. Specifically, when $\Phi = 0$, the particle containment condition is

$$\frac{v_{\perp 0}^2}{v^2} > \frac{B_0}{B_{\max}} \equiv \frac{1}{R} \, , \tag{24}$$

where $B_{\max}$ and B_0 are respectively the maximum and mid-plane values of the magnitude of the magnetic field, $v_{\perp 0}$ is the velocity component perpendicular to the magnetic field, the subscript 0 refers to the value at the mid-plane, and R is called the mirror ratio. This type of containment is referred to as mirror containment, where particles that satisfy Eq. (24) oscillate between two turning points inside the mirror peaks [for an axially symmetric machine where $B(-s) = B(s)$ the turning points are at $s = \pm s_T$, where $B(s_T)/B_0 = v^2/v_{\perp 0}^2$]. Particles for which $v_{\perp 0}^2/v^2 < 1/R$ are in the so-called loss cone, and they leave the mirror machine in one transit time.

The particles that satisfy Eq. (24) are axially trapped and remain there for many axial bounce periods. The limiting lifetime, τ_{sc}, is determined by collisions causing a particle to pitch-angle scatter into the loss cone. This time is roughly $\tau_{sc} \sim \tau_j(1 - 1/R)$ for $R - 1 \ll 1$ and $\tau_{sc} \sim \tau_j \ln R$ for $R \gg 1$, with τ_j given by Eq. (20).

In the absence of parallel electric fields, electrons are lost more rapidly than ions, as $\tau_{sce}/\tau_{sci} \approx (M_e/M_i)^{1/2}(T_e/\bar{E}_i)^{3/2}$. Hence the plasma will charge up positively, producing an axial electric field pointing outward toward the mirror peaks. This field reinforces the containment of electrons and weakens the containment of ions. The magnitude of the negative potential adjusts so that the axial losses of electrons and ions will be equal. Thus the electrostatic potential is of intrinsic importance in the containment of plasma in a mirror machine. It is called an ambipolar potential, as it regulates the charged-particle loss to occur with nearly zero current flow.

The containment condition for ions and electrons with an ambipolar potential is obtained using Eq. (23) by demanding that the turning point s_T lie inside the mirror peak position at $s = s_{\max}$. This modifies the containment condition given by Eq. (24), to

$$v_{\perp 0}^2 > \frac{v_0^2}{R} + \frac{2e_j\Delta\Phi}{M_j R}, \tag{25}$$

where $\Delta\Phi = \Phi(0) - \Phi(s_{\max})$. For ions, where the charge $e_j = Ze$ is positive, we see that all ions with kinetic energy in the midplane less than $e_j\Delta\Phi/(R-1) \equiv E_{\text{crit}}$ are lost in one transit.

On the other hand, for electrons, where $e_j = -e$ is negative, the containment region is enhanced. All low-energy particles for which $\frac{1}{2}M_e v_0^2 < e\Delta\Phi/(R-1) = E_{\text{crit}}$ are trapped independent of pitch angle. Such particles can only be lost if during their diffusion process they gain energy. Electrons with midplane kinetic energies greater than E_{crit} are lost by pitch-angle scattering caused by collisions.

In mirror machine operation the ambipolar potential $e\Delta\Phi$ is generally several times the electron temperature T_e, which, as we shall see, is an order of magnitude less than the ion mean thermal energy. Hence, most electrons are trapped independent of pitch angle, where they remain for many collision times. Thus the bulk of electrons relax to nearly a Maxwell distribution. Only a high-energy tail of electrons, whose density is roughly $n_e\exp(-e\Delta\Phi/T_e)$, do not thermalize since these electrons are lost by pitch-angle scattering. Hence, the effective rate of loss $\nu_e(\Delta\Phi)$ of electrons with an ambipolar potential present is roughly

$$\nu_e(\Delta\Phi) \approx \frac{1}{\tau_e} \exp\left(-\frac{e\Delta\Phi}{T_e}\right).$$

If $q\Delta\Phi/(R-1) \lesssim \bar{E}_i$, the ion loss rate is somewhat reduced, but basically comparable to $1/\tau_i$ given by Eq. (20). Thus equating the electron and ion loss rates, we find that the ambipolar potential is roughly given by

$$\frac{\Delta\Phi}{kT_e} \approx \ln\left[\left(\frac{M_i}{M_e}\right)^{1/2}\left(\frac{\bar{E}_i}{T_e}\right)^{3/2}\right]. \qquad (26)$$

Typically this factor is ~5 while $\bar{E}_i/T_e \sim 10$. The reason why such a large ratio of $\bar{E}_i/T_e$ can be maintained in steady state is because a typical ion is lost with an energy somewhat less than its mean value $\bar{E}_i$, while a typical electron is lost with a mean energy $e\Delta\Phi + T_e \gg T_e$.

4.2.1 Q Value in a Mirror Machine. The ratio of the power produced by fusion to the power lost by classical collisions is frequently referred to as Q. Detailed solutions of the Fokker–Planck equation (the equation that describes the diffusive evolution of particle distribution functions due to multiple small-angle scattering) in mirror geometry show that Q can only slightly exceed unity for the *d-t* reaction. This result severely limits using a simple mirror machine for net energy production from the fusion reaction. Therefore, various methods to enhance the efficiency of energy production have been proposed. One simple procedure is to convert the energy flux of outgoing ions directly to electrical potential energy so that the effective Q value then becomes $Q_0/(1-\eta)$ where Q_0 is the original Q value and η is the ultimate fraction of the outgoing energy that can be reintroduced into the plasma ($\eta \sim 0.7$ is a realistic expectation).

4.2.2 Electrostatic Potentials in Tandem Mirrors. An alternative idea is the tandem mirror concept, where parallel electric fields are actively used to enhance the containment. A schematic of a basic tandem mirror configuration is shown in Fig. 10. There is a central cell mirror containing the bulk of the energy, where the potential is negative with respect to the surrounding end cells so that ions can be contained, while the end cells are separate mirror machines whose electrostatic potential with respect to the wall is positive so that electrons are contained as they are in a conventional mirror machine. This potential structure can be established if the mean ion energy in the end plugs is larger than the central-cell ion temperature. However, because of the much larger volume of the central cell, most of the energy is stored there. The role of end plugs is to serve as a containment dam that comes from the electric field structure. Pitch-angle scattering of ions in the central cell does not cause particle ion loss, while the potential between the plasma and the end wall prevents pitch-angle scattering of electrons from causing particle loss. The bulk losses arise only from pitch-angle scattering of ions and electrons in the high-energy tail. The ions in the

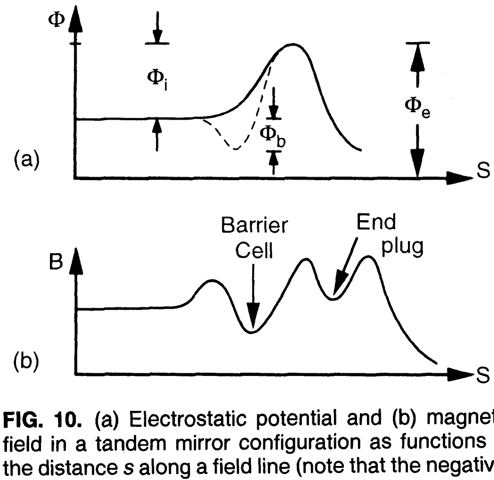

FIG. 10. (a) Electrostatic potential and (b) magnetic field in a tandem mirror configuration as functions of the distance *s* along a field line (note that the negative-*s* region is a reflection of the positive-*s* region). Φ_i and Φ_e are the containing potentials for ions and electrons. With a thermal barrier present, Φ_b is the potential that isolates electrons in the central cell from the end plug.

plugs are susceptible to the usual mirror losses, but their low inventory of total stored energy diminishes the seriousness of these losses. As a result the Q value of a tandem mirror can be increased substantially above that predicted for a simple mirror machine. Even further improvement in Q can be designed by actively controlling the ambipolar potential and forming so-called thermal barriers. The dashed curve in Fig. 10 indicates how the potential would look with a thermal barrier. With a thermal barrier present, the temperatures of electrons in the plug and central cell can be decoupled, which ultimately allows the ions in the plug to have a mean energy comparable to that in the central cell. Hence the parasitic losses due to collisions in the plug are not as severe as in the more conventional tandem mirror, and the Q value can be improved still further.

4.3 Orbits in a Toroidal Field

The alternative to an open-ended system is to have a toroidally shaped plasma. Then to the extent that particles follow field lines, one would expect containment inside the torus. However, toroidal containment is more subtle, as particle trajectories differ somewhat from the trajectory of a magnetic field even in the absence of electric fields. For example, consider the simplest magnetic field to return on itself, which arises from a straight wire, and has the form

$$\mathbf{B}=B_\phi(R_0/R)\hat{\boldsymbol{\phi}}\,, \tag{27}$$

where ϕ is the toroidal angle about the z axis, $\hat{\boldsymbol{\phi}}$ is a unit vector in the ϕ direction, R is the major radius, and R_0 is a convenient constant denoting the typical major radius. A magnetic field line in such a field is a circle of radius R. However, such a field does not allow charged particles to be contained in a closed volume. The magnetic field given by Eq. (27) has a finite magnetic field gradient $(1/|B|)\nabla|B| = -(1/R)\hat{\mathbf{R}}$ and field-line curvature $(\mathbf{b}\cdot\nabla)\mathbf{b} = -\hat{\mathbf{R}}/R$, where $\mathbf{b}=\mathbf{B}/|B|$ is the unit vector along a magnetic field line [note that in vacuum magnetic fields where $\nabla\times\mathbf{B}=0$, $\mathbf{b}\times(\mathbf{b}\cdot\nabla)\mathbf{b} = \mathbf{b}\times\nabla|B|/|B|$]. From Eq. (19) one can show that magnetic gradients and field-line curvature produce an orbit drift velocity transverse to the magnetic field, $\mathbf{v}_D$, given by

$$\mathbf{v}_D=\frac{v_\parallel^2}{\omega_c}\,\mathbf{b}\times(\mathbf{b}\cdot\nabla)\mathbf{b}+\frac{v_\perp^2}{2\omega_c}\,\frac{\mathbf{b}\times\nabla|B|}{B}\,. \tag{28}$$

In the field given by Eq. (28), particle trajectories primarily follow the ϕ-directed field, but in addition the drift velocity in Eq. (28) causes the orbits to drift indefinitely in the negative z direction transverse to the magnetic field with a speed

$$v_D=(\tfrac{1}{2}\,v_\perp^2+v_\parallel^2)/\omega_c R. \tag{29}$$

To prevent unbounded motion a poloidal magnetic field needs to be present. One simple way of establishing such a field is with a current ring carrying a current $I_{\phi 0}$ at a major radius $R=R_0$, which gives a magnetic field $\mathbf{B}_\theta=B_{\theta 0}\hat{\theta}r_0/r$ if $r\ll R$, with $B_{\theta 0}=\mu_0 I_{\phi 0}/2\pi r_0$, where r is the minor radius and r_0 is a constant. Such a configuration is referred to as a hard-core pinch or levitron. Alternatively, the toroidal current can be produced by the various toroidal diffuse pinches where the plasma carries toroidal current, as described in the previous section. The magnetic field then has the generic form

$$\mathbf{B}=B_\phi(R_0/R)\,[\hat{\boldsymbol{\phi}}+q(r)\hat{\boldsymbol{\theta}}], \tag{30}$$

with $q(r)$ the inverse rotational transform. In Fig. 11 we show typical drift orbits of positive charged particles in this field projected onto a plane $\phi=\text{const}$ when $v_\parallel/v \gg (r/R)^{1/2}$. In addition, not shown in the figure, there is rapid oscillatory motion about the drift trajectory due to the Larmor motion. Figure 11(a) is for passing particles, a terminology that applies to those particles where $v_\parallel/v>(2r/R)^{1/2}$. These particles always circulate in a fixed θ direction. The dotted line denotes the magnetic flux surfaces formed from the magnetic field given by Eq. (30). One should note that co-moving particles—i.e., those particles whose sense of motion produces a current along the magnetic field that is in the same sense as the prevailing current [in Fig. 11(a) the prevailing current points toward the reader]—are shifted inward, while counter-moving particles (i.e., those particles that move in the opposite direction) are shifted outward. This asymmetry produces a bias that helps sustain current in a toroidal discharge. This current bias also exists in the electron motion. The trajectory's structure can be understood by noting that the particles' velocity is primarily tangential to

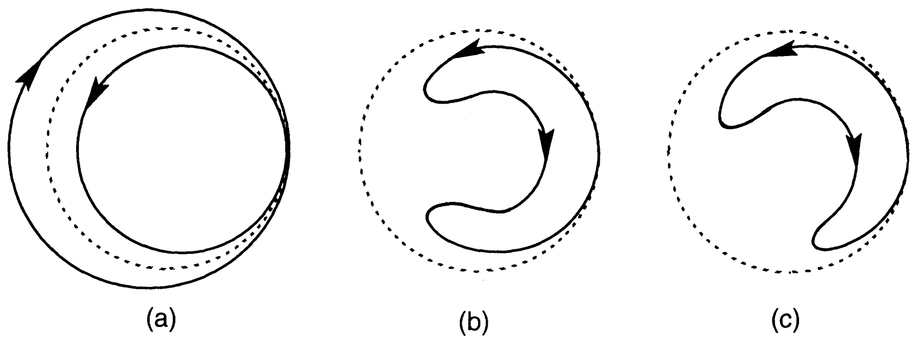

FIG. 11. Particle motion in a tokamak projected onto a fixed-ϕ cross section. In (a), particles moving counter to the toroidal current are shifted to orbits that are outside the dotted flux surface, while particles moving with the toroidal current have orbits interior to the flux surface. The orbit of a trapped particle is shown in (b) and (c). In (c) the orbit is displaced by a toroidal electric field, giving rise to an overall inward drift motion.

the flux surface. However, the additional drift velocity causes a positively charged particle moving in the clockwise direction to move radially inward from the flux surface when it is above the midplane. This inward displacement is compensated when the particle is below the midplane where the drift velocity takes the particle back to the flux surface. A similar argument holds for the counterclockwise rotating particle. The overall excursion from the flux surface

$$\delta r \approx q(r)\rho(r)(v_\parallel^2+v_\perp^2/2)/v_\parallel v_\perp$$

(recall that ρ is the Larmor radius $v_\perp/\omega_c$) is inward for "co-moving" particles (particles moving parallel to the current) and outward for "counter-moving" particles as indicated in Fig. 11(a).

On a flux surface the magnetic field varies, and the mirror ratio on the flux surface is approximately

$$R=\frac{B_\phi(R=R_0-r)}{B_\phi(R=R+r)}=\frac{1+\epsilon}{1-\epsilon}\approx 1+2\epsilon \qquad (31)$$

with $\epsilon=r/R$ the inverse aspect ratio. If $v_\parallel^2/v_\perp^2<2\epsilon$, particles are mirror trapped on the flux surface and they are constrained to remain on the outside of the torus. They are referred to as "trapped" particles. The orbit of a trapped particle, projected onto a cross-sectional plane where ϕ is constant, is shown in Fig. 11(b). Because of the shape of the trajectory, the orbit of a trapped particle is referred to as a "banana" orbit. These orbits are still contained in a finite volume, but their orbit width, given by

$$\delta r \approx q\rho/\epsilon^{1/2} \equiv r_b\,,$$

is somewhat larger than that of a passing particle.

4.4 Neoclassical Diffusion

The complications of the orbit structure in a toroidal magnetic field cause an enhancement of the previously estimated classical diffusion. The appropriate theory is called neoclassical diffusion (Galeev and Sagdeev, 1979) and we now present a heuristic discussion of its implications.

Using random-walk theory, we estimate the diffusion coefficient of a particle by noting that a particle will diffuse an orbit width of its trajectory, Δr, in an effective collision time τ_{eff}. The diffusion coefficient D can be estimated as

$$D=\Delta r^2/\tau_{\text{eff}}\,, \qquad (32)$$

while the overall energy containment time is then given by

$$\tau_E \approx a^2/D=(a^2/\Delta r^2)\tau_{\text{eff}}\,.$$

The majority of particles are passing and their effective relaxation time is a 90° scattering time τ_j [τ_j is either τ_i or τ_e, given in Eq. (20), depending on the type of particle], while their mean displacement is $\Delta r \approx q\rho$. Hence, the diffusion coefficient for passing particles, D_{pass}, is given by $D_{\text{pass}} \approx q^2\rho_j^2/\tau_j$, with ρ_j the Larmor radius of species j. However, this value for the diffusion coefficient turns out to be too small. Surprisingly, it is the diffusion of the trapped-particle minority that primarily determines the containment characteristics. This is because Δr is larger for a trapped particle than for a passing particle and τ_{eff} is shorter. For a trapped particle $\Delta r \approx q\rho/\epsilon^{1/2}$, which is the characteristic deviation of a trapped particle from a flux tube, and $\tau_{\mathrm{eff}} \approx \tau_j\, \epsilon$, which is the characteristic time a trapped particle remains trapped. The shorter τ_{eff} arises because of the diffusive nature of the Coulomb collisional process. Hence if τ_j is the time for a particle to diffuse 90° in velocity space, $\tau_j \sin^2 \Delta\theta$ would be the characteristic time to diffuse a pitch-angle width $\Delta\theta$; for trapped particles $\sin \Delta\theta \approx R-1 \sim \epsilon^{1/2}$, where R is the mirror ratio on the flux tube of a tokamak. Hence the diffusion coefficient of a trapped particle is

$$D_{\mathrm{trap}} \simeq \Delta r^2/\tau_{\mathrm{eff}} \simeq q^2\rho^2/\epsilon^2\tau_j\,.$$

The fraction of phase space that is occupied by trapped particles is approximately $\sin \Delta\theta \simeq \epsilon^{1/2}$, and hence the global diffusion coefficient due to both trapped and passing particles is

$$D \approx \epsilon^{1/2} D_{\mathrm{trap}} + D_{\mathrm{pass}} \approx \frac{q^2\rho^2}{\tau_j}\left(\frac{1}{\epsilon^{3/2}}+1\right).$$

Clearly the contribution to D from the trapped particles is more important than from the passing particles. The global energy lifetime due to thermal conduction is then determined by

$$n\tau_E \approx \frac{a^2 n}{D} \approx \frac{a^2}{\rho_i^2 q^2}\,\frac{n\tau_i}{(a/R_0)^{3/2}}$$

with ρ_i the ion Larmor radius. The large factor a^2/ρ_i^2 ensures that the intrinsic thermal conduction losses in a tokamak can satisfy the Lawson criterion for ignition by a large margin.

4.4.1 Bootstrap Current. The so-called bootstrap current is another important collisional effect. It arises because

1. co-rotating particles tend to be shifted inward while counter-rotating particles are shifted outward;
2. the primary diffusion process is significant only when particles are trapped or nearly trapped.

As a consequence the statistical weight of a particle, even when it is passing, is determined by its weight when it was trapped. At a given radius r the co-circulating passing particles then have a weight of trapped particles that were centered around an inward-shifted radius $r - q\rho/\epsilon^{1/2}$, while a counter-circulating particle has an equal weight shifted to the outward radius $r + q\rho/\epsilon^{1/2}$. The current density at the flux surface r is then given by

$$j_{\|} = e_j[n^+(r) - n^-(r)]\,v_{\mathrm{th}}\,,$$

where n^+ is the density (proportional to the statistical weight) of co-moving particles and n^- the density of counter-moving particles. Using $n^+(r + 2q\rho/\epsilon^{1/2}) \approx n^-(r)$ we find the bootstrap current density

$$j_{\|} \approx -2e_j\,\frac{\partial n}{\partial r}\,\frac{q\rho}{\epsilon^{1/2}}\,v_{\mathrm{th}}\,.$$

This can be a substantial fraction of the current required to maintain a discharge. It allows for a substantial decrease in the current drive needed to maintain a steady-state tokamak.

4.4.2 Ware Pinch. As the bootstrap current results from a spatial gradient that "drives" current, it follows from an Onsager relation that a toroidal electric field will induce a radial spatial gradient. The phenomenon is called the Ware pinch.

In this phenomenon the $\hat{\phi}$-directed electric field that is being used to drive current is not quite parallel to the magnetic field. For passing particles there is an inward flow speed $\mathbf{E}\times\mathbf{B}/|B|^2 \approx E_\phi B_\theta/|B|^2$. However, the flow speed is too slow for trapped particles, which actually move inward at the speed E_ϕ/B_θ. This enhanced speed arises for the following physical reason.

When Eq. (23) is used to determine the turning point of a trapped particle with the electric potential given by $\Phi = \int^s ds' E(s')$, one finds that the turning points are displaced. As a result, a banana orbit is shifted as shown in Fig. 11(c). In the figure shown, the particle spends more time above the mid-plane than below it. The downward curvature drift then directs the particle towards the flux surface more frequently inward than it is directed outward. As a result, after averaging over a particle's bounce orbit, a trapped particle will move inward at an inward radial speed given by

$$\dot{r} = -E_\phi/B_\theta\,,$$

where E_ϕ is taken positive if it is in the direction of the prevailing toroidal current. As only trapped particles with a density $n_T \approx (r/R)^{1/2} n$ move at this rate, the actual inward flux is

$$n_T \bar{v}_r \approx n(r/R)^{1/2}(E_\phi/B_\theta).$$

4.5 Radial Electric Field

The effect of a radial electric field can also cause a profound change in particle containment. Because electrons move rapidly along the field lines forming flux surfaces, there is a strong tendency for a magnetic flux surface to be an electric potential surface. Consequently, the strongest electric fields in a tokamak tend to be normal to the flux surface. Such an electric field produces the standard **E×B** drift, whose flow is tangential to a flux tube, nearly in the θ direction. This motion alters the characteristic displacement of a particle from a flux surface. Without an electric field, the magnetic drift motion of particles causes a typical radial flow speed $v_r \sim (v_\parallel^2 + \frac{1}{2}v_\perp^2)/\omega_c R$ that alternates towards and away from the flux surface, with a radian frequency $\omega_b \approx v_\parallel / qR$ in the poloidal direction, giving rise to a displacement

$$\delta r_b = v_r/\omega_b \approx q(v_\parallel^2 + \tfrac{1}{2}v_\perp^2)/\omega_c v_\parallel$$

from the flux surface. With a radial electric field present, the particle has an additional poloidal velocity component $v_{E\theta} \approx cE_r/B$, which should be added to the θ component of the parallel flow, giving a total θ-component flow speed

$$v_\theta = (\epsilon/q)(v_\parallel + qv_{E\theta}/\epsilon).$$

Hence the circulation frequency is

$$\omega_b \approx v_\theta/r = (v_\parallel + qv_{E\theta}/\epsilon)/qR,$$

and the radial displacement is

$$\delta r_b \approx q(v_\parallel^2 + v_\perp^2/2)\{\omega_c[v_\parallel + q(v_{E\theta}/\epsilon)]\}.$$

Without a radial electric field, the largest particle displacement occurs for small $v_\parallel/v$ where the distribution of particles peaks. The radial electric field changes the region of phase space for which the displacement from a flux tube is maximum. Instead of $v_\parallel \approx 0$, the displacement maximizes at $v_\parallel \simeq v_{E\theta}/\epsilon$. It is then possible for the large particle displacement to affect only particles in the tail of the distribution function where there are relatively few particles, while all the particles in the bulk remain close to the magnetic surface.

Recent tokamak experiments, e.g. (Asdex Team, 1989), have found that there is a profound improvement of plasma containment from more usual discharges in the so-called *H*-mode regime. The radial electric field appears to be an essential element in controlling particle transport.

4.6 Orbits in Stellarators

In stellarators, where toroidal symmetry is broken, particle containment can differ profoundly from systems with toroidal symmetry. In the latter case with a finite rotational transform, the particle displacement from a flux tube is guaranteed to be some factor of a Larmor radius. Hence with toroidal symmetry present, as B becomes larger the particle displacement from the flux surface becomes smaller. The lack of toroidal symmetry allows special classes of particles to deviate substantially from the flux surfaces, to distances that can be comparable to the machine size itself, independent of the magnitude of the magnetic field. In the absence of electric fields, the particles most susceptible to this large deviation are those that are mirror trapped by the magnetic-field modulations due to the combined toroidal and helical field structure. They form so-called super-banana orbits, where in one bounce time the orbit appears like a trapped banana orbit. As the magnetic moment is conserved, the banana orbit moves with the magnetic field at the banana tip, remaining constant. This constraint in itself does not guarantee orbit containment. Thus, many stellarator configurations in the absence of radial electric fields have inherent loss regions. With a radial electric field present, orbits will remain closer to flux surfaces, and containment can be improved. However, as the electrostatic potential tends to be comparable to the temperature of the plasma, it is very difficult to modify the containment properties of the energetic particles. This particularly applies to the charged fusion products that need to be retained in a reactor during ignition. Hence the large orbit displacement from a flux surface will give rise to a direct particle loss of a relatively large fraction of the fusion products in a stellarator (perhaps ~25%). Such a factor does not quench ignition scenarios, but does introduce additional problems. For example, losses tend to be concentrated in specific places of the wall, which induces very special heat load and sputtering problems that need to be addressed in reactor designs.

5. PLASMA INSTABILITY AND ANOMALOUS TRANSPORT

A plasma is characterized by several intrinsic and disparate spatial and temporal scales. Hence, even in the same system, several different types of instabilities can arise that cause different responses. Long-wavelength instability can cause rapid disintegration of a configuration, or can establish a threshold which prevents operation above a critical beta value. Short-wavelength instability tends to saturate at relatively low perturbed field values, so that while the integrity of a system can still be maintained, the plasma transport is frequently enhanced above intrinsic losses.

5.1 Ideal MHD Theory

A first approach to the description of plasma stability is to use ideal magnetohydrodynamic (MHD) theory (see MAGNETOHYDRODYNAMICS). In this model, viscosity, resistivity, and heat conduction are ignored, and the plasma pressure satisfies the ideal gas law. In Sec. 3 we discussed equilibria that arise from the MHD equations. If these equilibria are perturbed, the time-dependent response determines whether small perturbations remain small or grow to finite values. The former case implies stability, while the latter situation implies instability.

5.1.1 Simplified Dynamical Model. When a plasma is described by the ideal MHD model, the method of determining stability is a generalization of the principle of virtual work, that is readily illustrated in a one-dimensional system with two degrees of freedom. A potential $V(\xi)$ is given, say, in the shape of Fig. 12 with ξ the position and V the potential. The equation of motion is given by

$$\frac{d^2\xi}{dt^2}+\frac{\partial V(\xi)}{\partial \xi}=0. \tag{33}$$

In Fig. 12, equilibrium points exist at positions *a*, *b*, *c*, and *d*, where $\partial V/\partial \xi = 0$.

From the principle of virtual work the stability of the equilibrium points are determined from the sign of the perturbed potential energy,

$$\delta W \equiv \delta\xi^2 \frac{\partial^2 V(\xi_i)}{\partial \xi^2},$$

where ξ_i is the equilibrium point where $\partial V(\xi_i)/\partial\xi=0$, $\delta\xi \equiv \xi-\xi_i$ is an arbitrarily small displacement from ξ_i, and δW is the virtual work that must be applied to displace the system. If $\delta W>0$ for every arbitrarily small displacement, the system is locally stable and an initially small perturbation will remain small, while if $\delta W<0$, an initially small perturbation will grow to finite and perhaps even infinite amplitude. For this one-dimensional system determining the sign of δW is equivalent to determining the sign of $\partial^2 V/\partial \xi^2$.

In the simple system shown in Fig. 12 it is clear that initially small deviations about points *a* and *c* lead to finite deviations from these points, while small deviations from points *b* and *d* remain small. The system illustrated here is simple enough that we can ascertain that a small deviation about point *c* leads to a

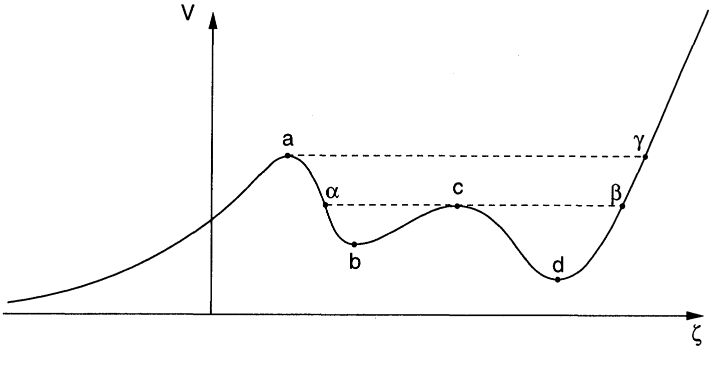

FIG. 12. Potential diagram for one-dimensional motion.

bounded oscillation between points α and β. With a small amount of dissipation present, one expects a state initially at c to relax to either of the points b or d. However, a small deviation about point a can quickly lead to an unbounded excursion. Hence this simple example illustrates how instability can lead to rapid disruptions or to a nonlinear bounded state that can eventually relax to a stable state.

5.1.2 Generalization to Plasmas. These relatively simple considerations can be applied to more complicated systems with many degrees of freedom and even to systems where the degrees of freedom form a continuum, as it does with the MHD equations; see for example Friedberg (1982) for a detailed derivation and detailed application of the method. If one can show that the virtual work (or, as it is frequently called, the MHD energy) is positive for every possible small displacement, stability of the ideal MHD equations is guaranteed. The MHD energy is a very physical quantity which describes the change caused by distortion of the configurational energy stored in magnetic and thermodynamic energies. An isolated system can only evolve with its total energy (including additional positive kinetic energy) conserved. Hence, if the MHD energy of the configuration increases for every possible distortion, it is clear that such perturbations are prohibited from spontaneously evolving to large amplitudes since the system will have more energy than in the equilibrium state. However, if MHD energy is negative upon distortion, it is energetically possible for the system to evolve from small amplitudes, with the excess energy taken up by the kinetic energy of the flow.

5.1.3 Role of Field-Line Curvature. From the detailed expression for the MHD energy, one can show that the field-line curvature plays a major role in determining MHD stability. Consider, for example, the plasma contained in the magnetic configurations shown in Fig. 4. In Fig. 4(a) the field lines are convex with respect to the contained plasma, while in Fig. 4(b) the field lines are concave. The MHD energy principle demonstrates that the configuration shown in Fig. 4(a) is unfavorable for stability, while the configuration shown in Fig. 4(b) is highly favorable to stability. For a low-beta system this can be shown to be equivalent to saying that systems where $|B|$ decreases outwardly are unfavorable to stability, while systems where $|B|$ increases outwardly are favorable to stability. Intuitively, one can argue that a plasma with a pressure p and mass density nM has a mean conserved magnetic moment $\mu \approx p/nMB$, so that the force density on the plasma is $\mathbf{F} = -n\mu\nabla|\mathrm{B}|$. For increasing $|B|$, as one moves away from the confined region, there is an inward force that restores plasma perturbations, while if $|B|$ decreases outwardly the force is outward and causes perturbations to convect outwardly.

Magnetic mirror machines offer a particularly insightful example of the importance of field-line curvature. In a symmetric mirror machine the field-line curvature is always unfavorable for stability at the mid-plane. This almost always causes symmetric mirror machines to be MHD unstable except under very restricted conditions.

To obtain a concave-outward field-line curvature system, as shown in Fig. 4(b), one needs to forsake azimuthal symmetry. For example, two axially aligned Helmholtz coils with currents flowing in the same direction can establish a simple mirror machine with unfavorable field-line curvature in the midplane. Placing four current-carrying rods parallel to the coils' axis but radially displaced and with the currents in the rods alternating in direction, as shown in Fig. 4(b), leads to a magnetic field with favorable concave field-line curvature properties nearly everywhere.

Experimentally, the entire character of plasma containment in mirror machines was decisively improved once minimum-B fields were used that prevented the extremely disruptive curvature-driven mode from being excited.

5.2 Deviation from MHD Stability Guidelines

The need to break azimuthal symmetry leads to several technological side problems such as stress problems at high fields, difficulty of access (e.g., for the injection of neutral beams), increased single-particle orbit loss, etc. Hence, considerable interest has remained in devising systems that are basically simple mirrors that maintain azimuthal symmetry. It is conjectured that instability can be attained by creating plasmas that do not obey the dynamics of an ideal MHD system.

5.2.1 Passive Current Carriers. The most common idea is to place an *in situ* current carrier within the plasma where the current carrier does not respond to the displacements of the plasma. The energetic particle beam in the Astron concept is a proposed example of one such current carrier. A passive current carrier can create a minimum-B field in a symmetric configuration, which can then produce stability in the MHD response of the background plasma. The crucial question is whether the current carrier indeed acts as a *passive* current carrier, and this question needs further study. There are numerous experimental studies in mirror machines and tokamaks that show stability enhancement with energetic particles in the system (e.g., Perkins and Post, 1963; Dandl *et al.*, 1971; JET Team, 1991). There are also regimes where new instabilities appear to be caused by the energetic particles.

5.2.2 Finite–Larmor-Radius Stabilization. Another idea to achieve stability in a symmetric mirror machine is to exploit the finite orbit size of the bulk plasma ions, which can lead to a plasma response that differs from MHD predictions and to so-called finite–Larmor-radius stabilization (Rosenbluth *et al.*, 1960). This mechanism readily stabilizes the shorter-wavelength modes, but has difficulty in stabilizing longer-wavelength modes. In fact, a mode that corresponds to a nearly rigid displacement of the plasma column is extremely difficult to stabilize. This mode can be stabilized either at extremely low densities (far below densities of interest in fusion) or at relatively high β where currents induced in neighboring conducting walls can serve as a passive feedback mechanism to restore the rigid displacements of the column. At intermediate densities active feedback mechanisms or ponderomotive force from radio-frequency fields is needed to achieve stability.

5.2.3 Migma Concept. An example of a finite–Larmor-radius concept is the Migma (Maglich, 1988) experiment. Here the machine size is roughly two ion orbits and all the ion orbits pass close to the axis of the machine. In this device, stability at low density has been achieved, but it is below the threshold density predicted for the onset of the unstable displacement mode. Further experiments are needed to test stability for the predictions of finite orbit theory.

5.3 Stability in Tori

In toroidal devices MHD stability based on the constraints imposed by field-line curvature is very important. The stability criteria are somewhat subtle to apply. The curvature direction alternates in sign, being unfavorable to stability at major radii R greater than that of the magnetic axis R_0, while it is favorable to stability at major radii R less than R_0. The net result depends on the average of the two effects.

5.3.1 Line-Average Stabilization. For a low-β circular tokamak, average favorable curvature arises if the safety factor satisfies $q > 1$, while unfavorable average curvature arises if $q < 1$. Tokamaks generally operate with most of the flux tubes having $q > 1$. In fact, in the center where $q \lesssim 1$, periodic bursts of instability are usually observed, so-called sawtooth oscillations. Though these instabilities are driven by the unfavorable curvature, ideal MHD theory usually does not properly predict them. They are usually a manifestation of resistive instability, which we shall shortly explain.

5.3.2 Beta Stability Limit. When both good and bad curvatures exist on a field line, unstable perturbations try to localize in the bad-curvature regions. This causes the field lines to bend, which according to the energy principle induces a stabilizing "bending energy." At sufficiently low β, ideal MHD theory predicts stability for a toroidal system, since the destabilizing energy perturbation driven by the unfavorable curvature cannot compensate the bending energy. Only above a critical beta value β_c can a perturbation be localized to the bad-curvature region and overcome the stabilizing bending energy. The result is that overall stable operation is limited to beta values below β_c, commonly called the Troyon limit (Troyon *et al.*, 1984), which is typically $\beta_c \approx 2I_n$ (with $I_n = \mu_0 I_p / aB_\phi$, I_p the plasma current, a the minor radius, and B_ϕ the toroidal field).

5.3.3 RFP Stability. If a perturbation has a given pitch along the torus, this pitch can be identical to the rotational transform on one magnetic surface. On that surface there is no bending energy produced by the perturbation. However, if there is magnetic shear, i.e., q varies with the flux surface ψ (i.e., $\partial q/\partial\psi\neq 0$), bending energy is produced on neighboring field lines which allows for a stable MHD response for beta values below the appropriate critical β_c. Only if there is a flux tube where $\partial q/\partial\psi=0$ can MHD instability occur at extremely low beta. In pinches, where $q\ll 1$, there will be a surface where $\partial q/\partial\psi=0$ if the toroidal magnetic field does not reverse, and this region is a source of virulent instability. When toroidal field reversal is experimentally achieved, there is a dramatic decrease in the magnetic fluctuation levels. As a result the reversed-field pinch (RFP), where toroidal field reverses direction inside the plasma, is considered the most interesting low-q toroidal configuration.

5.4 Resistive Stability

If plasma displacements can be localized to bad-curvature regions without inducing the stabilizing bending energy, then curvature-driven modes can be excited at low-β values. In ideal MHD theory, the ideal Ohm's law, $\mathbf{v}\times\mathbf{B}+\mathbf{E}=0$, with $\mathbf{v}$ the plasma flow speed, forces stabilizing bending energy to be induced when a displacement is localized on a flux tube. With finite resistivity η Ohm's law is altered to

$$\mathbf{v}\times\mathbf{B}+\mathbf{E}=\eta\mathbf{J},$$

with $\mathbf{J}$ the plasma current. The finite resistivity then allows plasma to slip through magnetic field lines. As a result the plasma displacement can be localized to the unfavorable-curvature region, without inducing stabilizing bending energy (Furth *et al.*, 1963). Thus, because of plasma resistivity, instability can arise from the unfavorable curvature even at low β.

When this mechanism applies, instability growth rates are much slower than the growth rates typical of MHD instability. This mechanism gives rise to the sawtooth magnetic signals inside the $q=1$ surface of tokamaks. The instability causes rapid thermal mixing of the plasma inside the $q=1$ surface. However, as the plasma is stable outside the $q=1$ surface, the integrity of the thermal insulation is maintained on the outside of the plasma. In fact the sawtooth oscillations have the favorable feature of preventing high-Z impurities from collecting in the center of these discharges, which would cause severe energy losses from radiation.

The RFP is also prone to resistive instability, and the level of magnetic fluctuations is much larger in the RFP than in the tokamak. Here instability tends to be caused throughout the plasma as q is much less than unity everywhere. There is a concern whether the thermal insulation properties needed for fusion can ultimately be achieved in an RFP with this instability drive present.

In addition to the curvature instability drive, the current profile itself is a source of instability. Here again resistivity allows the current profile drive to manifest itself at low beta, whereas MHD theory would predict stability. In RFP plasmas these current-drive instabilities force the configuration to relax close to the lowest energy state consistent with the amount of magnetic flux (or, as it is frequently called, magnetic helicity) pumped into the system. This state is one with toroidal field reversed in the inside of the plasma relative to the outside, and it is maintained indefinitely with a fixed amount of input voltage. Simple diffusion theory for a symmetric equilibrium predicts that a reversed-field state cannot be continuously maintained. However, a three-dimensional dynamolike effect that is driven by magnetic turbulence is what allows the maintenance of a reversed toroidal field (Taylor, 1986).

5.5 Microinstability

Another class of instabilities of importance, quite different from MHD-driven instabilities, is referred to as microinstabilities. They generally are of short wavelength (compared to the system size) and their fluctuations do not generally lead to catastrophic disassembly, but rather to an enhancement of transport. Even in MHD-favorable systems, it is the microinstabilities that often determine the intrinsic containment time of a plasma system.

A homogeneous plasma at a fixed global temperature T is, of course, in thermodynamic equilibrium and is free of instability. Any departure from thermodynamic equilibrium leads to intrinsic "free energy" drives that have the potential to cause instability and thereby to cause relaxation to the thermodynamic equilibrium state at a rate more rapid than predicted by binary collisions.

5.5.1 Velocity-Space Instability. The farther away a system is from thermodynamic equilibrium, the more virulent the drive of the free energy. In simple mirror machines where the ion kinetic distribution is not Maxwellian, there is a velocity-space containment condition that must be satisfied, which is given by Eq. (24). As a consequence the distribution function will have an "inverted" population of particles such that the phase-space density of low-energy particles is less than that of higher-energy particles. Such a situation gives rise to a laserlike instability (generally called loss-cone instability), in which the inverted distribution tries to relax through coherent oscillations (generally at harmonics of the ion cyclotron frequency) to a "monotonic" state where the phase-space density is a decreasing function of energy. However, as the low-energy particles are not contained, rapid loss arises on the scale of the particle bounce time.

In order to sustain a simple mirror plasma it was found necessary to supply low-energy particles, either through a gas feed or through a low-energy particle gun. In the 2X-IIB experiment it was found that with these techniques it was possible to achieve a high-β steady-state plasma. Particles that were injected at high energy were contained for a classical slowing-down time. The low-energy phase-space region was filled primarily with plasma arising from the external source, which either prevented instability or caused a low enough fluctuation level that it heated slightly the low-energy source but did not greatly perturb the energy-containment properties of the high-energy particles. The limitation of this method was that the electron temperature was constrained to remain low (typically $T_e/T_i \approx 0.01$ with $T_e \lesssim 100$ eV) and the high-ion-energy lifetime could not exceed several milliseconds.

One of the pleasing features of the tandem mirror configuration is that the loss-cone instability can be prevented. In the center of a tandem mirror the ions do not have a loss cone because these particles are contained by the electric field. In the end cells the loss-cone drive is quenched by the outflow of particles from the center. As a result tandem mirrors routinely operate without loss-cone instability.

5.5.2 Drift-Wave Instability. In toroidal plasmas one is generally not concerned with velocity-space instabilities. However, as intrinsic temperature and density gradients must exist to isolate the system thermally from the walls, the system cannot be in global thermodynamic equilibrium. The intrinsic gradients give rise to a diamagnetic flow rate, which from the equilibrium equations is

$$\mathbf{J}_j = \mathbf{B} \times \nabla p_j / B^2 \equiv e_j n_j \mathbf{v}_{Dj},$$

where the species j can refer to electrons or ions and v_{Dj} is the diamagnetic drift frequency of species j. In a frame moving at the equilibrium $\mathbf{E}\times\mathbf{B}$ speed, $\mathbf{v}_{De}$ and $\mathbf{v}_{Di}$ would be the mean flow speed of electrons and ions, respectively. These flows are in opposite directions and it is impossible to find a reference frame where the overall flow of every species can be ignored. These equilibrium flows are the free-energy source for instability. If we consider a perturbation with a spatial dependence proportional to $\exp(i\mathbf{k}\cdot\mathbf{r})$, a low-frequency response will arise near the angular frequency $\omega \sim \mathbf{k}\cdot\mathbf{v}_{Dj}$. It is found that when instability arises at this frequency, it causes anomalous relaxation of the plasma. Often the magnitude of the growth rate γ approaches that of the real frequency.

5.6 Turbulent Diffusion

The rate of diffusion caused by drift instabilities can be estimated by the following mixing-length argument. A wave with an electric field amplitude $\delta\mathbf{E}$ will grow until the $\delta\mathbf{E}\times\mathbf{B}$ drift velocity of the wave forces the plasma to displace a wavelength in a growth time, i.e.,

$$\delta\mathbf{r} \simeq \delta\mathbf{E}\times\mathbf{b}/\gamma B \approx 1/k,$$

where $\delta\mathbf{r}$ is the plasma displacement by the wave. The resulting wave breaking then forces saturation. Thus, we have a random motion $\delta r \sim 1/k$ in a correlation time $\tau = 1/\gamma \approx 1/kv_{Dj}$. Taking the diffusion coefficient to be $D_{\text{anom}} \approx \delta r^2/\tau$ gives

$$D_{\text{anom}} \approx \frac{\gamma}{k^2} \approx \frac{1}{e_j kBn} \frac{\partial(nT_j)}{\partial r}.$$

If $k \sim 1/r$, this diffusion coefficient yields so-called Bohm diffusion (taking $r\,\partial/\partial r \sim 1$)

$$D_{\mathrm{Bohm}} \simeq T_j/eB.$$

Such diffusion produced by drift waves is possible in a shearless system. In tokamaks and other toroidal devices, the magnetic shear often forces the wave number to scale as the ion Larmor radius ρ_i, giving rise to a modified Bohm scaling

$$D_{\mathrm{MB}} \approx (T_j/eB)(\rho_i/L_p)$$

with $L_p^{-1} = \nabla|nT_j|/nT_j$.

The interplay among the number of degrees of freedom is sufficiently complicated that a definitive description of turbulent transport still needs to be developed, and it is currently an extremely active research area (Callen, 1990).

6. STATUS OF MAGNETIC FUSION RESEARCH

6.1 Historical Overview

The quest to achieve controlled fusion developed soon after the successful development of the hydrogen bomb in the 1950s. The rapid success of new scientific technology, including fission power, produced great optimism that controlled fusion could be achieved relatively quickly. However, the instability problems in plasma containment were not fully appreciated. Indeed, many research groups initially inferred the achievement of thermonuclear conditions when neutrons were produced in experiments. It usually turned out that these neutrons resulted from runaway ions produced by the large electric fields associated with the turbulent disruption of the plasma.

By the early 1960s a general pessimism pervaded the program, as plasma confinement in nearly all devices was poor, with confinement properties often being attributed to Bohm diffusion. During this difficult period the subtleties needed to achieve good confinement began to be appreciated.

Major breakthroughs developed, often due to the understanding of "kitchen" physics, i.e., the solving of problems associated with wall conditioning, impurity control, vacuum conditions, etc., and to the understanding of how to achieve configurations that would be stable to gross instabilities. Experimental results demonstrated relatively long-lived containment in a variety of concepts. The experimental concept that received the greatest attention was the tokamak, which has become the leading magnetic fusion concept and is at present the most developed. There have been important breakthroughs in other concepts as well, including mirror machines, RFP, compact toroids, and stellarators.

By the mid 1970s the success of multiple approaches to achieving fusion and the appreciation of the need to develop a long-term energy source led to a broad support by the U.S. government of the many approaches in magnetic fusion. However, budgetary constraints became important in the U.S. fusion program in the 1980s. As a result, most of the research programs not connected to tokamaks were terminated, often before scientific issues were clarified. Thus, crucial questions in ascertaining the potential usefulness of many of the approaches remain unanswered. In some cases they can be addressed in fusion programs outside the U.S., where significant research facilities exist in stellarators, RFP, and mirror machines.

To present an overview of progress in magnetic fusion in somewhat more detail, we shall give a brief status report of the approaches that are alternative to tokamaks and then present a more detailed status report of the tokamak concept.

6.2 Status of Non-Tokamak Concepts

6.2.1 Mirror Machines. Initial mirror-machine experiments were in symmetric mirror fields, and if the density was not too low, they demonstrated poor confinement because of the destabilizing curvature-driven instability. A major breakthrough occurred (Ioffe and Sobolev, 1964) when it was demonstrated that the placement of quadrupole coils to form an MHD-stable minimum-B configuration resulted in an order of magnitude increase in the containment time.

The next major breakthrough in mirror research was the demonstration that a high-beta plasma can be sustained by neutral-beam injection (Coensgen *et al.*, 1976). This experiment also demonstrated the importance of neutral-beam technology, which was rapidly applied to tokamak and stellarator research.

An appreciation that the energy gain of a mirror machine under fusion conditions needed to be improved then led to the invention of the tandem mirror concept (Dimov *et al.*, 1976; Fowler and Logan, 1977). The experimental group at Lawrence Livermore Laboratory demonstrated feasibility of the tandem mirror and, in particular, showed that loss-cone instability can be completely suppressed as first suggested by theory (Post and Rosenbluth, 1966). The attempt to improve the tandem mirror concept by creating thermal barriers proved to be illusive. At present the GAMMA-10 tandem mirror, the only tandem mirror which is in operation in 1992, in Tsukuba, Japan, has shown that at relatively low density, quiescent long-lived tandem mirror plasmas can be obtained with thermal-barrier operation (Miyoshi *et al.*, 1991). The major improvement needed is to increase the density and the lifetime in thermal barrier operation.

Though simple mirror machines have marginal applicability as an energy source, they may have a special uniqueness for application as a 14-MeV neutron source which will be needed for testing the properties of materials that surround a fusion reactor (Berk and Ryutov, 1990). A *d-t* plasma in a mirror machine can supply neutron intensity to achieve a needed fluence in the shortest possible time and at relatively low cost, because a high-β (which allows a high intensity) and small-volume (which reduces overall cost) plasma can be achieved. Currently, studies of this application are ongoing in several laboratories, and may lead to a resurrection of interest in mirror-machine research.

6.2.2 Reversed-Field Pinch. Many different high-β pinch concepts were examined in the 1960s. The most successful ultimately turned out to be the Zeta experiment (which originally was designed as a stabilized *z* pinch), where a quiescent operational region was discovered (Robinson and King, 1969). In this regime the toroidal magnetic field in the center was reversed from its direction at the edge. Surprisingly, the reversal could be sustained by toroidal voltage, despite the prediction of two-dimensional diffusion theory that it would not be sustained.

Though the Zeta experiment was terminated, perhaps prematurely in light of its discovery, the reversed-field pinch configuration has now been studied in many facilities worldwide. These experiments have demonstrated reduced fluctuation level and improved containment with increasing temperature. These results are consistent with the theoretical understanding that the plasma will try to relax towards its lowest-energy state and that the relaxation process allows a steady plasma to be maintained through turbulent dynamo processes. In principle this mechanism can be extended to achieve steady operation with non-Ohmic helicity injection.

Though magnetic fluctuations in an RFP are low compared to most other high-β pinches, the fluctuations are appreciably higher than in tokamaks, and are present close to the plasma edge. Such fluctuations lead to impurity buildup, heat loading problems, and the penetration of magnetic fields into the walls, which in turn enhances fluctuations. It is foreseen that by increasing the current and temperature of an RFP, the fluctuation level will decrease, as the rate of relaxation needed to remain close to the lowest-energy state is reduced. The verification of this conjecture is the principal goal of the RSX experiment in Padua, Italy, which will have a plasma current of 4 MA (Antoni *et al.*, 1989).

6.2.3 Compact Toroids. Another offshoot of pinch research was the study of compact toroids. Early on it was found that by programming of the wall currents in a theta-pinch experiment, the *z*-directed magnetic fields could be reversed into an elongated compact toroid without any apparent toroidal magnetic field. However, these experiments would typically disrupt because of the onset of a rotational instability. By appropriate preparation it was demonstrated (Es'kov *et al.*, 1979) that elongated field-reversed theta pinches can be made free of the rotational instability. After a great deal of study these results were confirmed by other experimental teams. In the 1980s it was shown in Japan that minimum-*B* quadrupole fields could be used to ensure MHD stability (Ishimura *et al.*, 1989).

An alternative approach to compact toroids started in the late 1970s with the study of the spheromak, a compact toroid which has both toroidal and poloidal magnetic fields. Several novel ideas were developed to form plasmas using pulsed techniques. Both the poloidal magnetic flux and toroidal magnetic flux need to be embedded in the plasma during its formation phase, and then the plasma has to be guided into a storage region where it is contained. In the more successful experiments a relatively high electron temperature was attained, $T_e > 100$ eV (Yamada *et al.*, 1989), and external magnetic helicity injection was used to sustain the configuration (Jarboe *et al.*, 1983).

Perhaps the first compact toroid conceived was the Astron concept (Christofilos, 1962). Here field reversal is to be achieved with the current produced by energetic particles whose Larmor radius is comparable to the radius of the plasma. The demonstration of field reversal has been achieved (Andrews *et al.*, 1971), but there is still difficulty in achieving hot plasma containment in an Astron configuration.

One possible future direction in compact toroid research is to merge the Astron and field-reversed theta-pinch concepts. The joint system should stabilize the so-called tilt instability (Rosenbluth and Bussac, 1979), an MHD instability that might otherwise prevent the achievement of reversed-field theta-pinch devices with relatively small Larmor radii.

Finally, it should be noted that the reversed-field theta pinch is an intrinsically high-β device. If suitable plasma confinement can be successfully achieved, the configuration would be especially suitable for advanced fuel cycles, such as d-^{3}He, since synchrotron radiation losses would be insignificant and the fusion power production density would be high, while the total power production would be moderate because of the system's compactness (Kernbichler *et al.*, 1991).

6.2.4 Stellarators. Progress in stellarators was initially very slow, in part because of the complications in designing three-dimensional magnetic fields. For example, it was found that stellarators were frequently built improperly without the existence of magnetic flux surfaces. Careful field design by the research team at the Max-Planck-Institut für Plasmaphysik led to more favorable stellarator containment by the late 1960s (Berkl *et al.*, 1969). Further innovations by the Kyoto group in Japan were successful (Uo *et al.*, 1977). With these studies research teams found that by heating with rf fields or with high-energy neutral beams, confinement times could be achieved that were similar to those in comparable size tokamaks. Further, it was shown that the radial electric field could be controlled to improve particle containment significantly, even that of the injected high-energy particles.

The stellarator has considerable flexibility of design, and indeed new interesting designs emerge every few years. Some of the more interesting magnetic-field design concepts that have emerged are (Grieger *et al.*, 1992) modular magnetic coils that allow for ready disassembly for maintenance, and magnetic field design that can minimize the particle excursion from a flux tube, produce large stabilizing magnetic shear, produce favorable minimum-B properties, etc.

Stellarators are now the principal backup to tokamaks. The often-cited advantages of stellarators over tokamaks are that stellarators have been free from the catastrophic disruptive loss to which tokamaks are susceptible and that there is no need for an elaborate current drive mechanism. The complexity of a stellarator is also its virtue as the optimum stellarator is probably yet to be designed. A large stellarator (LHD) is now under construction in Nagoya, Japan, and plans for a large stellarator exist in Garching, Germany.

6.3 Status of Tokamak Research

Tokamak research achieved a major breakthrough in 1968 when a favorable regime of operation was reported (Artsimovich *et al.*, 1969). The favorable regime was rather narrow, with too strong a current producing violent MHD instabilities since $q < 1$ on axis, whereas too weak a current could not produce enough power to sustain the discharge. The discovery of a window of favorable operation truly changed the direction of controlled-fusion research. Many groups throughout the world converted to tokamak research.

A great deal of progress has occurred since the initial breakthrough was reported in 1968. Some of the crucial developments are described below.

6.3.1 Impurity Control and Fueling. The development of wall preparation and fueling techniques has mitigated the impurity problem in tokamaks. Initially tokamaks operated with a high Z_{eff} ($\sim$5–10), whereas $Z_{\mathrm{eff}} < 2$ is now standard in tokamak operation. Recently, technology has been developed for injecting pellets that allows for central fueling which often leads to substantially improved confinement characteristics at low Z_{eff}. However, the issue of whether impurity buildup can be prevented over extremely long pulse times (> 10 sec) and under high heating power remains crucial and will be investigated in future experiments.

6.3.2 Auxiliary Heating. Auxiliary heating is generally necessary at high temperature as Ohmic heating loses its effectiveness because, at fixed current, the heating rate is proportional to $T_e^{-3/2}$. Only if large plasma current densities are present, which can occur in high-field machines with $B_\phi > 10$ T, is it conceivable that Ohmic heating can bring a plasma to ignition conditions. The advances in neutral-beam and radio-frequency technologies have made possible the achievement of the plasma temperature needed for producing fusion. For example, the TFTR experiment at Princeton, New Jersey, and the JET experiment in Culham, England, have produced plasmas with ion temperatures in excess of 20 keV and electron temperatures of ~10 keV. In the TFTR experiment the best confinement characteristics are obtained in the "supershot" regime (Bell *et al.*, 1989), where neutral beams directly fuel the center of the discharge. Neutral beams have also been used to simulate collective alpha-particle effects of a fusion-producing plasma (Wong *et al.*, 1991; Heidbrink *et al.*, 1991). In the JET experiment, high-energy tails have been generated with ion cyclotron heating that simulate the effect of charged energetic fusion products in the plasma (JET Team, 1991). In this experiment sawtooth instability is eliminated, perhaps as a result of hot-particle stabilization of MHD instability.

6.3.3 Plasma Shaping. The shaping of a tokamak plasma has become a crucial feature in tokamak performance. The initial tokamak experiments were with circular-shaped poloidal cross sections which lead to relatively low critical beta values for the onset of MHD stability. By means of plasma shaping, MHD stability properties can be substantially improved. Recently the D-III-D tokamak, a shaped tokamak at General Atomic in San Diego, California, has achieved peak beta values of 40% and an average beta value of ~10% (Lazarus *et al.*, 1991). It is believed that this plasma can test the so-called second stability regimes (Coppi *et al.*, 1979), where stability can be attained in a tokamak even at high β. If such a high-β stability regime can indeed be achieved it makes d-^{3}He operation feasible in a tokamak.

In addition, with shaping it is easier to cause field lines near the edge to be deliberately diverted to the wall (such field-line design is called a divertor). The purpose is to decouple the properties of the plasma–wall interactions from the properties of the confined plasma and thereby prevent impurity buildup in the plasma. In addition, it is found that divertor operation facilitates H-mode operation, where the plasma develops a sharp pressure gradient at the edge and the overall plasma confinement increases by a factor of ~2–3 from the usual operating scenario (Jackson *et al.*, 1992).

Another type of shaping is for the current profile. It has recently been observed (Zarnstorff *et al.*, 1991) that there is better confinement if the current profile is altered from the natural profile reached in steady operation. Techniques to develop favorable current profiles in steady state need to be developed.

6.3.4 Current Drive. Noninductive current-drive techniques have made considerable progress. Tokamak currents have been successfully driven by rf sources (at lower hybrid and electron cyclotron frequencies) and by neutral beams. At low plasma currents, these current-drive mechanisms allow long-time plasma operation in large and small machines (Jacquinot *et al.*, 1992). However, these current-drive schemes are intrinsically less efficient than the inductive (Ohmic) drive methods, and the efficiency decreases at higher densities. In reactor operation at relatively high β, the requirements of current drive are lowered by the large bootstrap current induced, and it is conceivable that an acceptable current-drive efficiency can be achieved (Cordey, 1988).

In addition to the above-mentioned current-drive mechanisms there are alternative ideas being investigated, such as magnetic helicity injection (Jarboe *et al.*, 1983), which was first studied in RFP research.

Without current drive the duty cycle of a tokamak reactor needs to be high, and thermal stresses, due to wall cooling and heating as the tokamak is turned on and off, need to be minimized. The JET facility has recently shown that the plasma current can be reversed by ac cycling of the Ohmic drive (Tubbing *et al.*, 1992). They demonstrated that the time interval in which no plasma equilibrium exists can be short. This mode of operation can conceivably mitigate the heat-stress problem.

6.3.5 Achieved Confinement Parameters. The historical progress in tokamak containment can be observed in Fig. 13, which presents values of the parameter $n\tau T$ achieved in various tokamaks during the last two decades. Note that the quality of plasma confinement now being achieved in tokamaks is nearly equivalent to achieving energy breakeven with the *d-t* fusion reaction. In addition, the JET facility (JET Team, 1992) has now actually operated with *d-t*, producing $Q{\sim}0.15$ in a lean *d-t* mixture ($Q{\sim}0.45$ would have been produced in an optimum *d-t* mixture in the same experiment; in addition, plasma confinement conditions that would have produced $Q > 1$ in an optimum *d-t* mixture were produced in a *d-d* discharge). Similar runs are being planned for TFTR.

6.4 Conclusion

The advances in tokamak research have reached the point where the next major step is to build an ignition experiment and to study the system during its burning phase. It is proposed that this experiment be run by an international collaboration that is now called ITER (Tomabechi *et al.*, 1991). In addition, work on smaller tokamaks is necessary in order to understand physical phenomena better and to find ways to improve the intrinsic operation of tokamaks. As the advances in tokamaks have often occurred in unplanned areas, substantial improvements can certainly be expected.

Research in alternative confinement schemes has not had support comparable to tokamaks, and it is not surprising that their achievements lag behind the tokamak. Some of these schemes may evolve to reactor-grade concepts, while others might be highly favorable for nonenergy-producing applications such as a compact neutron source for materials testing or a compact source for producing medically desired radioactive isotopes. Re-

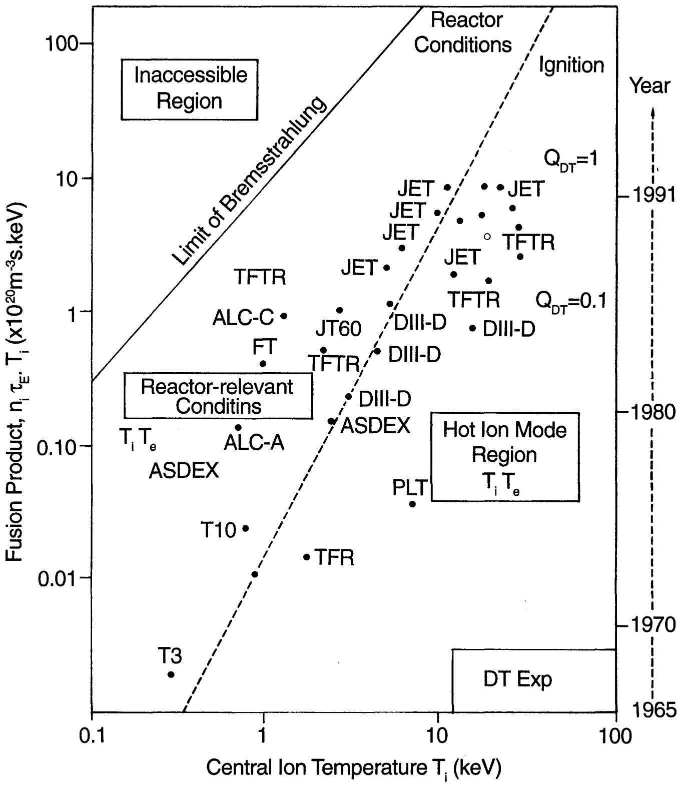

FIG. 13. Fusion parameter $n\tau_E T_i$ vs central ion temperature $T_i(0)$ for a number of machines worldwide in the period 1965–1991 (figure published with permission from JET Joint Undertaking, which retains copyright of the material).

search in these alternative concepts has frequently contributed significantly to the overall progress in the physics of plasma containment and to the generation of technological tools. Hence, the controlled fusion program will continue to profit by continuing its support of alternative directions of research.

GLOSSARY

Ambipolar Potential: The electrostatic potential that a plasma establishes for maintaining overall charge neutrality.

Anomalous Transport: The transport in a plasma due to self-generated electromagnetic fluctuations.

Banana Orbit: The shape of an orbit of particles in a tokamak that are trapped by the increasing magnetic field.

Beta: The ratio of kinetic pressure of a plasma to the magnetic field pressure.

Classical Transport: A theoretical description of transport of a plasma in a uniform magnetic field.

Compact Toroid: A confinement concept of a toroidal plasma without magnetic field coils through its center.

Lawson Criterion: The product of density and plasma lifetime, which is a parameter that measures the quality of plasma confinement with respect to what is needed to achieve fusion conditions.

Magnetic Flux Surfaces: The surface on which magnetic field lines lie in a toroidal confinement concept.

Magnetohydrodynamics (MHD): The fluid description of ionized gases.

MHD Energy: The perturbed energy of a system described by the MHD equations.

Mirror Machine: A confinement concept consisting of open-ended magnetic field lines with the magnetic field intensity increasing towards the ends.

Neoclassical Transport: A collisional transport theory that is based on the finite orbit size due to drift orbit excursions in tokamaks and other plasma confinement machines.

Pinch: A generic plasma confinement configuration with large plasma currents.

Plasma: Ionized gas.

Reversed-Field Pinch: A pinch device where the toroidally directed field reverses between the plasma center and the edge.

Rotational Transform: The number of times a field line winds around the poloidal cross section of a torus for each time it winds around the toroidal cross section.

Safety Factor (q): The inverse of the rotational transform; $q > 1$ generally indicates stability in tokamaks, while $q < 1$ indicates a likelihood of instability.

Stellarator: A three-dimensional magnetic configuration that does not require large plasma currents to achieve plasma containment.

Tokamak: A pinchlike configuration with a strong toroidal magnetic field and a strong toroidal current carried by the plasma.

INTRODUCTION

Fusion is the primary source of energy in the universe—it is the phenomenon that powers the sun and the stars. In a fusion reaction, two light nuclei combine to produce a heavier nuclide, thus liberating a large amount of energy. Because the reacting nuclei have positive charges, their relative speed must be high enough to overcome the electrostatic repulsive forces. Relative kinetic energies of 100–200 keV are required to fuse hydrogen-isotope nuclei, which have the smallest Coulomb barrier because they are singly charged. For a thermalized mixture of the fusing nuclei (i.e., with Maxwellian velocity distributions), production of an appreciable amount of fusion energy requires a temperature of more than 5 keV (6×10^7 K) and peaks at tens of keV. At these high temperatures, the fusing fuel is in the plasma state, i.e., a completely ionized gas in which electrons are not bound to the nuclei. Obviously, no material wall can contain the fusion plasma, nor is the gravitational confinement of the fusion plasma (as in the sun) practical. The two principal methods for isolating the fusion plasma from the surroundings are magnetic- and inertial-confinement schemes (see FUSION, MAGNETIC CONFINEMENT; FUSION, INERTIAL CONFINEMENT).

The fusion reaction that involves two isotopes of hydrogen, deuterium (D) and tritium (T),

$$D+T\rightarrow {}^4He(3.52\ \text{MeV})+n(14.06\ \text{MeV}),$$

is the least difficult one to achieve in terrestrial conditions. This is because it has the largest cross section and occurs at the lowest plasma temperature. Other fusion reactions of hydrogen isotopes, which are usually referred to as advanced-fuel reactions, have also been considered for terrestrial application and are discussed in Sec. 4.

Examination of the above-mentioned D-T fusion reaction has underlined the potential desirable features of fusion and caused a worldwide quest for a practical fusion reactor. It has also highlighted the challenges in achieving this goal. First, fusion reactions produce a large amount of energy from a small amount of fuel. For example, a 1000-MWe power station requires about 1 kg/day

digital Encyclopedia of Applied Physics

of D-T fuel, while a similar coal-fired plant would require 2000 tonne/day of coal. The fuel for fusion reactions is readily available. Since for every 6700 hydrogen atoms there is a deuterium nucleus, the water in the Earth's oceans contains a virtually inexhaustible supply of fusion fuel. Because tritium is radioactive with a half-life of 12.3 years, it is not found in significant quantities in nature. It can, however, be produced from lithium, which is an abundant natural resource. If the fusion plasma chamber is surrounded with a blanket containing lithium or lithium compounds, the neutrons produced in a D-T fusion reaction interact with the lithium to produce tritium, which is subsequently burned in the reactor.

Second, fusion reactors have the potential to be environmentally benign. The amount of fusion fuel in the reactor is limited. Therefore, even if an uncontrolled fusion burn occurs, it quickly consumes the available fuel and is extinguished. The "ashes" from fusion reactions are α particles, the nuclei of helium, which are not radioactive. There are two sources of radioactivity in a fusion reactor. The first is the tritium fuel itself. Because the tritium is generated in the reactor and is burned *in situ*, the amount of tritium in the system is much smaller than the amount of nuclear fuel in a fission reactor. The second source is from the neutrons produced by the D-T reactions, which can transmute the materials in the reactor and make them radioactive. Fortunately, research has shown that by the proper choice of materials and by careful design, the level of induced radioactivity can be kept low (many orders of magnitude smaller than a comparable fission reactor).

Achieving and maintaining the high temperatures, T, required for the fusion burn are the most fundamental challenges for fusion energy research. Basically, the fusion fuel should be heated from ambient temperature to about 10^8 K for fusion reactions to start. At these temperatures, the plasma loses its energy through radiation (bremsstrahlung, synchrotron, and line radiation), heat conduction, turbulent convection of plasma particles, etc. The average time it takes before the energy escapes from the plasma is referred to as the energy-confinement time τ_E. To maintain the fusion temperature, energy must be supplied. Although one of the by-products of fusion reactions (the energetic neutron) leaves the plasma, the other (charged α particle) slows down by colliding with the plasma particles and deposits its energy into the plasma, which sustains the plasma temperature. The necessary condition for a sustained D-T thermonuclear burn is that the "triple product" $nT\tau_E$ exceed 2×10^{21} s keV/m^3 (n is the plasma density). If the triple product is smaller than this value, the α-particle power is not sufficient to sustain the burn and the temperature decreases.

Most of the fusion research in the past 40 years has focused on achieving the necessary plasma temperature and triple product for fusion burn. The required fusion temperature has been attained and several experiments are approaching the required triple product. To date, almost all of the experiments have been performed in hydrogen or deuterium plasmas in order to avoid difficulties associated with handling radioactive tritium. Thus fusion-power production has been small and from D-D reactions (see Sec. 4). Operation with D-T plasmas is planned for two major experiments in the world. The Joint European Torus (JET) at Culham Laboratories has already produced 2 MW of D-T fusion power for 2 s with a small amount of T fuel, in preparation for extensive and powerful (several tens of MW) tritium operation planned for 1995. The Tokamak Fusion Test Reactor (TFTR) at the Princeton Plasma Physics Laboratory is expected to start D-T operation in 1993 with a fusion power of about 10 MW. The fusion ignition and long-pulse operation remain to be demonstrated in a larger experiment, the International Thermonuclear Experimental Reactor (ITER), proposed as a joint venture by the European Community, Japan, the Russian Federation, and the United States. The ITER project is now in the engineering design activity phase with construction planned to begin before the year 2000.

Conceptual fusion-reactor design studies have been carried out since the early 1970s. In addition to assessing whether a confinement system is attractive as a fusion-power reactor, these studies have uncovered potential problems, proposed solutions that are consistent with other reactor subsystems, and identified critical areas that should receive priority in experimental programs. It is a characteristic of this field that many of the research papers appear as laboratory reports or proceedings of conferences. The most up-to-date assessment of fusion reactors can be found in the ARIES Tokamak Reactor Study reports (Najmabadi *et al.*, 1991, 1992, 1993) the SSTR report (Seki *et al.*, 1991), and the overviews of Sombrero, Osiris, and Prometheus IFE reactors (Abdou and Waganer, 1993; Bourque *et al.*, 1992; Sviatoslavsky *et al.*, 1992), all of which have been national efforts involving scientists from major national laboratories, universities, and industry involved in fusion research.

1. FUSION-REACTOR OVERVIEW

Although several experiments are approaching the triple product that is required for fusion ignition, many other technological issues must be resolved before an economical fusion-power reactor can be realized. These issues can be loosely divided into two sets, the first of which relates to the plasma itself (Sec. 2). It is necessary to be able to create a plasma reliably, provide auxiliary heating to achieve fusion temperature and burn, and provide control of the major plasma parameters (e.g., n and T) for the duration of the burn. For steady-state or long-pulse reactors (e.g., the majority of the magnetic-confinement schemes), the plasma must be replenished with new fuel and the fusion ash (α particles produced by the D-T reaction) removed from the plasma. Obviously, the plasma technologies are confinement-method specific (see FUSION, MAGNETIC CONFINEMENT; FUSION, INERTIAL CONFINEMENT).

The second set of fusion-reactor technology issues relates to the systems surrounding the plasma (Sec. 3). The functions of these systems are mainly to convert the energy produced by the plasma into heat and then into electricity, to attenuate the neutron flux produced by the D-T plasma, and to produce sufficient tritium to fuel the reactor. Not only must these systems operate reliably in a harsh radiation environment, but they should also convert the plasma energy into electricity efficiently so that the reactor is economically viable. Furthermore, these systems must be built of special materials and designed in such a way that the attractive safety and environmental features of fusion are realized.

The technologies of a fusion reactor encompass many fields of science and engineering such as plasma physics, plasma–material interaction physics, materials science and engineering, heat transfer and fluid dynamics, chemical engineering, electrical engineering, electronics, power-systems engineering, vacuum-system engineering, all aspects of nuclear engineering, and (for magnetic-confinement concepts) superconductivity or (for inertial-confinement concepts) lasers, optics, accelerators, and pulse-power technologies. In some areas, new fields of science (e.g., plasma physics) had to be established, and in others, new frontiers had to be sought.

2. FUSION PLASMA TECHNOLOGIES

2.1 Magnetic Fusion-Energy Reactors

The most advanced magnetic-confinement approach is that of the tokamak (see FUSION, MAGNETIC CONFINEMENT). Therefore the plasma technologies for a tokamak reactor are emphasized here. A conceptual tokamak reactor design is shown in Fig. 1. (Alternative magnetic-confinement concepts are briefly described in Sec. 2.1.5.)

In the tokamak, which is similar in shape to a doughnut, the confining magnetic field is the result of combining a "toroidal field" (the long way around the doughnut), produced by coils outside of the plasma, and a "poloidal field," which is produced by the toroidal current flowing in the plasma. This combination causes the formation of a magnetic configuration that consists of nested surfaces. Each field line wraps helically and endlessly around one of these nested surfaces. The plasma heat and particles that flow quickly along the magnetic field lines are, therefore, well confined in this magnetic configuration. The plasma then diffuses slowly across the flux surface through cross-field transport processes.

The most efficient way to produce the toroidal current flow in the plasma is by magnetic induction (i.e., transformer action). A solenoid coil is placed in the center of the tokamak doughnut. Then, as the current flows in the solenoid coil, it induces a toroidal current in the plasma. Unfortunately, the toroidal current is induced only when the field produced by the solenoid is increasing (i.e., its current is rising)—a state that is practically impossible to maintain. Therefore, in most of the present-day experiments, when the cur-

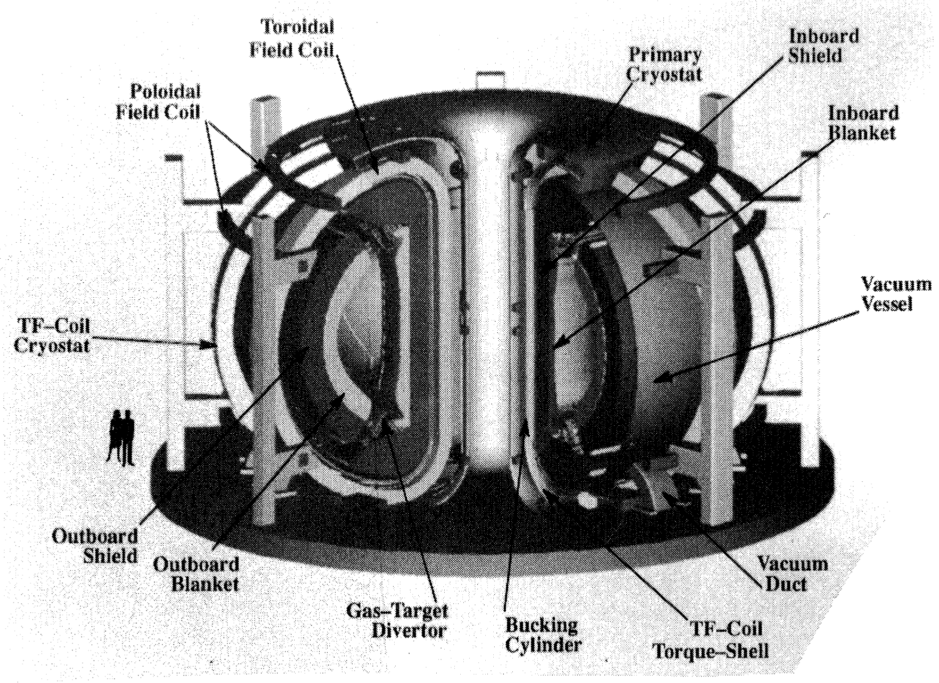

FIG. 1. The ARIES-IV conceptual tokamak fusion-reactor design (Najmabadi, 1993). The D-T plasma is located in the vacuum chamber inside the torus and is surrounded by the tritium-breeding blanket, the magnetic shield, the toroidal magnetic-field coils, and the vacuum vessel. The poloidal-field coils (the ohmic-heating, equilibrium-field, and shaping coils) are also shown. Divertor plates are also visible at the top and the bottom of the plasma region.

rent in the solenoid has reached its maximum, the plasma is shut down, the solenoid current is reset, and a new discharge is initiated. Theoretical and experimental research, however, has shown that the toroidal current can be produced by noninductive means (Sec. 2.1.2).

2.1.1 Plasma Generation and Heating. The plasma is usually generated by breaking down the deuterium gas that fills the plasma chamber. This is accomplished by initiating a current ramp in the solenoid coil set. The resulting induced voltage in the chamber then breaks down the gas. To facilitate plasma generation in most tokamaks, microwaves are also employed to ionize the initial gas partially.

As the plasma current is raised to its final value, the plasma heats Ohmically. However, since plasma electrical resistivity is reduced drastically as plasma temperature increases, an Ohmically heated tokamak plasma can only reach temperatures of about 2–3 keV. Auxiliary plasma heating is, therefore, required to achieve fusion ignition temperatures (~ 10 keV).

One of the most common methods of auxiliary heating employs an intense beam of high-energy neutral particles (neutral beam), since neutral particles can move through the magnetic field unaffected and penetrate the plasma. The beam particles are then ionized and trapped in the plasma as a result of collisions with plasma ions and electrons. The resulting high-energy ions then "slow down" by Coulomb collisions and deposit their energy in ions and electrons. The mean distance that a neutral ion travels in a given plasma before it is ionized scales directly with its energy. Since it is most efficient to heat the center of the plasma, the beam energy is usually determined by the plasma density, temperature, and size. For a fusion-reactor plasma, beam energies of 100–200 keV are required for perpendicular injection (perpendicular to the toroidal circumference of the plasma) and 500–3000 keV for tangential injection (e.g., for current-drive purposes, Sec. 2.1.2).

The schematic of a neutral-beam injector is shown in Fig. 2. The neutral beam begins as a hydrogen plasma produced by a radio-frequency (rf) plasma generator or by a high-current discharge. Then the ions leaving the source are accelerated, in one or several stages by a series of electrostatic grids, to their final energy. The resulting ion beam is then neutralized by passing through a neutralizer chamber containing cold hydrogen gas. The beam ions pick up electrons from the neutral gas via the charge-exchange process and travel out of the neutralizer chamber as high-energy neutral particles. The neutral gas, which is ionized by the ion beam, drifts slowly to the walls of the chamber. Meanwhile, the neutralized beam passes through a drift tube before entering the reactor plasma. The small fraction of the original ion beam that is not neutralized in the neutralizer chamber is deflected by a small magnet in the drift tube. At present, the neutral-beam injectors on the TFTR experiments are capable of operating at 120 keV and delivering ~30 MW of heating power to the plasma for a pulse length of ~2 s (easily upgradable to steady-state operation).

Because the efficiency of the gas neutralizer chamber to neutralize the positive-ion beams degrades rapidly for a beam energies larger than ~150 keV, negative-ion beams should be utilized for higher energies. A completely different technology is required for this scheme. To produce a beam of negative ions, either the plasma in the ion source is seeded with cesium atoms, or the ions extracted from the source are reacted with specially coated surfaces. The negative ions are then accelerated by either electrostatic or rf quadrupoles. The high-energy negative-ion beam is then neutralized either through the charge-exchange process in a xenon plasma or by using the laser photodetachment process. Negative-ion beam accelerators are under development. At present, negative-ion sources are capable of 50-keV H^--ion beams with a current of ~0.5 A at steady state. Stable H^- beams at 300 keV for 0.5 s have also been achieved. The first heating experiments with negative-ion beams, which are planned for JT-60U (a large toka-

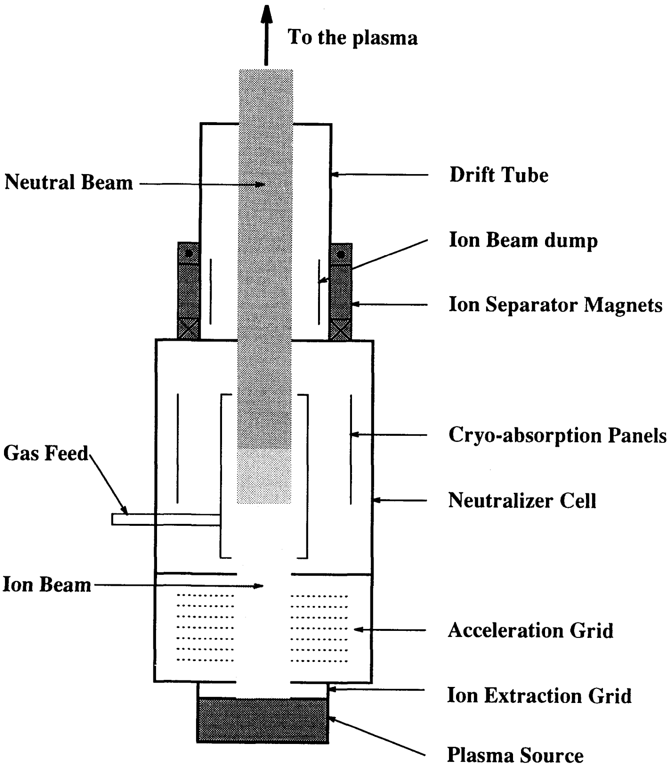

FIG. 2. A schematic of a positive-ion neutral-beam injector system.

mak experiment at the Japan Atomic Energy Research Institute) around 1995, will employ 500-keV deuterium beams (22 A for 10 s).

Another common method of auxiliary heating is by rf waves. In principle, the electromagnetic wave energy can be converted into plasma-particle kinetic energy through resonant wave–particle interaction. Because the plasma consists of charged particles, a variety of wave modes exist in a magnetized plasma and several rf heating schemes are possible and have been successfully demonstrated on present experiments (e.g., Alfvén, lower-hybrid, and electron-cyclotron resonance heatings, etc). One of the most advanced rf-heating techniques is ion-cyclotron range-of-frequencies (ICRF) heating. Depending on the wave frequency and the launcher design, ICRF waves can heat electrons, ions, or a minority ion species. In the latter scheme, a deuterium plasma is doped with a small amount of hydrogen or helium, and the ICRF wave frequency is matched to the cyclotron frequency of this minority species (~ 100 MHz, similar to television broadcast frequencies). Then the rf wave heats these minority species to the MeV range of energies, and their energy is transferred to plasma electrons and ions by Coulomb collisions.

All rf heating systems are, in essence, similar to a radio transmitter. They include an oscillator, an amplifier, a transmission line, and a launching structure inside or at the plasma chamber wall. The oscillator and amplifier can be a tetrode, a klystrode (a linear beam device having features of both klystron and tetrode), or a solid-state device based on field-effect transistors. The transmission line is a coaxial cable or waveguide, and the launching structure can be either an antenna or a waveguide. The major fusion-specific component of the rf heating system is the launcher.

In order for the launched rf power to couple well to the plasma, the wave number and polarization of the launched wave must be strictly controlled. Then the wave is able to penetrate the plasma and be absorbed at the desired location. To protect the launcher from electromagnetic radiation from the plasma, a "Faraday shield" is usually placed in front of it. The launcher should also be hardened against damage from the neutrons and charged particles from the plasma (Sec. 3.1).

2.1.2 Noninductive Current Drive. As mentioned before, plasma current driven by inductive means cannot be sustained indefinitely. Even though a pulsed tokamak reactor with a burn time of a few hours is a possibility, extensive research has also been directed towards noninductive means of driving the plasma current.

Theoretical research in the early 1970s predicted that in a sufficiently hot plasma, the radial pressure gradient and the dynamics of plasma flow on the flux surfaces combine to produce a self-driven current, usually referred to as the bootstrap current. Existence of the bootstrap current was experimentally confirmed only recently. Major tokamak experiments have operated with up to 80% of the plasma current driven by the bootstrap effect. Unfortunately, no tokamak plasma equilibrium has yet been found (either theoretically or experimentally) in which all of the plasma current is driven by the bootstrap effect. The difference between the plasma and bootstrap currents must still be driven by some other means.

Research has shown that both neutral-beam and rf-wave heating can be used to drive the plasma current. For example, by tuning the ICRF launching structure, most of the energy of rf waves can be used to accelerate the electrons parallel to the field line, which generates toroidal currents. The efficiency of these noninductive current-drive schemes, however, is low, and most steady-state tokamak reactor designs operate in regimes that maximize the bootstrap current, reducing the necessary current-drive power to a manageable level (~ 100 MW of current-drive power in a 1000-MWe power station).

2.1.3 Magnets. In addition to the toroidal-field magnets and the "Ohmic-heating" solenoid discussed above, other magnets are required for a tokamak. In principle, since a current-carrying loop can move along its axis freely, a tokamak plasma can move up or down and hit the plasma chamber walls. To keep the plasma at its location, a pair of "equilibrium-field" coils with currents flowing in the toroidal direction (but opposite to that of the tokamak plasma) are required. These coils are usually located symmetrically at about the toroidal midplane of the tokamak torus (one above and one below) and have radii that are usually larger than that of the plasma.

An important measure of the efficiency of a magnetic-confinement concept is the plasma β, the ratio of the plasma pressure to the pressure exerted by the external magnetic field that confines the plasma. The higher the β value, the smaller and more economical the external magnets can be. A major accomplishment of plasma physics research during the last decade has been achieving an understanding of the relationship of the plasma β to plasma shape, current, toroidal field, etc. It has been shown, both theoretically and experimentally, that elliptical or D-shaped plasma cross sections (with an elongation of about 2) can lead to improved plasma β. Plasma shaping, however, requires additional coils, all having toroidal currents, strategically placed around the plasma.

Most of the magnetic fusion-reactor concepts use superconducting magnets because the power consumed by normal-conducting magnets would be very large. Basically, superconductivity occurs in certain materials when their temperatures are reduced below some critical temperature. Most of the superconducting magnets, at present, use niobium–titanium (NbTi) or niobium–tin (Nb_3Sn) alloys as the superconducting material cooled by liquid helium to temperatures of about 4 K (some designs use either of these superconductors at lower temperatures). The commercial superconducting magnets available today mainly use NbTi and are of medium size (e.g., those used for magnetic-resonance imaging). Nearly all experience with large-size superconducting magnets to date is in high-energy physics (e.g., accelerators, bubble chambers) or in fusion. Compared to other superconducting magnets available today, fusion magnets are usually larger (many meters in diameter), may have noncircular cross sections (e.g., D-shaped toroidal-field coils), and have a high magnetic stored energy (tens of GJ). As a result, the design of these magnets is dominated by the structure, which is embedded in the coil to support the massive electromagnetic forces. Furthermore, the design of fusion magnets is also severely constrained by fusion-specific issues, such as allowable location for the coils and the structure, ability to operate in a radiation environment, and capability to produce and withstand high rates of field change (i.e., several T/s for poloidal-field coils).

Because of the engineering constraints, the peak field produced by a practical superconducting magnet is usually well below the critical field limit of the superconducting material. The maximum field produced by a Nb_3Sn superconducting magnet (a small-bore solenoid) is 21 T. The maximum field produced by a fusion magnet with a noncircular cross section is $\sim$9 T. It should be noted that the magnetic field strength on the plasma axis in a tokamak is considerably lower than the peak field on the toroidal-field magnets because of geometrical effects. For the ITER design, research and development are directed towards superconducting magnets with peak fields of 11–14 T, while conceptual tokamak-reactor designs have envisioned magnets with a peak field ranging from 14 to 21 T (depending on the value of plasma β).

A cross section of a toroidal-field magnet is shown in Fig. 3. In this type of design, filaments of niobium and tin are twisted together in groups and embedded in a copper sleeve to form a cable. Several cables are then placed together in a steel conduit, which also has passages for liquid-helium coolant. This conduit is heat treated so that the niobium and tin filaments interact, forming the superconducting alloy. A layer of insulating material is placed on the outside of the conduit, and layers of the superconductor conduits are interleaved with steel supports. The coil is then placed in a stainless Dewar or cooling vessel.

The superconducting magnets must be kept insulated from the nearby plasma because neutrons produced by fusion reactions can damage the superconducting material. Furthermore, so much heat would be generated by the interaction of neutrons with the magnet material that refrigeration of the magnets would be impractical. In order to attenuate the neutron flux on the magnets, they are usually placed behind the blanket and shield components (Sec. 3.2).

2.1.4 Particle Exhaust and Fueling. In most modern tokamaks, the plasma-shaping coils are energized such that a magnetic separatrix is formed inside the plasma chamber (Fig. 4). In the region inside this separatrix,

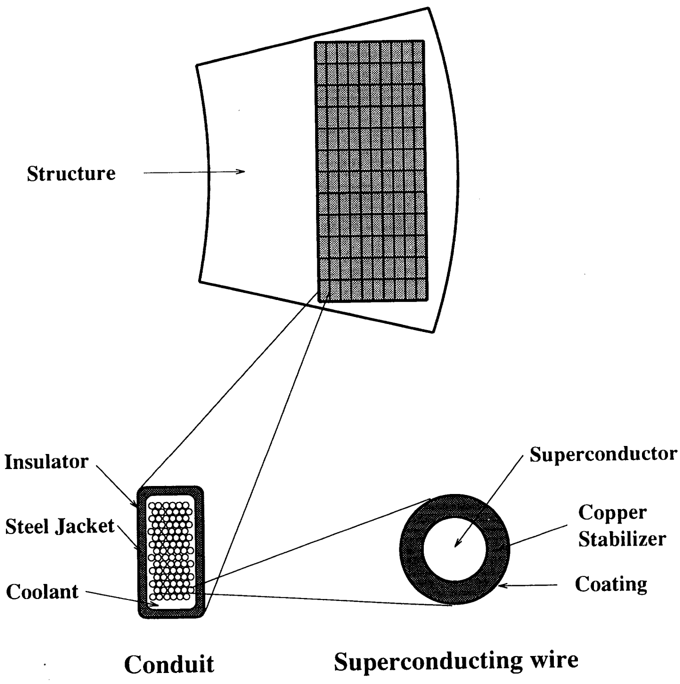

FIG. 3. A cross section and internals of the inner leg of a superconducting toroidal-field magnet.

called core plasma, the nested flux-surface structure of the tokamak is preserved. The field lines outside the separatrix, however, leave the vicinity of the plasma within a single poloidal transit (but many toroidal transits) and intersect material walls (divertor plates) in certain locations. The heat and particles from the core plasma diffuse outward through the separatrix into the scrapeoff-layer region and then flow rapidly along the field lines to the divertor plates. Clearly, very high heat and particle fluxes appear at the intersection of the separatrix with the divertor plate (strike point). Note that there is a large body of experimental evidence that shows that controlling the scrapeoff-layer plasma properties has profound influence on the quality of core-plasma confinement. In fact, the best tokamak discharges have been obtained in a divertor configuration.

The plasma that intersects the divertor plates is neutralized through surface recombination processes. Some of the neutral atoms are ionized, follow the field lines, and flow back to the divertor plate and, in effect, are recycled in the divertor region. If the separatrix plasma density is high enough, a high-recycling divertor regime is formed in which more than 90% of the neutral particles from the divertor plate are re-ionized in the plasma and are recycled. This mode of operation spreads the heat and particle load on the divertor plate and reduces the peak fluxes at the strike point. Further reduction in heat and particle fluxes can be achieved by slanting the divertor plate with respect to the field lines (Fig. 4).

At present, the design of the divertor represents one of the most fundamental challenges in designing fusion reactors, and it is not yet clear whether the high-recycling divertors will be able to reduce the particle and heat fluxes to manageable values. Many other concepts are, therefore, being pursued. In one, the plasma near the divertor is doped with impurities that cool the divertor plasma through line radiation. Another involves terminating the divertor plasma in a dense, but much cooler, neutral gas. Both of these concepts would spread the heat and particle load over a much larger area in the divertor.

Most of the neutral atoms that are produced on the divertor plate are ionized and flow back to the divertor plate. The rest, which are a mixture of fusion fuel (D and T) and α particles, is pumped, which removes the fusion ash from the system. Cryosorption pumps (see CRYOGENICS) are a leading technology for fusion reactors. Cryopumps include an array of sieves that are cooled to liquid-helium temperature. The sieves are surrounded by chevrons that are cooled to liquid-nitrogen temperatures. Impurity gases such as oxygen and nitrogen are adsorbed by the chevrons while hydrogen isotopes condense on the sieves. Helium can also be trapped by the sieves if liquid argon is sprayed onto the surfaces to overlay the helium atoms. Cryopumps are simple and attain very high pumping speeds at low pressures (10^{-7} atm). Their drawbacks are that they require periodic warming up to remove the gases trapped on the surface, and that the trapping of tritium onto the cryopump surfaces will result in a high inventory of tritium in the reactor. An alternative approach is to design the divertor system such that the neutral pressure at the front of the pumping duct is relatively high ($\sim 10^{-5}$ atm). In this case, nonadsorbing pumps, such as turbomolecular pumps, can be used. The exhaust gas from the reactor is processed to remove the helium ash and impurities.

For the fusion burn to continue, the reactor must be refueled with the D and T atoms that have been exhausted from the reactor, together with a supply of fuel to replenish that which was burned. In most current experiments, fueling is performed primarily by puffing the fuel gas at the edge of the plasma. This fueling technique is not very effective because most of the fuel does not reach the plasma center. An alternative method, also currently used in major tokamak experiments, is to inject high-speed pellets of frozen fuel. A typical pellet is several millimeters in diameter and is accelerated to speeds of ~2 km/s by high-pressure gas propellant in a gas gun (Fig. 5).

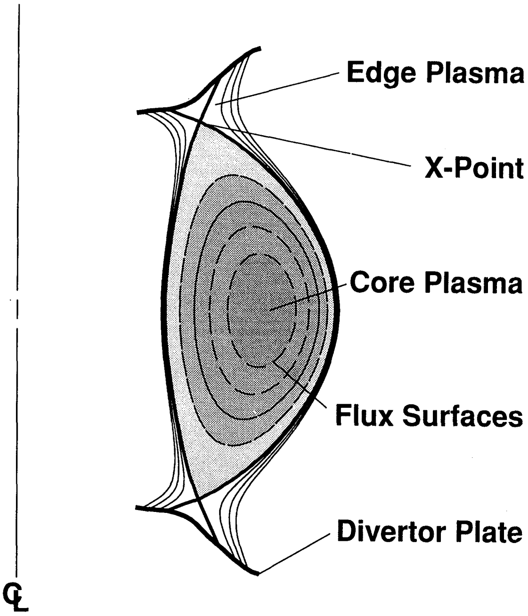

FIG. 4. A cross section of a tokamak plasma. The lines indicate the cross sections of flux surfaces (magnetic field lines are located on these surfaces). The "separatrix" surface marks the boundary between closed magnetic surfaces of the core plasma and the field lines in the scrapeoff-layer plasma that leave the vicinity of the plasma and intersect the divertor plates.

2.1.5 Alternative Magnetic-Confinement Concepts. Of the many magnetic-confinement concepts that have been investigated in the past 30 years, the tokamak is the most advanced. Other promising concepts include the stellarator, reversed-field pinch, and field-reversed configurations (see FUSION, MAGNETIC CONFINEMENT). Each has desirable features that simplify or eliminate plasma support technologies. These features are highlighted below.

The confining magnetic field structure in a stellarator is similar to that of a tokamak, although it is produced by complicated coils external to the plasma. The major advantage of the stellarator is that because it does not require a toroidal current in the plasma, it can operate in steady-state mode without a current-drive system.

The reversed-field pinches also have nested flux surfaces similar to those in the tokamak. However, most of the toroidal field is produced by current flowing in the plasma. The direction of the toroidal field is reversed near the plasma edge and only a weak external toroidal field is required to maintain the plasma configuration. Ohmic heating to ignition may also be possible. Elimination of the auxiliary heating system and major simplification of the external magnets are major features of this concept. Steady-state operation, however, requires a noninductive current-drive technique.

The field structure in a field-reversed configuration is very different from the above-noted concepts; it resembles that of a current loop (plasma) in an external solenoidal field. The experimentally achieved plasma β is very high, the external magnets are simple, and it is more amenable to direct conversion of charged-particle energy to electricity. At this

time, however, the experimental data base for this concept is limited.

2.2 Inertial Fusion-Energy Reactors

Because of its inertia, material at fusion temperature stays together for a finite, albeit short, period of time (nanosecond time scale). Since fusion ignition and burn require attainment of the triple product $nT\tau_E$, inertial-confinement fusion can be achieved if the fusion fuel is compressed to a very high density (1000 times liquid density). Such a compression can also adiabatically heat the fuel to fusion temperatures.

In the inertial-confinement scheme (see FUSION, INERTIAL CONFINEMENT), a small pellet containing the fusion fuel is bombarded by powerful lasers or particle beams (typically 100–1000 TW of power is needed). Ablation of the material on the pellet surface, therefore, causes an implosion that compresses the center of the pellet to high density and high temperature. A small region in the center of the pellet can become hot enough to initiate a fusion reaction. The energy released from the fusion reactions can heat the surrounding colder fuel to fusion temperature, resulting in a fusion-burn front that rapidly propagates outward and consumes the rest of the fusion fuel before the pellet flies apart.

Candidate drivers include lasers and particle-beam accelerators. Solid-state neodymium (Nd) glass lasers are presently used in inertial-confinement experiments. The efficiency of this laser (~1%) is too low for reactor applications, however. Krypton fluoride (KrF) gas excimer lasers are predicted to have a higher efficiency (~10%) and are under development as a potential driver. Particle beams are more attractive since they have higher intrinsic efficiency (~25%). Low-energy light-ion beams with a high current are used in the present experiments, but high-energy heavy-ion beams with a low current, which are under development, are thought to be the best driver for a power reactor. The technologies of the above drivers are covered in detail in FUSION, INERTIAL CONFINEMENT, Sec. 5.

The ratio of the energy released by pellet explosion to the driver energy is usually referred to as the pellet gain G. A high pellet gain (typically 100 for a D-T reaction) is required to compensate for the inefficiencies in the driver and thermal-power-conversion system. Achieving ignition and high pellet gain imposes severe constraints on the driver and pellet designs. First, the driver pulse should be shaped properly in order to maximize the fraction of the driver energy that is used in compressing the pellet. Second, and more importantly, the pellet implosion should be highly uniform (pressure nonuniformity should be less than 1%). This requires that the pellet surface should be very smooth (less than 100-Å imperfections). Also, the pellet should be heated uniformly, either by ensuring that the driver beam strikes the pellet uniformly (direct drive) or by converting the driver energy into x rays in a *Hohlraum* (indirect drive).

In an inertial-fusion reactor, the pellet microexplosion occurs in the reactor chamber. Practical constraints on the size and lifetime of the reactor chamber limit the yield of pellet explosions to a maximum of 500–1000 MJ (a pound of high explosive releases about 2 MJ of energy). Therefore, a typical power reactor (1000 MWe) requires a pulse rate of a few Hz. During each pulse, a pellet is injected several meters into the reactor chamber and should be tracked until it is in the precise location and alignment for the driver. The driver should deliver its energy with the precise pulse shape and focus on the target. After the implosion, the debris of the pellet (and the *Hohlraum*, if used) should be evacuated from the reactor chamber so that the beam can propagate through the reactor chamber with minimum loss while maintaining adequate focus. These pulses should be repeated reliably millions of times per year, and the wall of the reactor chamber should be able to withstand the many microexplosions (see Sec. 3.6). Mass production of millions of highly smooth pellets at an acceptable cost is also a challenging technological issue. Research is ongoing on most of these issues.

3. FUSION-REACTOR TECHNOLOGIES

3.1 First Wall, Blanket, and Shield

3.1.1 Function. The plasma reaction chamber is the first material boundary that faces the plasma. Usually referred to as the first wall, this region is subjected to bombardment by electromagnetic radiation from the plasma (mainly x rays), the flux of charged particles diffusing from the plasma, fast neutral atoms produced by charge-exchange processes in the plasma, and energetic neutrons produced by the D-T reaction. Each component of this harsh environment imposes severe constraints on the first-wall design (Sec. 3.1.2). The energy deposited in the plasma by the auxiliary heating system and by the fusion α particles must eventually leave the plasma. This energy appears mostly as surface heat flux on the first wall (radiation and charged-particle flux) and should be removed as useful heat. Sputtering of the first wall by plasma and neutral particles would cause erosion of the first-wall material, and the first wall may have to be coated with a low-Z material so that eroded material will not contaminate the plasma dramatically.

The fusion-produced neutrons have a long mean free path between collisions with solid and liquid materials (typically ~10 cm for 14-MeV neutrons). Most of these neutrons pass through the first wall and are absorbed in the blanket. The main function of the blanket is to moderate and capture these neutrons, extract their energy, and simultaneously breed enough tritium to replace that which is burned in the fusion process.

Typically, blankets are 0.8 to 1 m thick and attenuate the neutron flux by about 2 orders of magnitude. In MFE reactors, a shield is usually placed behind the blanket in order to attenuate the neutron flux by about 4 orders of magnitude so that a superconducting magnet can be located behind the shield. Such shields are typically 0.5 to 1 m thick.

3.1.2 Tritium Breeding. The primary reactions leading to tritium production are

$$^{6}\mathrm{Li}+n\rightarrow \mathrm{T}+{}^{4}\mathrm{He}$$

and

$$^{7}\mathrm{Li}+n\rightarrow \mathrm{T}+{}^{4}\mathrm{He}+n.$$

The first reaction leads to energy production (4.8 MeV released per reaction). The second consumes energy (2.87 MeV) but it gives rise to a second neutron that can subsequently react with ^{6}Li. The natural abundances of these lithium isotopes are 7.4% ^{6}Li and 92.6% ^{7}Li. The technology for enriching the natural lithium in the ^{6}Li isotope is available and is not very expensive. In some conceptual blanket designs, therefore, enrichment of up to 20% in ^{6}Li is utilized in order to optimize the nuclear performance of the blanket.

The number of tritium atoms produced in the blanket for each D-T neutron is referred to as the tritium breeding ratio (TBR). Since each fusion reaction uses one tritium atom to produce one neutron, a TBR of 1 or greater is required for tritium self-sufficiency. In a fusion reactor, not all of the fusion neutrons are absorbed in Li; some are absorbed in the structural material or coolant of the blanket. Therefore, in certain designs, a neutron-multiplying material is added to the blanket. Of particular interest is beryllium, which interacts with one neutron and produces two neutrons. These extra neutrons then compensate for neutron absorption in the blanket structural material.

The tritium-breeding materials can be lithium or lithium compounds. The choice is usually based on high-temperature capability; chemical compatibility with the coolant and the structural material; the desire for a high tritium-release rate (the tritium produced leaves the material rapidly, leading to a low tritium inventory in the blanket); the availability of, or the need for, a neutron-multiplier material; the tritium-recovery method; simplicity of design; etc. The first and most obvious choice is lithium itself in liquid form, to be used as both the breeder and coolant. Lithium eutectic compounds such as lithium–lead ($\mathrm{Li_{62}Pb_{38}}$), aqueous solutions of lithium salts, and fused lithium salts such as FLiBe can also be used as the coolant and breeder. Lastly, solid lithium compounds, such as lithium oxide ($\mathrm{Li_2O}$) and lithium orthosilicate ($\mathrm{Li_4SiO_4}$), have also been considered.

3.1.3 Structural Material. Material choices are critical in designing the fusion first wall and blanket. Structural material choices are usually based on their ability to operate at high temperatures, to withstand radiation damage by neutrons, and to have only a minimum amount of induced radioactivity caused by the fusion neutrons. Radiation damage is the most important criterion because it has the greatest influence on material performance and lifetime. During neutron irradiation, the absorption of a neutron by the material through scattering and absorption reactions can induce two major nuclear effects: atomic displacement and production of impurities and gas (hydrogen and helium).

During the scattering events, the energy transferred from the neutron to the nuclei can cause an atom in the solid structure to be displaced from its equilibrium lattice site, leaving behind a vacancy in the lattice. A scattered neutron, as well as the displaced atom, can interact with other atoms in the lattice and cause displacement cascades. This process continues until the energy transferred to the lattice atom becomes low enough so that it can be absorbed as vibrational energy by the lattice. The displaced atoms themselves usually come to rest at locations that are not regular lattice sites and, therefore, are referred to as interstitials. Even though each neutron produces many vacancy-interstitial pairs, most recombine rapidly and leave quite small net levels of point defects in the lattice structure. Voids in the material form if the vacancies are mobile enough (if the material temperature is high enough) to combine and if some agent, such as a small amount of gas, is present to stabilize the embryonic void. The void will then subsequently grow and cause dimensional changes of the structural material, referred to as "swelling," which can easily reach several tens of percent. Because the swelling rate depends on the material temperature and neutron flux, which are not uniform in a fusion blanket, the swelling rate will not be uniform, which can lead to large internal stresses in the structure.

The strength (or hardness) of annealed metals usually increases under irradiation and typically both the yield strength and the ultimate tensile strength increase. Unfortunately, this increase in hardness is generally accompanied by a loss of ductility, or embrittlement (material fails under small levels of strain). Embrittlement can have several causes; the most important is related to the large amount of helium gas that is produced in the structural material through (n,α) reactions. At high temperatures, the helium atoms become mobile and diffuse to the boundaries between grains in the metal. Subsequently, helium bubbles form and intergranular failure occurs.

In addition to swelling and embrittlement, physical, mechanical, and thermal properties of the material change by neutron irradiation (e.g., through the production of point defects or by the change in the composition of the alloying elements). As mentioned before, the irradiation effects are very sensitive to both neutron flux and fluence and also to the operating temperature of the material. Chemical interaction among the structural and breeding materials and the coolant, as well as gradients in the temperature, flux, and stress, can also have a dramatic impact on the response of the material to radiation and on its lifetime.

During the 1970s, most of the research effort on structural materials was focused on stainless steels because of the experience in the fission industry. During the 1980s, research focused on low-activation structural material (nuclear waste produced in a reactor built with these materials does not require geological disposal as is needed for fission plants). Primary materials in this category are low-activation ferritic steels (in which induced activation is reduced by substituting for certain alloying elements) and vanadium alloys. Recently, ceramic composites such as silicon carbide (SiC) and fiber-reinforced SiC-matrix composites have received considerable attention. Ceramic composites are of particular interest because the level of induced radioactivity is very low, as shown in Fig. 6 (6 orders of magnitude lower than a metallic structure one day after shutdown).

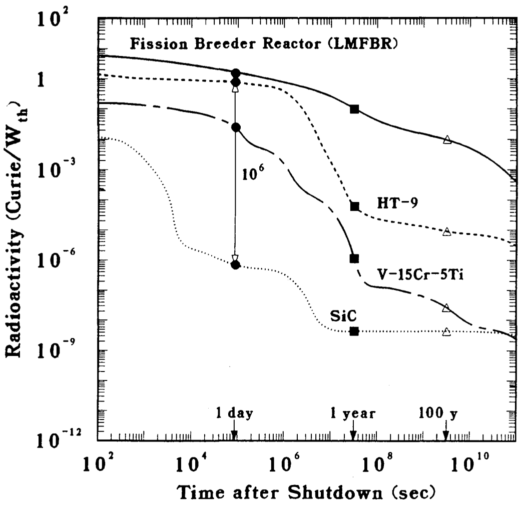

FIG. 6. Normalized radioactivity inventories after shutdown in D-T fusion reactors made of various structural material: HT-9 ferritic steel, V–15Cr–5Ti vanadium alloy, and SiC composites. For comparison, radioactivity levels of a liquid-metal fast-breeder reactor are also shown.

Because of the radiation damage, the lifetime of the first wall and blanket of a D-T reactor is limited and they should be replaced periodically (about every three to six years would be acceptable). Unfortunately, experimental radiation-damage data are limited to a small number of materials and to a low value of neutron fluence. Furthermore, experiments are usually carried out in fission reactors (14-MeV fusion neutrons cause a much higher production of gases, which drastically impacts the material behavior). Fusion-reactor–material test facilities, therefore, have been proposed that incorporate an intense 14-MeV-neutron source.

3.1.4 Conceptual Designs. In addition to liquid lithium or lithium eutectic compounds, water and helium gas have been considered as the coolant. In principle, engineering issues such as chemical compatibility and operating temperature determine the coolant once the structural and breeder material are chosen. Three design types are favored at present. The first is a water-cooled system with steel struc-

FIG. 7. Internal structure of one of the blanket modules of the steady-state tokamak reactor, SSTR-1 (Seki *et al.*, 1991). This design uses stainless steel as the structural material, pressurized water as the coolant, beryllium as neutron multiplier, and solid tritium breeding material (figure courtesy of Y. Seki of Japan Atomic Energy Research Institute).

ture and a solid breeder material such as lithium oxide (Fig. 7). This combination requires a neutron multiplier (e.g., Be) in order to achieve a TBR > 1. This design builds upon pressurized-water fission-reactor experience. The main drawbacks to this design are that the outlet temperature of the water coolant is low, which results in a low thermal-to-electrical conversion efficiency, and that the radioactivity induced in the steel structure, even though lower than a fission reactor, is still large by fusion-reactor standards. Tritium leakage into the water coolant also requires expensive tritium-separation systems.

The second type of design (Ehst *et al.*, 1987) uses vanadium alloy as the structural material and liquid lithium as the coolant (no multiplier). Actually, because most of the energy is deposited in the lithium itself, the lithium is a heat-transport fluid rather than a coolant—a major design simplification. Because lithium is electrically conductive, the magnetohydrodynamic (MHD) pressure associated with a conductive fluid moving perpendicular to a magnetic field can lead to high pressure and high pumping power. Reducing the pressure and pumping power to a manageable level will require either a low-velocity, large-area flow channel or nonconducting coolant-channel walls. The thermal-to-electrical conversion efficiency is high. From safety and environmental viewpoints, it ranks better than the water–steel design discussed above; however, lithium fires, which may be caused by an accident, are safety concerns. Lastly, vanadium manufacturing is not as mature as that of steel.

The third class of designs uses a ceramic composite such as SiC composite as structural material, inert helium gas as the coolant, and a solid breeder material such as lithium oxide (Fig. 8). This type of design can achieve the full safety and environmental potential of fusion because the radioactivity inventory is several orders of magnitude lower than fission reactors, and the level of decay afterheat is similarly smaller. Although ceramic composite manufacturing is still in its infancy, it is being pursued vigorously by the aerospace industry.

3.1.5 Tritium-Recovery Systems. Tritium that is bred in the blanket should be recovered rapidly to minimize the T inventory

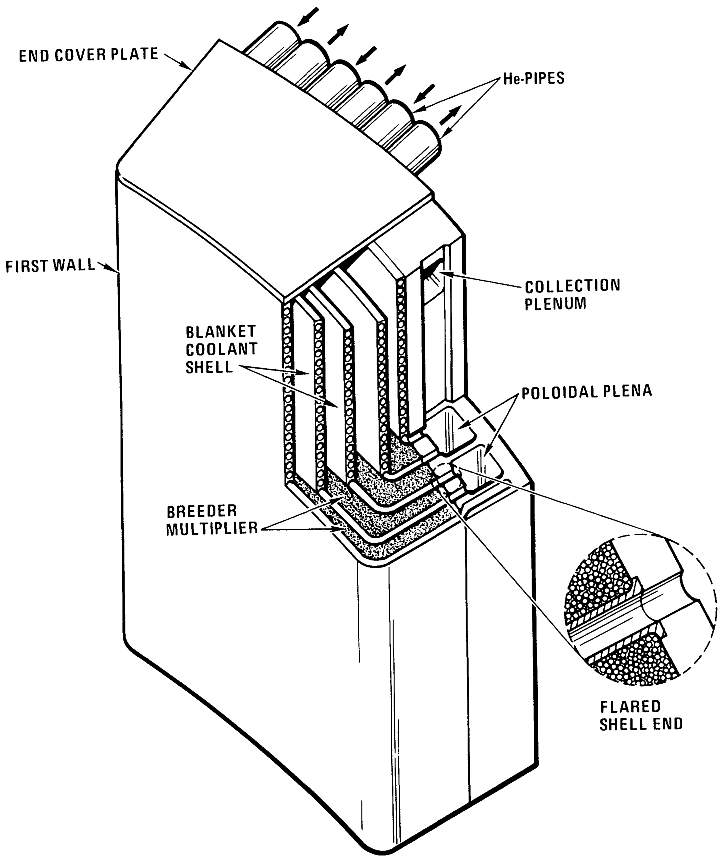

FIG. 8. Internal structure of one of the ARIES-I blanket modules. This design uses SiC composite as the structural material, helium gas as the coolant, Be as the neutron multiplier, and lithium zirconate tritium breeders (Najmabadi *et al.*, 1991).

in the reactor. Designs with solid breeder material rely on diffusion of T out of the solid. As such, the breeder is usually fabricated in small pellets to increase the surface area of the solid. The temperature of the breeder material is also chosen to maximize T diffusion. The T diffusing from the breeder is transported out of the blanket by a purge stream of helium gas. In designs with liquid-lithium breeder, T is in the form of lithium tritide. A small side stream of liquid lithium is brought into contact with an equal volume of a molten lithium salt. Lithium tritide tends to pass to the salt stream and can be readily separated because it is several times lighter. Tritium is then recovered by electrolysis. The molten-salt process is similar to that developed to reprocess fission-reactor fuel.

3.2 Power-Conversion Systems

Most conceptual fusion-reactor designs utilize thermal-to-electrical power-conversion systems similar to those in existing fission or coal-burning power plants. The energy produced in the reactor is used to heat a gas (usually steam) to high temperatures. The hot gas, in turn, expands and cools down in a turbine, producing mechanical energy that is converted to electricity. Of the three types of blanket designs discussed above, the water-cooled system probably needs an intermediate coolant loop and has a low conversion efficiency. Liquid-metal–cooled designs also require an intermediate liquid-metal loop because tritium is present in the primary coolant. Gas-cooled designs can either use a Brayton cycle (coolant sent directly to the turbine) or advanced Rankine steam cycles similar to those proposed for near-term coal-fired power plants. Intermediate loops can be eliminated from these designs if care is taken to keep the tritium separated from the primary coolant.

The power produced in the fusion plasma is carried away by radiation (microwaves and x rays) and by charged particles with energies from several tens of eV (scrapeoff-layer plasma) to several keV (bulk plasma) to the MeV range (fusion by-products) depending on the magnetic-confinement concept. Because the "effective" temperatures of the charged particles or radiation photons are very high, the Carnot bound for the efficiency of converting their energy into electricity is virtually 100%. Furthermore, such direct-conversion schemes can avoid expensive and complicated "conventional" thermal-power-conversion systems.

Several schemes have been proposed for converting charged-particle energy directly into electricity. Such a system would operate as an inverse of a particle accelerator (i.e., the charged particles are slowed down and absorbed by a series of electrodes at different voltages). Since the plasma particles move readily along the magnetic field lines, direct conversion of charged-particle energy is more amenable to confinement schemes in which some field lines leave the main plasma (a field-reversed configuration as opposed to a tokamak). Furthermore, each electrode only absorbs particles with energies close to its biasing voltage. Therefore if the plasma exhaust has a Maxwellian energy distribution, the conversion efficiency for a practical system (limited number of electrodes) is not very high. In certain magnetic-confinement concepts (such as mirrors), the plasma has a positive voltage with respect to the ground and, therefore, the energy distribution of exhausted plasma particles is narrow. In this case, conceptual designs predict a conversion efficiency of ~80% (Logan *et al.*, 1984).

Several schemes have also been proposed for converting plasma radiation into electricity. In one proposal, the plasma radiation is utilized to superheat the coolant for use in an advanced thermal-conversion scheme such as MHD generators. In another, solid-state rectennas (a rectenna is combination of an antenna and a rectifier) have been used to convert synchrotron radiation from the plasma into electricity. These devices have been studied for conversion of microwave energy into electricity (for use with solar-power satellites, which transmit their energy to Earth stations through microwaves). One of the major difficulties, which is similar to that of the charged-particle conversion scheme, is that each rectenna is tuned to a certain frequency range while the synchrotron radiation from the plasma has a broadband spectrum.

3.3 Inertial Fusion-Energy Reactors

The major difference between IFE and MFE reactors is the first-wall design. While the first-wall design is a challenge in an MFE reactor, the design constraints are even more severe for an IFE reactor. This is because of the thermal and structural fatigue caused by millions of microexplosions as well as erosion caused by debris. Any beam-steering or -focusing element that is in direct sight of the explosion should also be protected.

Several innovative designs have been suggested for an IFE reactor. They include

1. inclusion of sacrificial coating on the first wall that would be reapplied *in situ* occasionally,
2. a thick flowing layer of small lithium ceramic granulates,
3. a wetted first wall in which liquid metals such as lithium or lead diffuse through the wall onto its surface, and
4. a thick flowing waterfall (or jet) of lithium.

These concepts are reviewed in detail in FUSION, INERTIAL CONFINEMENT, Sec. 6 and Fig. 12.

In an MFE reactor, the external magnets are usually placed as close as possible to the plasma in order to minimize their costs. The first wall, blanket, and shield are, therefore, squeezed into the space between the plasma and the magnet, making maintenance operations difficult. In an IFE reactor, there are no magnets. The first wall and blanket have a more regular geometry (cylindrical or spherical), which would facilitate maintenance.

4. ADVANCED FUELS

In addition to the D-T fusion reaction, the following have cross sections that are large enough to be of interest in terrestrial applications (as expected, all involve hydrogen isotopes):

$$\mathrm{D}+\mathrm{D}\rightarrow{}^{3}\mathrm{He}(0.92\ \mathrm{MeV})+n(2.45\ \mathrm{MeV}),$$

$$\mathrm{D}+\mathrm{D}\rightarrow\mathrm{T}(1.01\ \mathrm{MeV})+p(3.03\ \mathrm{MeV}),$$

$$\mathrm{D}+{}^{3}\mathrm{He}\rightarrow{}^{4}\mathrm{He}(3.67\ \mathrm{MeV})+p(14.67\ \mathrm{MeV}).$$

The two D-D reactions occur with equal probability. The resulting T and ^{3}He produced by these reactions can subsequently undergo D-T and D-^{3}He reactions. Roughly 40% of the fusion energy is released in neutron power in a D-D reactor. Even though the D-^{3}He reaction does not produce neutrons, D-D reactions occur in a D-^{3}He plasma, which lead to neutron production.

These advanced-fuel reactions require a triple product that is ~ 10 times larger than that required for D-T fusion. They also require a higher plasma temperature (40–60 keV) and, obviously, require more efficient confinement concepts. It also appears that the required pellet gain for an IFE reactor is so large that an advanced-fuel IFE reactor may be impractical.

The major advantage of advanced fuels is that no T breeding is required, making blanket design less difficult. Tritium-handling systems, however, are still needed because T is produced in the plasma, albeit in smaller quantities. Because the neutron flux in a D-^{3}He reactor is 10 times less than in a D-T reactor, the first-wall and blanket component may last the reactor lifetime and need not be replaced. In should be noted that the choice of structural material has a more drastic impact than advanced fuels on achieving the safety and environmental features of fusion (the amount of induced radioactivity in a D-^{3}He reactor is only a factor of ~ 5 lower than that in a D-T reactor with similar structural material, while the induced radioactivity can be reduced by up to 6 orders of magnitude by choosing the appropriate structural material). Lastly, ^{3}He is not available in appreciable quantities on Earth. The proposed eventual source of ^{3}He is the regolith of the lunar surface, which contains about 10 parts per billion of ^{3}He, deposited by the solar wind.

5. CONCLUSIONS

Long-term energy needs require energy sources that are inexhaustible and environmentally benign. Fusion is one of the very few long-term energy options.

Achieving and maintaining the high temperatures required for the fusion burn are the most fundamental challenges for fusion-energy research. Technical progress towards achieving a fusion reactor has been dramatic in the past decade. The required fusion temperature has been attained, and several experiments are approaching the required triple product for maintaining fusion burn. These results, together with the D-T experiments planned for JET and TFTR, serve to demonstrate the scientific feasibility of fusion power.

These accomplishments have initiated an internationally coordinated strategy to address the remaining technological issues that will demonstrate the economic feasibility of fusion power. The first step in this direction is the International Thermonuclear Experimental Reactor (ITER), proposed as a joint venture by the European Community, Japan, the Russian Federation, and the United States.

Conceptual fusion-reactor design studies have been carried out since the early 1970s in order to uncover potential problems, to propose solutions that are consistent with other reactor subsystems, and to identify critical areas that should receive priority in experimental programs. These studies have also shown that potential safety and environmental attributes of fusion can be realized at least at the level of a self-consistent conceptual design study.

At present, the national energy strategy of the United States calls for a fusion demonstration power reactor to begin operation, following the ITER program, in 2025. For this goal to be realized, several other major facilities are required in order to develop the necessary technologies. Steady-state tokamak experiments, a high-fluence 14-MeV-neutron source for material testing, and a technology device for testing blanket concepts (usually referred to as the volumetric neutron source) are necessary and are in various stages of planning.

GLOSSARY

Auxiliary Heating System: The system which heats the plasma to fusion temperatures ($\sim 10^8$ K).

Blanket: The components that surround the fusion chamber and convert the fusion energy into heat. In a D-T fusion reactor, the blanket contains lithium or lithium-containing compounds to breed the tritium fuel.

Breakeven: Refers to a fusion plasma condition in which the fusion energy released is equal to auxiliary-heating energy needed to sustain the plasma temperature.

Cryopump: A high-vacuum pump that uses plates cooled to cryogenic temperatures to adsorb gas atoms and molecules.

Current Drive: A system to drive an electric current in a magnetically confined plasma.

Direct Drive: The inertial-confinement fusion method in which the driver directly irradiates the pellet surface.

Driver: A very high-energy laser or a particle beam used for implosion of the pellets (inertial-confinement fusion).

Embrittlement: A process caused by neutron irradiation which leads to a decrease in the ductility and fracture toughness of the material.

Energy-Confinement Time: The average time it takes before the energy escapes from the plasma.

First Wall: First material wall facing the plasma in a fusion device.

Gain: The ratio of fusion energy released during pellet implosion to the driver energy.

Hohlraum: An enclosure in which the energy of the driver is converted into x rays. It is used in the indirect-drive approach to the inertial-confinement fusion.

ICRF Heating: An efficient method of auxiliary heating of the magnetically confined plasmas by using electromagnetic waves. ICRF is an acronym for ion cyclotron range of frequency.

ITER: The acronym for International Thermonuclear Experimental Reactor, a large tokamak experiment proposed as a joint venture by the European Community, Japan, the Russian Federation, and the United States.

Ignition: A fusion plasma condition in which the fusion energy released supplies enough energy to the fusion plasma to sustain the fusion reactions.

Indirect Drive: The inertial-confinement fusion method in which the driver energy is first converted into x rays in a *hohlraum.* The x rays then irradiate the pellet surface.

Inertial-Confinement Fusion: A method for isolating the fusion plasma from the material wall. In this scheme, bursts of fusion energy are produced by using lasers or particle beams to implode small pellets containing deuterium and tritium. The fusion reaction takes place in the short time before the pellet flies apart.

JET: An acronym for Joint European Torus. It is the largest tokamak experiment in the world today and is located at Culham Laboratories in the United Kingdom.

JT60: A large tokamak experiment located at Japan Atomic Energy Research Institute at Naka, Japan.

Low-Activation Material: Certain material for which the radioactivity induced by neutron irradiation is low. In particular, disposal of such material does not require geological storage as is required for nuclear-fission waste. It is proposed that fusion-power reactors will be built of this sort of material.

Magnetic Confinement Fusion: A method for isolating the fusion plasma from the material wall. In this scheme, the plasma is confined in a magnetic bottle.

Neutral Beam Injector: An efficient method of auxiliary heating of magnetically confined plasmas. It employs an intense beam of high-energy electrically neutral particles, since neutral particles can move through the magnetic field unaffected.

Ohmic Heating: Heating of the plasma by the electric current flowing in the plasma.

Pellet Injector: A method for fueling magnetically confined plasmas. A frozen pellet of deuterium and tritium is injected at high velocity (~ 2 km/s) into the plasma.

Plasma: A state of matter; an ionized gas in which electrons are not bound to the nuclei.

Radiation Damage: Processes leading to degradation in the properties of materials, caused by neutron irradiation. Examples includes atomic displacement, swelling, and embrittlement.

Scrapeoff Layer: The region of the plasma in a tokamak in which the field lines intersect a material wall (i.e., limiter or divertor plates).

Shield: A component located behind the blanket of a magnetic-confinement fusion reactor to protect the superconducting magnets.

Superconductivity: A state achieved by certain alloys and compounds in which electrical current can flow without any resistance. It usually occurs at cryogenic temperatures.

Swelling: A process caused by neutron irradiation that leads to an increase in the size of the material.

TFTR: An acronym for Tokamak Fusion Test Reactor. It is a large tokamak experiment located at the Princeton Plasma Physics Laboratory.

Tokamak: The most advanced magnetic-confinement concept.

Triple Product: The product of plasma density, n, temperature, T, and energy-confinement time, τ_E. The necessary condition for a sustained D-T fusion burn is that the triple product exceed 2×10^{21} s keV/m^3.

Tritium Breeding Material: Lithium or a lithium-containing compound included in the blanket of a D-T fusion reactor to produce tritium to fuel the reactor.

Tritium Breeding Ratio: The number of tritium atoms produced in the blanket for each D-T neutron. Since each D-T fusion reaction uses one tritium atom to produce a neutron, a TBR of 1 or greater is required for tritium self-sufficiency.

INTRODUCTION

Cosmology is the branch of physical science that treats the structure, origin, and evolution of the physical universe as a whole. Although people have speculated about these questions for millennia, cosmology became a full-fledged science, in the modern sense, only in the 20th century, when telescopes powerful enough to yield abundant data about stellar systems outside the Milky Way became available. The history of scientific cosmology falls naturally into three main periods. The first period begins with the ancient Greeks and goes right through the 19th century, at the end of which the prevailing cosmological notions were actually farther from contemporary notions than were those of the Greek atomists. The second period begins in 1912 with Henrietta Swan Leavitt's discovery of the period–brightness relation of Cepheid variables—still the foundation stone of cosmological distance estimates—and ends in 1965. In that year, Arno Penzias and Robert Wilson announced the discovery of the cosmic microwave background, a uniform sea of blackbody radiation at a temperature of 2.7 K. Contemporary cosmology deploys Earth-, balloon-, rocket-, and satellite-based telescopes that explore deep space over virtually the entire electromagnetic spectrum, from radio wavelengths to γ rays. Three questions are central to modern observational cosmology: How are galaxies distributed in space on all scales? What is the rate of cosmic expansion, and how does it vary with distance? And what is the mean

cosmic mass density? The answers to these questions are crucial to an understanding of how the universe began and how it has evolved.

Modern theoretical cosmology is dominated by Einstein's theory of gravitation. Relativistic cosmology rests on that theory and on the assumption that, apart from "local" irregularities, the universe looks the same everywhere and in all directions. Relativistic cosmology, together with modern estimates of Hubble's constant (the mean rate of cosmic expansion), predicts that the universe began to expand from an initial state of exceedingly high density between 10 and 20 thousand million years ago. It says nothing, however, about the temperature of that initial state. As discussed below, most workers during the past quarter century have assumed that the cosmic microwave background is the remnant of a primordial fireball. But that scenario, despite its popularity, is encountering serious observational and theoretical difficulties. It is not yet clear whether these difficulties are growing pains or symptoms of a fatal disease.

1. ANCIENT AND CLASSICAL COSMOLOGY

1.1 Greek Cosmology

In the sixth century B.C., Greek natural philosophers constructed the first nonmythical accounts of the structure, origin, and evolution of the physical universe. These early cosmogonies postulated an infinitely extended, uniform, static, and structureless primordial cosmic medium that gradually differentiated under the action of opposed, indwelling tendencies.

The fifth-century atomists Leukippos and Demokritos invented a radically different picture of the world. Unlike their predecessors, they thought of reality not as a continuum but as fundamentally discrete and discontinuous. Behind the world of appearances they imagined an infinite variety of indivisible atoms moving in otherwise empty space. They suggested that the Sun, the Moon, the planets, and the stars are hot, glowing rocks. And they argued that the order of the cosmos was not purposeful but merely a consequence of motions governed by "blind Necessity."

An opposing tradition of Greek scientific cosmology put the Earth at the center of a system of nested concentric spheres containing, respectively, the Moon, the Sun, the planets, and the stars. Eudoxos and other Greek mathematicians tried to account for the observed motions of celestial bodies by attributing to these spheres various combinations of uniform circular motions.

1.2 The Revival of Greek Cosmology

Greek cosmology played an important role in the revival of Greek science that took place in Europe in the 16th and 17th centuries. Copernicus rejected the received cosmology of his day, a geocentric model of the solar system constructed by Ptolemy (second century A.D.) on lines laid down by Aristotle, in favor of the mathematically simpler heliocentric cosmology of Aristarchus (third century B.C.), which he reconstructed from hints that he found in newly translated Greek texts. Copernicus, in the first half of the 16th century, and Kepler, at the end of the century, considered the Sun to be at the center of the universe. The opposing view, that the Sun is just a nearby star and that the stars are uniformly sprinkled throughout an infinite space, was advocated by Giordano Bruno, who was executed by the Church in 1600 for his vigorous advocacy of it. The hypothesis nevertheless grew in popularity, along with the other major tenets of Greek atomism. Huygens and Newton not only accepted the picture of an infinite universe more or less uniformly populated by stars but devised scientifically sound methods for estimating the distances of nearby stars on the assumption that they are intrinsically as bright as the Sun (described in Layzer, 1984). Huygens wrote a popular book, *Cosmotheoros*, expounding the notion that each star has its own family of planets, many or all of which are abodes for life.

1.3 Newton's Cosmology

Newton's theory of gravitation, published in 1687, opened up the possibility of constructing a physical theory of the universe as a whole. The second of Newton's "axioms or laws of motion" states that the acceleration of any object is proportional to the net force acting on it (and inversely proportional to the object's mass). Newton posited that accelerations are to be measured relative to a cosmic reference frame that he called "absolute space." He conjectured that the "fixed stars" are on average at rest in this frame, but his theory did not explain why. Newton's universal law of gravitation states that the gravitational force acting on any particle of matter is the (vector) sum of the gravitational attractions exerted by all the other particles in the universe, each such attraction being proportional to the mass of the attracting particle and inversely proportional to the square of its distance. In a letter to the theologian Richard Bentley written in 1692, Newton discussed the application of his theory of gravitation to the universe as a whole. He argued that if matter was initially distributed evenly within a finite volume of space, it would,

> by its gravity ... fall down into the middle of the whole space and there compose one great spherical mass. But if the matter was evenly disposed throughout an infinite space, it could never convene into one mass; but some of it would convene into one mass and some into another, so as to make an infinite number of great masses, scattered at great distances from one to another throughout all that infinite space. And thus might the sun and the fixed stars be formed, supposing the matter were of a lucid nature.

Newton argued, correctly, that the laws of motion and gravitation cannot by themselves explain why the planets all move around the Sun in the same sense in nearly circular, nearly coplanar orbits. These regularities, he said, are consequences of *initial conditions,* which are not prescribed by his theory and must therefore have been laid down by the Creator. Newton also suggested that the Creator intervenes from time to time to restore the orderly arrangement of planetary orbits, which is constantly being degraded by the planets' mutual gravitational attractions.

1.4 Kant and Laplace

During the second half of the 18th century, Newton's view of the Creator's cosmological role was challenged by Immanuel Kant and by Pierre Simon de Laplace. In his *General History of Nature and Theory of the Heavens* (1755; discussed in Layzer, 1984) Kant proposed a new picture of the cosmos and a new theory, based on Newtonian physics, of its evolution from a simple initial state. Kant's ideas are important not only because they anticipated modern findings but also because they rested for the most part on sound physical inferences from observational evidence.

The Solar Nebula. Kant believed that a diffuse gas cloud would collapse into a spinning, flattened disk. He suggested that the planetary system evolved from such a cloud.

The Galaxy. Developing an earlier suggestion by Thomas Wright, an English amateur astronomer and theologian, Kant inferred from the observed distribution of stars and diffuse starlight on the celestial sphere that the Sun and its neighbors belong to a huge, highly flattened, rotating, self-gravitating swarm of stars whose structure and dynamics are similar to those of the planetary system. Just as the Earth orbits the Sun, so, Kant argued, the Sun orbits the distant center of our stellar system, the Galaxy. Moreover, Kant argued, the Galaxy, like the solar system, evolved from a huge, initially spherical gas cloud that flattened as it shrank.

External Galaxies. Extending Huygens's and Newton's hypothesis that the stars are suns, Kant conjectured that the Galaxy is comparable in size, shape, and intrinsic brightness to innumerable similar systems (external galaxies) sprinkled throughout an infinite space. Kant reasoned that external galaxies would appear in the telescope as faint, extended patches of starlight, because their individual stars would be too faint to be resolved by the telescope. Astronomers had observed such faint, fuzzy patches, and Kant boldly speculated that some of these, at least, were not nearby clouds of diffuse, glowing gas but distant galaxies. Pushing his analogy between the Galaxy and the solar system still further, Kant speculated that galaxies, including our own, are themselves members of huge, flattened, spinning, self-gravitating systems.

Late in the 19th century, Laplace revived and developed Kant's hypothesis that the Sun and planets formed from an initially structureless gas cloud whose dimensions were comparable with those of the present solar system. Laplace argued that as the cloud radiates away energy, its angular momentum remains constant. Most of the mass collapses into a central star, but the matter that carries the indestructible angular momentum remains behind to form a thin, differentially rotating disk. Later, according to Laplace, the planets form from condensations in this gaseous disk. Although Laplace's hypothesis was not—and still has not been developed into—a complete theory, it accounted in a natural way for the most conspicuous regularities of the planetary system and the satellite systems of Saturn and Jupiter. (See ASTRONOMY.)

Laplace also showed by ingenious and elaborate calculations that the orbits of the planets are stable over long periods, thereby demolishing Newton's argument that divine intervention is needed to maintain order in the planetary system. Although Laplace's calculations represented a major advance, they did not completely resolve the issue of the planetary system's long-term stability. Even today important questions remain. Numerical calculations have shown that at least in the inner solar system the planetary orbits are unstable in the sense that infinitesimal deviations from any given orbit increase exponentially with time. But numerical calculations also indicate that the characteristic times for the development of finite deviations (large eccentricities and inclinations) are many orders of magnitudes greater than the characteristic times associated with the exponential growth of infinitesimal deviations from the unperturbed orbit. It has been suggested that a planet's representative point in a "parameter space" whose points represent all possible Keplerian orbits performs a random walk. Finite deviations from the initial orbit would then grow only as the square root of the elapsed time. But a rigorous mathematical theory is still lacking.

1.5 Cosmology in the 19th Century

The 19th century saw the development of powerful mathematical theories of the dynamics and stability of gravitating systems (the work of Henri Poincaré is especially noteworthy) and an accumulation of useful data, but little progress in observational or theoretical cosmology. At the end of the century, most astronomers believed, on the basis of star counts, that the Sun lay close to the center of the Galaxy, and Kant's hypothesis that the "spiral nebulae" are stellar systems comparable in size and composition to the Milky Way was still highly controversial.

2. THE MILKY WAY AND OTHER GALAXIES

The main outlines of our present picture of the astronomical universe emerged between 1912 and 1929. During this brief period astronomers recognized and solved two major problems. They developed a strategy and a set of effective techniques for estimating the distances of exceedingly remote stars and stellar systems, and they recognized the importance of the dimming and reddening of starlight by intervening interstellar dust and learned how to allow for these effects.

2.1 Cepheids as Distance Indicators

The initial breakthrough came in 1912, when Henrietta Swan Leavitt, a research assistant at the Harvard College Observatory, discovered a remarkable property of certain exceptionally bright stars called Cepheids (Leavitt, 1912). These stars vary periodically in brightness, with periods ranging from 1 to 100 days. Leavitt found a number of Cepheids in the Small Magellanic Cloud, a huge cloudlike aggregation of stars in the southern sky, and she measured their periods and mean apparent brightnesses. She discovered that the period of a Cepheid is tightly correlated with its mean brightness. So the period of a Cepheid, which is unaffected by distance or intervening obscuration, is a reliable index of its apparent brightness, and hence—because the Cepheids in the Cloud are all at nearly the same distance—of its intrinsic brightness. A modern version of this plot is shown in Fig. 1.

To calibrate Leavitt's period–brightness relation, Hertzsprung (1914) used a statistical technique to estimate the distances of 13 Cepheids in the Milky Way. This enabled him to convert Leavitt's relation between period and apparent brightness into a relation between period and intrinsic brightness. Now astronomers could deduce the true brightness of a Cepheid from its (easily measured) period, and, by comparing its true and apparent brightnesses, estimate its distance. A new era of astronomical exploration had begun.

Hertzsprung himself made two important applications of the period–brightness relation. He found that the Cepheids and hot blue stars of the Milky Way were, as expected, strongly concentrated toward a plane passing through the Sun, but that within this plane they were

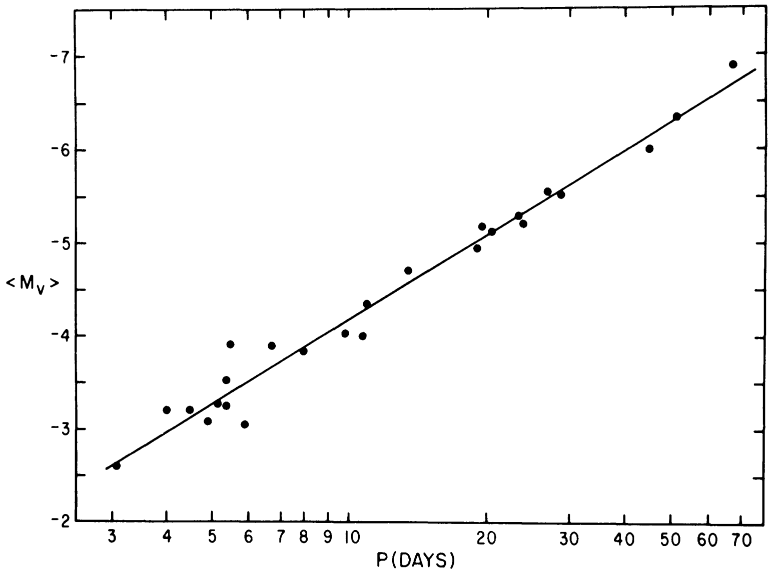

FIG. 1. Period-brightness relation for classical Cepheids belonging to galactic star groups. From Stothers (1983).

not evenly distributed in direction. Their space density increased in the direction of the constellation Sagittarius. Hertzsprung concluded that, contrary to contemporary astronomical opinion but in agreement with Kant, the Sun is not at the center of the Galaxy. Hertzsprung was also able to estimate the distance of the Small Magellanic Cloud. Although his estimate was too small by a factor of 7, it supported the conclusion that this system and its companion, the Large Magellanic Cloud, are external galaxies rather than (as many astronomers believed) star clouds within the Galaxy.

2.2 Shapley's Galaxy

In 1918 Shapley (1918; see also Shapley, 1961, and Hubble, 1936) published the results of an ambitious study of globular star clusters based on data taken with the 60-in. reflector on Mount Wilson, then the world's largest telescope. (Globular clusters are compact, nearly spherical systems, containing from a hundred thousand to ten million stars.) By extrapolating the Leavitt-Hertzsprung period–brightness relation to RR Lyrae stars (Cepheid variables with periods less than 1 day, found in globular clusters), Shapley was able to estimate the distances of 69 clusters. He found that the globular clusters outline a vast spheroidal system whose central plane coincided with that of the Milky Way (the disk-shaped system defined by Galactic Cepheids and hot blue stars). The center of the spheroidal system lay in the direction found by Hertzsprung, but at a much greater distance, and the diameter of the spheroidal system greatly exceeded that of the disk-shaped system.

Shapley's Galaxy was much larger than any astronomer had ever suggested, and the Sun's position was much more peripheral. Two features of Shapley's model, however, were not merely surprising but incomprehensible on the basis of gravitational theory: the precise coincidence between the central plane of the spheroidal system and the central plane of the Milky Way, and the absence of globular clusters in a slab centered on the Galaxy's central plane; see Fig. 2 (left).

2.3 The Role of Dust

These incomprehensible features of Shapley's model of the Galaxy disappear if one postulates a thin layer of obscuring matter, in the form of dust, strongly concentrated toward the common plane of the system of globular clusters and the Milky Way; see Fig. 2 (right). The Milky Way then expands in the direction of the Galactic center, while the system of globular clusters shrinks. Indeed the postulate of a dust layer allows the centers

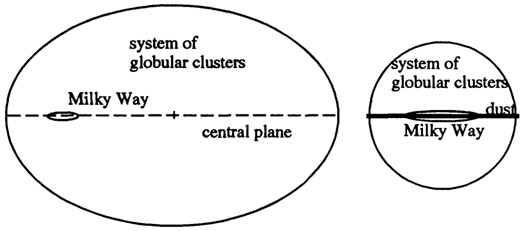

FIG. 2. Left: Shapley's system of globular clusters (large ellipse) had the same central plane as the Milky Way but its diameter was ten times greater. Right: The hypothesis of a dust layer concentrated toward the central plane brings the centers of the two systems together, makes the system of globular clusters more nearly circular, and reduces the discrepancy in size. Both figures are schematic.

of the two systems to coincide and causes the globular clusters to be concentrated toward this new common center. The absence of globular clusters in a slab centered on the central plane becomes a straightforward consequence of obscuration in this plane. Supporters of this idea pointed out that many spiral galaxies, viewed nearly edge-on, show evidence of heavy obscuration in a thin central layer.

Definitive evidence for such an obscuring layer in the Milky Way was presented by Trumpler (1925). Trumpler estimated the distances of 100 so-called Galactic star clusters. Unlike globular clusters, Galactic clusters are found mainly within the flattened disk-shaped system defined by hot blue stars and Cepheids, and they contain, typically, a few hundred stars. Trumpler found that the colors of stars in these clusters vary systematically with the cluster's distance from the Sun: the more distant the cluster, the redder its stars. In addition, the diameters of the clusters, inferred from their distances and angular diameters, increased systematically with distance. Both systematic effects were explained by the postulate of a uniformly dense layer of dust in the Galactic plane, which would both redden and dim the light of distant stars.

In 1932, Stebbins (1933) succeeded in inferring the thickness of the obscuring layer from photoelectric measurements of the colors of globular clusters. This enabled him to correct Shapley's estimates of the distances of globular clusters, which were then seen to form a nearly spherical system, densest at its center, with the Sun at a distance of 30 000 light-years. This value is close to current estimates.

2.4 Galactic Rotation

Kant's hypothesis of 1755 that the stars of the Milky Way revolve about a distant center under the action of gravity, like planets around the Sun, was revived in 1925 by Lindblad (1925), who showed that certain striking statistical properties of the observed motions of nearby stars relative to the Sun are explained by the hypothesis that stars in the Sun's neighborhood are moving in nearly circular orbits about a distant center. Oort (1927) looked for and found evidence of differential rotation in the motions of distant stars in the Galactic plane. He showed that the velocity of a star in a circular orbit about the Galactic center varies with the radius of the orbit just as the orbital velocity of a planet varies with its distance from the Sun. Oort's analysis yielded the first well-founded estimates of the period of the Sun's orbit around the center of the Galaxy (about 10^8 years), the radius of the orbit (about 30 000 light-years), and the mass inside the orbit (about 10^{11} solar masses).

2.5 The Nature of Spiral Nebulae

While the Galaxy was taking shape, astronomers were assembling evidence and arguments bearing on Kant's hypothesis that "spiral nebulae" are galaxies comparable in size and composition with the Milky Way. In 1917 G. W. Ritchey photographed a nova in a spiral nebula, using the 60-in. telescope on Mount Wilson (see Hubble, 1936). Ritchey and Heber D. Curtis of the Lick Observatory immediately began to search the photographic-plate collections of the Mount Wilson and Lick Observatories for evidence of other novae in directions well away from the plane of the Galaxy. They soon found five more, all in spiral galaxies. Curtis argued that because these novae were 10 000 times fainter than the faintest novae in the Milky Way, they had to be 100 $(=\sqrt{10000})$ times as far away; he showed that the linear diameters of spiral galaxies, inferred from their angular diameters on the assumption that their novae have the same intrinsic brightness as Galactic novae, were indeed comparable to the diameter of the Milky Way.

Six years later, Hubble (1936) published the results of a detailed study of three bright nebulae, including the spiral nebula in Andromeda. Plates made with the newly completed 100-in. reflector on Mount Wilson resolved many individual stars in each of these objects, including a number of Cepheids, from which Hubble could estimate the distances of the three systems by using the Leavitt-Hertzsprung relation between period and intrinsic brightness. The derived distances agreed well with those estimated earlier by Curtis; and the statistical properties of the stellar populations in all three systems resembled those of stars in the Galaxy.

2.6 Composition of Galaxies

In calibrating his distance indicators, Hubble assumed that samples of stars drawn from different galaxies or from different regions in the same galaxy have the same statistical properties—that they are drawn, in effect, from a single, homogeneous population. Distance estimates based on this assumption implied that globular clusters in the Andromeda galaxy are intrinsically four times fainter than their counterparts in the Milky Way. This conclusion was troubling, because it cast doubt on its own premise: if globular clusters differ systematically from one galaxy to another, why shouldn't the stars of which they are composed also differ systematically from one galaxy to another?

In 1944 Walter Baade proposed that there are two qualitatively distinct stellar populations; see Baade (1956, 1963). Population I inhabits the disks of spiral galaxies while Population II inhabits the spheroidal component of spiral galaxies and nearly all of elliptical galaxies. Thus spirals are mixtures of the two populations, with population I dominant in the disk and population II in the nucleus or central bulge and in the halo, while elliptical galaxies are nearly pure population II. Population I includes the Sun and its neighbors. Its most distinctive constituents are hot blue stars (supergiants), long-period Cepheids, galactic clusters like the Hyades and the Pleiades, and interstellar dust and gas. In a first approximation, these constituents have the same statistical properties in all spiral and irregular galaxies. Typical members of population II include globular clusters, RR Lyrae stars, and stars with very low abundances of elements heavier than helium. Although astronomers now subdivide both populations into subpopulations, Baade's original distinction is still meaningful and important.

Baade suspected that Cepheids in the two stellar populations would turn out to obey different period–brightness relations. A decisive test of this conjecture had to await the development of telescopes and photographic techniques capable of producing photometric images of population II stars in an external galaxy, where their apparent brightness could be compared directly with the apparent brightnesses of bright population I Cepheids. (In the Galaxy, this comparison depends on a large and uncertain correction for interstellar dimming.) In 1950 the 200-in. reflector on Mount Palomar became functional. The first long-exposure photographs of the Andromeda galaxy made with this instrument contained excellent images of the red giants that are the brightest stars in population II. Knowing the brightness ratio between such stars and RR Lyrae stars in the Milky Way, Baade could infer the apparent brightness of RR Lyrae stars in Andromeda, although these stars were too faint to show up on the 200-in. plates. The inferred brightnesses of Andromeda's RR Lyrae stars were smaller by a factor of 4 than they would have been if they conformed to Shapley's extrapolation of the Leavitt-Hertzsprung period–brightness relation for population I Cepheids. Confirming evidence followed quickly, when RR Lyrae stars were recorded in globular clusters of the Large and Small Magellanic Clouds: their apparent brightnesses agreed perfectly with Baade's prediction. The inferred brightness of Andromeda's globular clusters—and indeed of the Andromeda Galaxy—could now be increased by a factor of 4, making them and it comparable, respectively, to our own globular clusters and the Milky Way.

2.7 Galaxy Types

From their appearance on photographic plates, Hubble assigned galaxies to two great classes: spirals and ellipticals. The photographic images of ellipticals are smooth and regular, and the contours of constant surface brightness are concentric ellipses with an axial ratio greater than 0.3. The photographic images of spirals suggest a more or less foreshortened disk marked by bright knots and dark lanes arranged in a more or less regular spiral pattern. Seen edge-on, spirals show dark equatorial lanes and often, though not always, a central bulge.

These differences between the photographic appearances of ellipticals and spirals reflect basic structural differences. The ellipticals are spheroidal (or perhaps ellipsoidal) stellar systems in which the space density of stars increases strongly and smoothly toward the center. The disks of spirals are more highly flattened and less centrally condensed than ellipticals. The spiral markers—hot blue stars, often in compact groups, glowing ionized gas clouds, dark clouds, dark lanes—are all characteristic of Baade's population I. But most spirals also contain a spheroidal component of population II objects. This component contributes the central bulge (if there is one) and a spheroidal halo, as in our Galaxy.

The photographic images of spirals differ in several conspicuous ways, including the relative size of the spheroidal nucleus, the pitch or openness of the spiral arms, the conspicuousness of spiral markers, and the conspicuous of a central bar. Hubble showed that the first three characteristics vary together and thus define a linear sequence. Figure 3 shows Hubble's original "tuning-fork" diagram. Figure 4 shows exemplars of some of the galaxy types. The sequence begins with galaxies that have large spheroidal nuclei and disks but no spiral markers; these are designated by the symbol S0. As we proceed along the sequence, the relative size of the spheroidal nucleus decreases, and spiral markers appear, defining tightly wound, nearly circular arms (type Sa). Between types Sb and Sd, the markers become more conspicuous, the arms open out, and the spheroidal nucleus becomes less conspicuous, eventually disappearing entirely. The sequence ends with galaxies like the Magellanic Clouds (Sm), which are disks with extremely open arms and exceptionally bright spiral markers. The fourth characteristic, conspicuousness of a central bar, adds a second dimension to the classification scheme.

More recent classification schemes use additional characteristics, such as the relative thickness of the spiral arms and the conspicuousness of a ring enclosing the central bar.

2.8 Chemical Composition and Age

Studies of stellar evolution have shown that the stars that make up spheroidal galaxies and the spheroidal components of spirals—population II—are very old. The ages of population II stars do not differ significantly from the age of the universe (Sec. 3.6). Population I is younger than population II, but the ages of population I stars span a wide range, from a million years or less to a few thousand million years. The bright blue stars and clumps of bright blue stars that largely define spiral arms have ages of only a million to a few million years.

The two populations also differ markedly in chemical composition. Spectroscopic analyses and studies of stellar evolution have shown that elements heavier than helium are

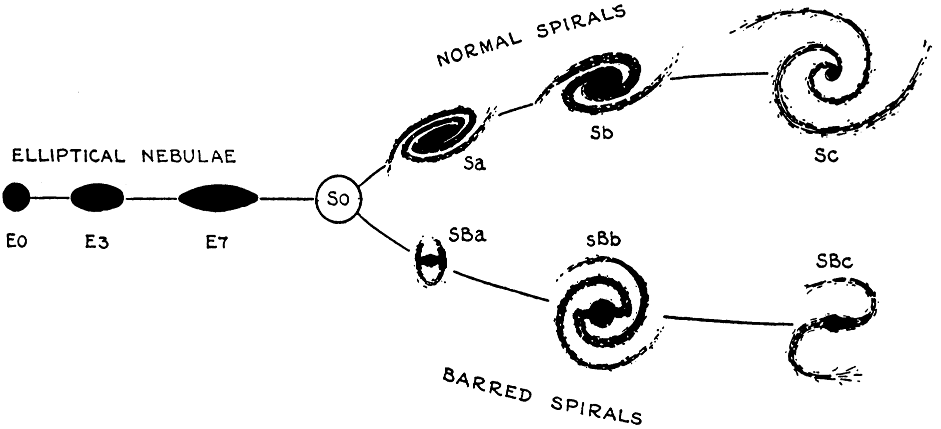

FIG. 3. Hubble's "tuning-fork" diagram. From Hubble (1936).

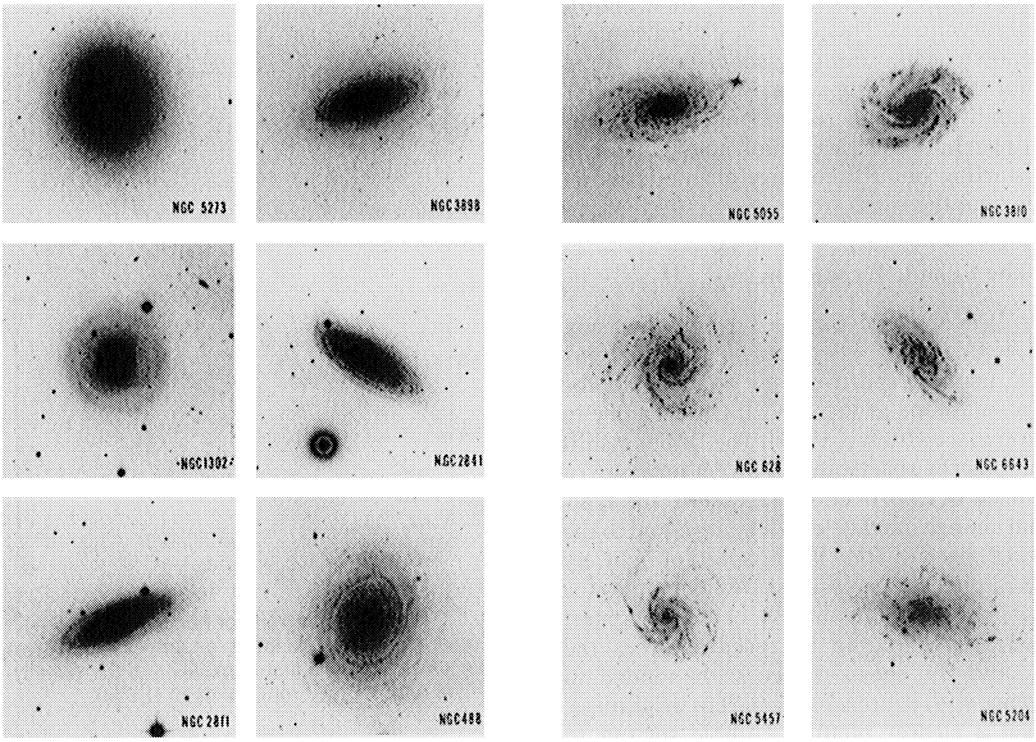

FIG. 4. Illustrating the progressive change of appearance along the classification sequence, from type S0 (upper left) to Sm or Irr (at the bottom right). From Sandage (1975a).

less abundant in population II stars than in population I stars by factors of 10 to 100 or more.

These observational findings suggest the following evolutionary hypotheses.

1. Population II stars, globular star clusters, and the spheroidal components of galaxies formed early in the history of the universe from "primordial" material consisting almost entirely of hydrogen and helium.
2. Chemical elements heavier than helium were synthesized in the deep interiors of short-lived massive stars, which eventually exploded, ejecting heavy-element–rich gases into interstellar space. As the enriched gas cooled, it settled into a thin disk, along with dust formed from the gas.
3. Population I stars formed from gas enriched (or contaminated) by this heavy-element–rich gas.

More detailed evolutionary scenarios have been proposed but are still highly speculative.

3. "THE REALM OF THE NEBULAE"

3.1 The Cosmological Principle

Having confirmed that the "spiral nebulae" are galaxies comparable to our own stellar system, Hubble set out in 1923 to chart their distribution in space, using data from the 100-in. telescope. Allowing for the effects of obscuration by dust in the Galaxy's central plane, Hubble concluded from counts of galaxies in small patches randomly distributed over the whole sky that the spatial distribution of galaxies is statistically uniform—that its statistical properties are the same in all directions and at all depths. In *The Realm of the Nebulae* (Hubble, 1936) he summed up his findings in these words: "There is no evidence of a thinning-out, no trace of a physical boundary. There is not the slightest suggestion of a supersystem of nebulae isolated in a larger world." Hubble's study provided the first solid evidence to support the ancient hypothesis that the astronomical universe is unbounded and that it looks much the same from every vantage point and, from a given vantage point, in all directions. This hypothesis has come to be known as the *cosmological principle.* Since Hubble's pioneering work, the quantity and the quality of the astronomical evidence supporting it have increased enormously. It forms the starting point for nearly all modern cosmological theories.

3.2 The Cosmic Expansion

In 1912 Vesta M. Slipher began to measure Doppler shifts in the spectra of external galaxies, using a spectrograph attached to the 24-in. telescope at the Lowell Observatory in Arizona (see Hubble, 1936). The Doppler shift in an object's spectrum is a direct measure of its speed of approach or recession, the fractional change in wavelength being equal to the object's speed divided by the speed of light. By 1925 Slipher had measured Doppler shifts for 45 galaxies. All but a few of the brightest galaxies appeared to be receding from the Sun, and the speed of recession tended to increase with decreasing apparent brightness. To get a clearer picture, Hubble set out to estimate the distances of the galaxies in Slipher's sample, using a strategy similar to the one Shapley had used to estimate the distances of globular clusters: He used Cepheids in nearby galaxies to calibrate brighter distance indicators, which he then used to calibrate still brighter distance indicators, and so on. In 1929 Hubble published a plot of Doppler shift versus distance for 22 galaxies on Slipher's list. The data suggested a linear relation between distance and redshift, with considerable scatter in redshift, especially among nearby galaxies. Later Hubble and Milton Humason were able to extend the plot to much fainter galaxies, strongly confirming the suggestion of a linear relation between redshift and distance. Figure 5 shows a modern version of the empirical redshift–apparent-brightness relation. Deviations from this relation can be attributed to clumpiness in the spatial distribution of galaxies, which gives rise to local gravitational fields and local gravitationally induced motions.

The ratio between velocity and distance is called the Hubble constant. Once its value is known, the measured redshifts of galaxies can be used as distance indicators. Our present maps of the universe of galaxies rest mainly on measured redshifts.

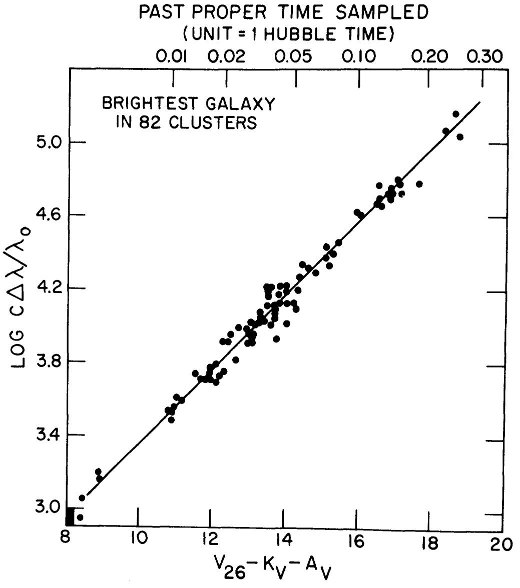

FIG. 5. The Hubble diagram for 82 first-ranked cluster galaxies. The box in the lower left corner is the range within which Hubble's first formulation of the velocity-distance relation lay. From Sandage (1975b).

Present estimates of the Hubble constant range from 45 to 90 (km/s)/Mpc (1MPc=1 megaparsec=3.26 million light-years). The estimates cluster around two widely separated values, 50 and 85 (km/s)/Mpc. The wide range of estimates reflects in part the variety of objects that have been used as distance indicators beyond the range of Cepheids (the original, and still the primary, extragalactic distance indicators). Such objects must have observable characteristics tightly linked to intrinsic brightness, in the way that the period of light variation of a Cepheid is tightly linked to its intrinsic brightness; and they must be bright enough to be visible at distances well beyond the scale of "local" structure. The most popular current indicators are spiral galaxies with measured rotation curves (Tully and Fisher, 1977; see also Sec. 3.4), giant elliptical galaxies with measured internal velocity dispersions, novae, supernovae of a particular type (Ia), and planetary nebulae. Estimates of the Hubble constant also differ because astronomers disagree about how to correct the data for the effects of large-scale clustering on the measured velocities. Finally, there is disagreement about how to correct in specific cases for the so-called Malmquist effect: in any sample limited by apparent brightness, the intrinsically brightest members of a given class of objects—supernovae of a particular type, say—are overrepresented. At the time of this writing (August 1992), excellent cases have been made for both the high and the low values of the Hubble constant; see Huchra (1992) and Tammann (1992).

As discussed in Sec. 3.6, the Hubble constant is one of two measurable quantities that determine the age of the universe; the other is the mean cosmic density.

3.3 The Spatial Distribution of Galaxies

Studies of the spatial distribution of nearby galaxies have revealed a pronounced tendency toward hierarchic clustering.

Many galaxies belong to binary and small multiple systems. Many, perhaps most, large- and medium-sized spirals have smaller satellites. For example, the Magellanic Clouds are satellites of the Milky Way.

Single galaxies and small multiple systems often belong to groups with diameters ranging from 3 to 12 million light-years. The Local Group contains two main subgroups, one dominated by the Galaxy, the other by Andromeda, as well as a dozen or so dwarf galaxies not attached to either subgroup.

The Local Group and many other nearby groups belong to less distinct aggregates called clouds, and some groups and clouds are clumped in clusters with as many as a thousand or more visible members and diameters of up to about 30 million light-years. Some clusters contain subclusters; others have a smooth, spherically symmetric structure analogous to the structure of globular star clusters.

Galaxy clusters are not uniformly distributed in space; there is a higher order of clustering—superclustering, first detected in the late 1930s. But in the late 1970s evidence began to accumulate that the character of the spatial distribution of galaxies changes qualitatively beyond the level of clusters. By the mid-1980s it had become clear that galaxies and galaxy clusters are concentrated in sheetlike structures that form the interstitial regions of a vast network of "bubbles"—convex, significantly underdense regions with diameters of the order of 100 to 300 million light-years (for a review, see Rood, 1988). The large-scale distribution of galaxies and galaxy clusters resembles the distribution of soap in soap suds; see Fig. 6. Thus a qualitative change in the character of clustering seems to take place at the very largest scales on which the distribution is nonuniform. On scales up to the scale of galaxy clusters, the overdense regions are convex. At the scale of superclustering, it is the underdense regions that are convex.

3.4 Prevalence of Dark Matter

Newton's theory of gravitation allows us to infer the mass of a self-gravitating system from the velocities of its members and its diameter. For example, we can infer the mass of the Sun from the Earth's orbital velocity and orbital radius, and the mass of the Earth from the Moon's orbital velocity and orbital radius. Application of this principle has led to the conclusion that *a large fraction—indeed the bulk—of the mass gravitationally bound in galaxies and larger systems is nonluminous, not only in visible light but also at shorter (ultraviolet, x-ray, γ-ray) and longer (infrared, millimeter and submillimeter, radio) wavelengths.*

Several different kinds of evidence, including those listed below, support this conclusion.

1. Neutral atomic hydrogen emits and absorbs radiation at a rest wavelength of 21 cm. In spiral galaxies, atomic hydrogen is concentrated in a thin sheet that coincides with the galaxy's central plane. Parcels of atomic hydrogen circle the galactic nucleus like planets around a central sun. When we look at a spiral galaxy edge-on, we see, on one side of the center of the disk, parcels of atomic hydrogen that are approaching us; on the other side, parcels that are receding. Measurements of the Doppler shift of the 21-cm line at different angular distances from the center of the disk, corrected for foreshortening, yield the orbital velocity of hydrogen in the galaxy's central plane as a function of radius (provided the distance of the galaxy is known). From this "velocity profile" one easily calculates the mass within each radius for which the velocity has been measured. Using this technique, Rubin and colleagues (for a summary, see Rubin, 1979) have shown that the mass density in a typical bright spiral decreases

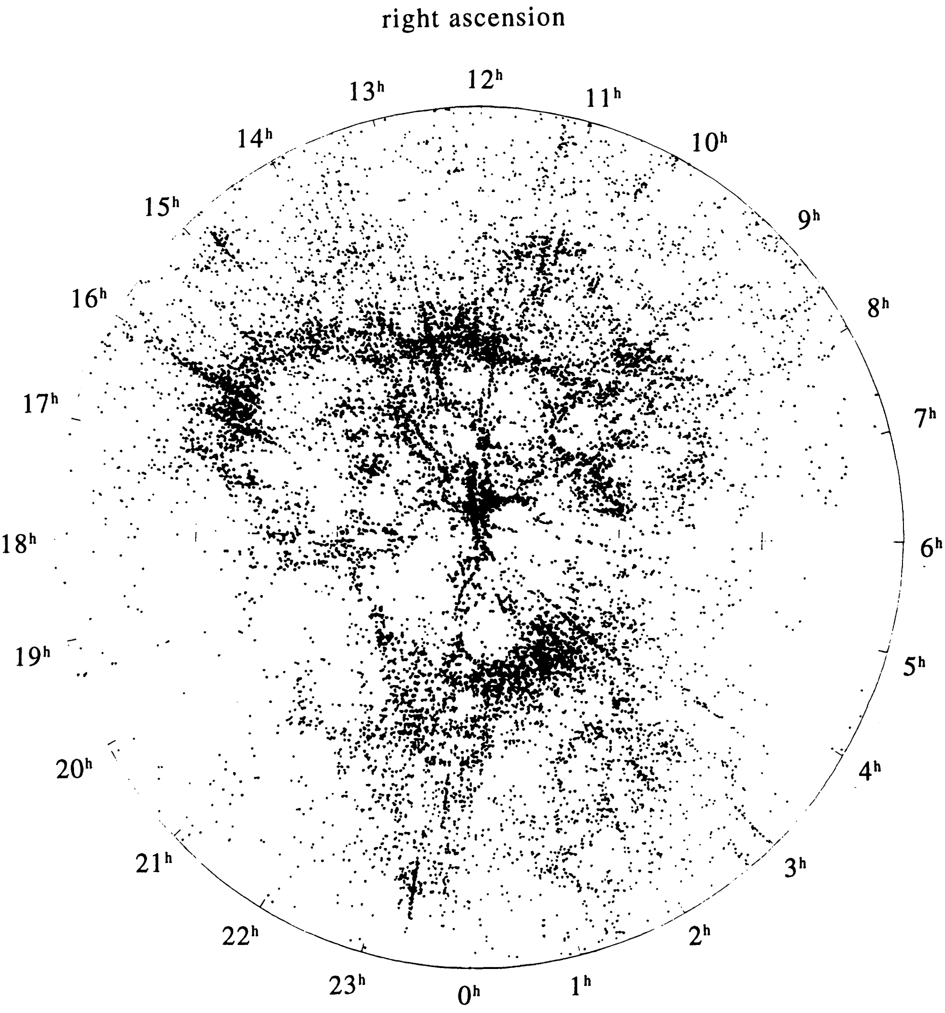

FIG. 6. Large-scale distribution of galaxies. A "pie slice" of the Universe about 500 million light years in radius, with the Earth at the center. The map represents a wedge bounded by celestial longitudes 8.5 degrees and 44.5 degrees. Convex underdense structures some 100 million million light years in diameter are clearly visible. Diagram courtesy of John Huchra, Smithsonian Astrophysical Observatory.

with radius much more slowly than the brightness. The actual radius of a typical bright spiral probably lies between 10^5 and 3×10^5 light-years, as much as 10 times the radius of the visible galaxy. The masses of bright spirals estimated in this way are typically of the order of 10^{12} solar masses, about 10 times the mass associated with visible stars.

2. Estimates of the mass of the Galaxy based on the velocities of distant globular clusters and small satellite galaxies also yield values of order 10^{12} solar masses.
3. Doppler-shift measurements for galaxies in small multiple systems, groups, and clusters yield estimates of the total mass and the mass:light ratio.

These and other kinds of evidence consistently indicate that 90% to 95% of the mass bound in self-gravitating systems is not in the form of visible stars. Observations at radio, ultraviolet, and x-ray frequencies show that only a small part of the invisible mass is in the form of interstellar and intergalactic gas (though in galaxy clusters intergalactic gas does contribute significantly). In what form does the dark mass reside?

The most conservative candidates are compact stellar remnants (white dwarfs, neutron stars, and more massive objects that are in the process of collapsing into black holes); objects of planetary or subplanetary mass; and very faint stars of low mass. All these possibilities, however, conflict with inferences that have been drawn from a widely held cosmological hypothesis. This hypothesis, discussed in Sec. 4.2 below, posits that the cosmic microwave background (Sec. 3.5) is the remnant of a primordial fireball. As discussed in Sec. 4.3, the results of calculations of helium production in the fireball can be reconciled with astronomical estimates of the primordial abundance of helium only if much (or perhaps all) of the nonluminous mass in the universe is in some form other than ordinary matter.

3.5 The Cosmic Microwave Background

In 1964–1965 Arno Penzias and Robert Wilson of Bell Laboratories, Holmdel, N.J., stumbled on an important new constituent of the universe (Penzias and Wilson, 1965). While calibrating a radiometer tuned to a wavelength of 7.3 cm, they discovered a signal that could not be attributed either to their instruments or to external sources of known kinds. The signal was equally strong in all directions and showed no diurnal or seasonal variation. Meanwhile, in Princeton, N.J., a few miles from the observing site where Penzias and Wilson had set up their radiometer, another group, headed by Robert Dicke, was preparing an experiment to detect radiation, at a wavelength of 3 cm, with precisely these properties. A mutual colleague put the two groups in touch.

Dicke's group was looking for evidence of an early, extremely hot, radiation-dominated phase in the history of the universe. In 1948, George Gamow, Ralph Alpher, and Robert Herman had posited such a "primordial fireball" on theoretical grounds, and had predicted that it would leave a relic in the form of a uniform, isotropic sea of thermal (blackbody) radiation with a temperature of a few degrees above absolute zero; see Peebles (1971). The isotropic radiation field discovered by Penzias and Wilson fitted this prediction. Its measured temperature was close to 3 K. A few months later Dicke's group detected the radiation at 3 cm and derived the same value of the temperature. Measurements carried out with the COBE (Cosmic Background Explorer) satellite in 1990 (Mather *et al.*, 1990) showed that, over the whole of the relevant wavelength range, the spectrum of the radiation deviates by less than one part in a hundred from the spectrum of a blackbody at a temperature close to 2.7 K.

Measurements carried out from the ground, from balloons and aircraft, and from the COBE satellite have yielded important information about angular variations in the temperature of the radiation on angular scales from arc minutes to tens of degrees. Because of the Doppler effect, the radiation should appear brighter in the direction of the Earth's motion relative to the local standard of rest defined by the radiation field, fainter in the opposite direction—and it does. The observed deviations yield an estimate of the velocity of the Galaxy relative to the local standard of rest that is consistent with estimates based on measurements of galactic redshifts; see Jerjen and Tammann(1992).

On arc-minute scales, variations in the temperature of cosmic microwave background are less than 2 or 3 parts in 100 000. As discussed in Sec. 4.4, this upper limit rules out the simplest theories for the origin of structure in a hot universe.

In 1992 measurements made with a differential radiometer on board COBE gave the first strong evidence for deviations from isotropy not due to the Earth's motion relative to the radiation background (Smoot *et al.*, 1992). On scales larger than the radiometer's beamwidth of 7° the temperature variations have a noiselike character. Their amplitude is one part in 10^5 and is independent of the angular scale. The significance of these findings is discussed below (Sec. 4.8).

3.6 The Age of the Universe

Several independent arguments indicate that the oldest astronomical systems have comparable ages and that the universe as a whole began to expand from a highly compressed initial state in the finite past.

The Age of the Solar System. Unstable atomic nuclei (radioactive elements) decay exponentially. From comparisons between the measured abundances in rocks of a radioactive element with a measured half-life, its decay product, and a stable element chemically similar to the decay product, planetary scientists have been able to estimate the ages of the Earth's solid crust, meteorites, and the Moon. These estimates indicate that the Moon and the meteorites solidified 4.6×10^9 years ago and that the Earth's solid crust formed about 0.8×10^9 years later.

Ages of the Elements (for a review, see Cowan *et al.*, 1991). Theoretical studies of nucleosynthesis in supernovae predict relative abundances of stable heavy elements that agree reasonably well with measured abundances in meteorites. These studies provide estimates of the initial abundances of radioactive elements. A comparison between the estimated initial abundance of a radioactive element with a known half-life and its measured present abundance, relative to the initial and present abundances of a chemically similar stable element, yields an estimate of the time elapsed since the radioactive element was synthesized. Such estimates yield "ages" in excess of 7×10^9 years. An "age" estimated in this way is a weighted average of the ages of the supernovae that produced the heavy elements present in meteorites and other solid objects in the solar system.

Ages of Star Clusters (for a review, see Cowan *et al.*, 1991). The brightness and color (or effective temperature) of a star depend on its initial mass, its initial chemical composition, and its age. Theoretical calculations show how the brightness and color of a star with given initial mass and chemical composition vary with age. In a plot of brightness versus color, a star's representative point traces out a certain evolutionary track (Fig. 7). Stars of different mass trace out different tracks. If all stars in a cluster had the same age and chemical composition and hence differed only in mass, their representative points in a brightness–color diagram would lie on a curve whose shape would change as the cluster evolved; see Fig. 7. The measured brightness–color diagrams of clusters are in fact consistent with the hypothesis that stars in a cluster form at the same time and have the same initial chemical composition. In principle, then, the ages of clusters can be deduced from their brightness–color diagrams, interpreted in the light of theories and calculations of stellar evolution.

The ages of Galactic clusters (clusters that lie close to the Milky Way's central plane) range from a few million years to $(7 \text{ or } 8) \times 10^9$ years. The ages of globular star clusters are more difficult to estimate for a variety of technical reasons. Current estimates of the ages of the *oldest* globular clusters range from 14 to 18 thousand million years.

The Age of the Universe. The measured redshifts of distant galaxies imply that the system of galaxies is uniformly expanding. That is, the distance between any two sufficiently widely separated galaxies doubles in a fixed period of time. Relativistic cosmology (Sec. 4.1) allows us to calculate the time that has elapsed since the beginning of the cosmic expansion, given the present value of velocity–distance ratio (Hubble constant) and the present value of the cosmic mass density. The uncertainties in estimates of both values are still large. The resulting estimates of the time elapsed since the beginning of the cosmic expansion are between 10 and 20 thousand million (10^9) years.

4. MODERN COSMOLOGY

4.1 Relativistic Cosmology

In constructing his theory of gravitation, general relativity, Einstein set out to remedy two shortcomings of Newton's theory of gravitation. The first was its failure to explain the phenomenon, noted by Galileo and later confirmed by accurate experiments, that gravitational acceleration is independent of the physical properties of the accelerated object. In Einstein's theory the presence of mass distorts the structure of the four-dimensional space-time manifold. A gravitationally accelerated object moves along a geodesic (straightest line) in curved space-time. Since geodesics are determined by the structure of the manifold itself, Einstein's theory explains why grav-

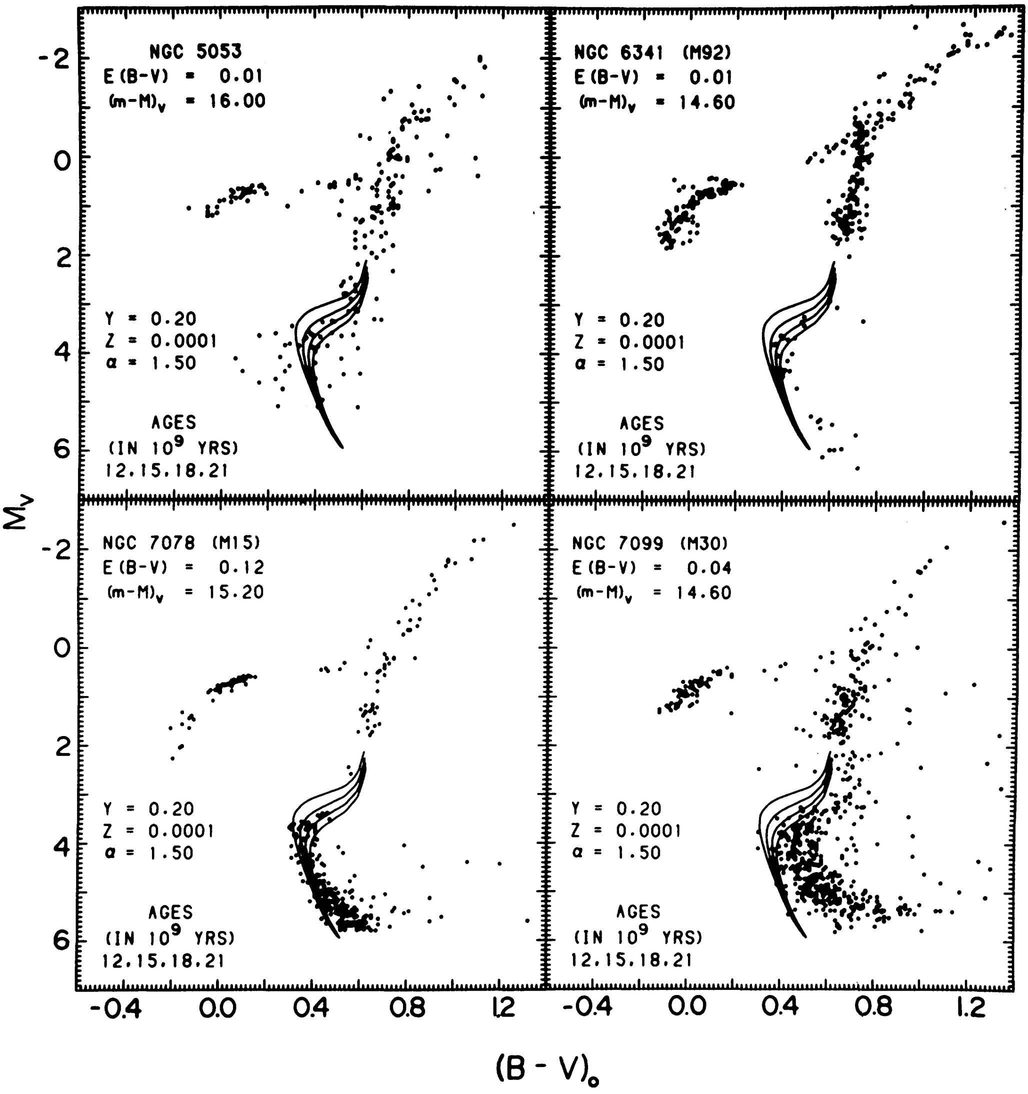

FIG. 7. Comparison on the observational plane of isochrones computed in this study with the published observations of NGC 5053, M92, M15, and M30. In each case, the cluster name and the adopted reddening and apparent distance modulus are specified in the top left-hand corner. The set of theoretical isochrones is characterized by the noted values of *Y*, *Z*, and *a*, and ages in the order of decreasing turnoff luminosity are given the lower left-hand corner of each plot. From Vandenberg (1976).

itational acceleration does not depend on any property of the accelerated object (and predicts that no such dependence will ever be found).

The second defect in Newton's theory was its failure to explain "Mach's principle": the coincidence between the local inertial reference frame (in which Newton's laws of motion are valid) and the cosmological reference frame (defined by the large-scale distribution of matter and motion). As mentioned earlier, Newton himself defined absolute acceleration as acceleration relative to absolute space, and he asserted that the "fixed stars" are at rest relative to absolute space. Ernst Mach, at the end of the 19th century, argued that absolute space is a scientifically empty notion. He suggested that the distribution of matter and motion on a cosmic scale somehow determines the local inertial reference frame. Newton's theory, however, does not explain the connection. Indeed, Newton's theory cannot even be applied in a consistent way to a uniform, unbounded distribution of mass filling all space.

In 1916 Einstein applied his recently published theory of gravitation (see GRAVITATION AND GENERAL RELATIVITY) to a uniform, static cosmic distribution of mass. He found that such a distribution of mass was inconsistent with his law of gravitation. At this point he made what he later described as the greatest scientific mistake of his career: instead of modifying his cosmological assumptions he modified the law of gravitation, adding a term whose coefficient is the so-called cosmological constant. The resulting equations do have a static solution, provided space is finite and has positive curvature. (A three-dimensional space of constant positive curvature is the three-dimensional "surface" of a sphere in four-dimensional Euclidean space; but its properties can also be specified without reference to a fourth spatial dimension, just as the properties of the two-dimensional surface of a sphere in three dimensions can be specified without reference to a third dimension.)

Alexander Friedman (1922), a dynamical meteorologist, discovered that Einstein's law of gravitation in its original form predicts that a uniform cosmic medium expands uniformly from a singular state of infinite density in the finite past (or contracts toward such a state in the finite future). Hubble's relation between distance and redshift, announced in 1929, confirmed this prediction. Because it is a consequence of Einstein's theory of gravitation and the cosmological principle, both of which enjoy strong observational support and neither of which has been seriously challenged, Friedman's theory is now accepted by nearly all contemporary cosmologists.

In Friedman's theory, space itself—not just the material medium filling space—is expanding (or contracting). This feature of the theory has a variety of observable consequences. For example, the travel time for light from a distant source is greater in an expanding space than it would be in a static space because the distance between the source and the observer is continually increasing. Because of the expansion of space, there are, at any given moment, objects so distant that light emitted by them at that moment never reaches the observer. Thus the theoretically observable universe is finite. Its (spherical) surface is called the event horizon. In a Friedman universe the mass within the event horizon increases with time; the radius of the event horizon increases at a greater rate than the radius of a sphere that contains a fixed quantity of mass.

The cosmological principle allows space to be curved but requires the curvature to be the same at every point. The curvature may be positive, negative, or zero. In space of zero curvature, Euclidean geometry prevails. For example, the angle sum of every triangle is exactly equal to 180° and the ratio between the circumference of a circle and its diameter is exactly equal to π. If space has negative curvature, the angle sum of every triangle is less than 180° and the ratio between the circumference of a circle and its diameter is greater than π. If space has positive curvature, the angle sum of every triangle is greater than 180° and the ratio between the circumference of a circle and its diameter is less than π. Friedman's theory specifies the temporal variation of the curvature, and so the curvature of a Friedman universe is characterized by the value of a single parameter.

Whether the curvature is positive, negative, or zero, the cosmic medium expands from a singular state of infinite density in the finite past. This "cosmological singularity" marks the beginning of time. If the curvature is negative or zero, the expansion continues forever and the mass density decreases steadily toward zero. In both cases, the medium is infinite. If the curvature is positive, space has finite volume (just as the surface of a sphere in three dimensions has finite area). In this case the universe expands to a state of minimum but finite mass density, then contracts toward a final cosmological singularity.

Friedman's theory predicts a simple relation between the mean cosmic mass density, the velocity–distance ratio (the Hubble constant), and the curvature of space. In a flat (zero-curvature) Friedman universe the cosmic mass density is a fixed multiple of the square of the Hubble constant. Depending on whether the cosmic mass density is less than or greater than this value, the spatial curvature is negative or positive.

Observational estimates of the cosmic mass density rest mainly on measurements of the velocities of galaxies, in groups, clusters, and larger aggregates. These estimates strongly suggest that the cosmic mass density is somewhere between 10% and 30% of the value that corresponds to zero spatial curvature. Inflationary cosmology (Sec. 4.6) predicts that the cosmic mass density is equal to the value that corresponds to zero spatial curvature. There is no direct observational support for such a high value.

Given the Hubble constant and the spatial curvature, Friedman's theory predicts the age of the universe—the time elapsed since the initial singularity. With a Hubble constant of 50 (km/s)/Mpc, the predicted age of the universe is about 17 thousand million years if the cosmic density is one-fifth the critical value. With the same Hubble constant, the predicted age is only 13 thousand million years if the cosmic density is equal to its critical value, as inflationary cosmology (Sec. 4.6) predicts. The second estimate is *smaller* than current estimates of the ages of the oldest globular star clusters. Doubling the Hubble constant halves the estimated ages.

4.2 The Primordial Fireball

The background radiation discovered by Penzias and Wilson has all the characteristics of thermal (blackbody) radiation at a temperature of 2.7 K. As mentioned above, observations from the COBE satellite have shown that its spectrum closely resembles the Planck spectrum. This observation implies that the background radiation must have been produced (or have already been in existence) at a time when the universe was opaque in the relevant range of wavelengths. This in turn requires the mass density of the universe to have been much greater in the past than it is now; no other way of accounting for the accurate blackbody spectrum of the background radiation is known. In the opinion of most cosmologists, these considerations rule out alternatives to relativistic cosmology that postulate a nonexpanding universe or a universe whose average mass density remains constant in time.

Theory predicts that after the expanding universe became transparent, the radiation, once thermalized, would have kept its thermal character. Its temperature, however, would have decreased at a rate proportional to the cube root of the number density of nucleons (protons and neutrons) or of photons. Since the average energy per photon in blackbody radiation is proportional to the temperature, the ratio between the energy density of the radiation and the energy density of matter, including rest energy, decreases continually as the universe expands. Extrapolating backward in time to the very early universe, one finds that nearly all the energy was in the form of thermal radiation at exceedingly high temperature. This is the primordial fireball. The fireball hypothesis accounts simply and accurately for the blackbody spectrum and the nearly perfect isotropy of the cosmic microwave background.

4.3 Origin of Helium and Other Light Elements

At very early epochs, the temperature of the universe (according to the fireball hypothesis) was so high that atomic nuclei heavier than the proton could not exist (Peebles, 1971; Weinberg, 1972). As the universe expanded, it cooled. At a temperature around 10^9 K deuterium began to form. Nearly all the deuterium subsequently burned to helium. As the temperature and density fell still further, nucleosynthetic reactions ceased and the relative abundances of the various nuclei were frozen in. These are the so-called primordial abundances, characteristic of the gas from which the first self-gravitating systems later formed, according to the fireball hypothesis.

The abundances of helium, deuterium, and other light elements produced in the fireball have been calculated with great accuracy. They depend on a single cosmological parameter, the cosmic mass density of ordinary matter (that is, matter composed of neutrons, protons, and electrons). If the fireball hypothesis is correct, it should be possible to choose this parameter to satisfy observational estimates of the cosmic mass density, the primordial abundance of helium, and the primordial abundance of deuterium and other light elements.

The most widely accepted current estimate of the primordial helium abundance is 23% by mass. The corresponding predicted value of the contribution of ordinary matter to the cosmic mass density is close to current estimates of the average mass density of *luminous* matter. Since, as discussed in Sec. 3.4, luminous matter accounts for at most 5% to 10% of the mass bound in self-gravitating systems (as deduced from their internal motions), the fireball hypothesis requires that at least 90% to 95% of the mass in the universe—essentially all the mass we cannot actually see—resides in "nonordinary" matter. What form does this "nonordinary" matter take?

During the 1970s many cosmologists believed that massive neutrinos, whose existence is predicted by grand unified theories of the strong, weak, and electromagnetic interactions (Sec. 4.5), could account for the nonluminous mass, but this possibility fell from favor in the 1980s because it failed to account for the distribution of nonluminous mass over the observed wide range of linear scales. "Cold dark matter," consisting of relatively massive particles of an unspecified kind, subsequently became the favored candidate, but this hypothesis fails to account for the spatial distribution of nonluminous mass on the largest scales (Saunders *et al.*, 1991).

As for deuterium, its predicted abundance is about 10 times greater than estimates based on observations of deuterium in interstellar space. The interstellar medium, however, has been formed in part from gas ejected by stars, where deuterium is burned into helium. Calculations that take this into account reduce but have not yet succeeded in eliminating the discrepancy between the observational evidence and the theoretical prediction.

The predicted abundance of lithium agrees well with astronomical estimates, but recent work (Gilmore *et al.*, 1991) suggests that beryllium is far more abundant than it should be according to the fireball hypothesis.

4.4 The Primordial Fireball and Particle Physics

The present-day universe is thought to contain no appreciable quantity of antimatter. But it is a consequence of the fireball hypothesis that proton–antiproton pairs and neutron–antineutron pairs would have been present in great numbers at very early times, when the cosmic temperature (measured in energy units) exceeded the rest energy of a proton–antiproton pair. At very early times the number densities of baryons would have been very nearly equal to the number densities of the corresponding antibaryons. If the number densities of baryons and antibaryons had been exactly equal, all the baryon–antibaryon pairs would have annihilated as the universe expanded and cooled. Only radiation would have remained, and the present ratio between the number densities of photons and baryons would have been infinite. Its actual value, 10^9 give or take a factor of 10, is indeed very large.

In 1967 André Sakharov outlined a scheme by which a tiny imbalance between baryon and antibaryon number densities might have evolved from a symmetric initial state with equal numbers of particles and antiparticles. Sakharov suggested that unstable superheavy particles produced in the very early universe might have decayed in ways that produced slightly more baryons than antibaryons as the universe expanded and cooled. This hypothesis required that the laws governing the decay of unstable particles discriminate between (a) particles and antiparticles, (b) left and right, and (c) the two directions of time. The first two "broken symmetries" were established experimentally in 1957 and the third in 1964. Sakharov's hypothesis also presupposed a theory of strong, weak, and electromagnetic interactions that would allow decay processes in which the net baryon number (the difference between the number of baryons and the number of antibaryons) changes. This is a feature of grand unified theories, developed in the 1960s and 1970s.

Grand unified theories allow neutrinos to have a finite rest mass. As mentioned above, massive neutrinos were once (but are no longer) a favorite candidate for the nonluminous mass of the universe.

Grand unified theories give protons a finite lifetime, because they allow particle-decay processes that violate baryon conservation. The simplest grand unified theory, however, predicts a proton lifetime that is shorter than the present experimental lower limit of about 10^{31} years.

4.5 Phase Transitions, Domain Walls, and Magnetic Monopoles

The now-standard unified theory of electromagnetic and weak interactions, developed by Sheldon Glashow, Steven Weinberg, and Abdus Salam, posits a uniform field of massive spinless particles called Higgs bosons. This field, which is part of the physical vacuum, is in its lowest energy. But in this state, the field itself has a nonzero value. This fact is ultimately responsible for the huge differences in strength and range between the weak and electromagnetic interactions.

In 1972, D. A. Kizhnits and A. D. Linde pointed out that at temperatures greater than a certain critical value (about 3×10^{15} K) the Higgs field vanishes in its state of lowest energy. At these temperatures, symmetry between the weak and electromagnetic interactions is "restored." It follows that when the temperature of the early hot universe fell below the critical value, the physical vacuum underwent a phase transition, somewhat analogous to the phase transition that occurs in a piece of iron when its temperature drops below the Curie point. At temperatures higher than the Curie point, the iron is unmagnetized; its physical state defines no preferred direction. At temperatures below the Curie point, spontaneous magnetization occurs, defining a preferred direction (or directions) and thus breaking the directional symmetry that prevailed at high temperatures. Similarly, when the cosmic temperature fell below its critical value, the physical vacuum underwent a phase transition, resulting in a breaking of the symmetry between the weak and electromagnetic interactions.

In a large piece of iron that has undergone spontaneous magnetization, the magnetic field may have different directions in contiguous "domains." Analogously, when the vacuum undergoes a phase transition, the Higgs field assumes different values in adjacent domains. The energy density in the walls separating adjacent domains turns out to be very high. Indeed, the contribution of domain walls to the energy (or mass) density of the universe has been estimated to be several powers of 10 higher than the upper limit set by cosmological observations.

An analogous phase transition is associated with the physical vacuum posited in grand unified theories. (The critical temperature for this transition is around 10^{27} K). Besides domain walls, this phase transition also produces, in great profusion, extremely energetic structures called magnetic monopoles (or grand monopoles). The estimated contribution of these structures to the cosmic energy density is many powers of 10 higher than the limit allowed by observation.

So the promising line of development initiated by the union of particle physics and the fireball hypothesis encountered seemingly insuperable difficulties.

4.6 Inflationary Cosmology

A way out of these difficulties was found in 1981 by Alan Guth. Guth proposed the following "scenario" for the very early universe. An initially hot universe, whose temperature exceeds the critical grand-unification temperature (10^{27} K) expands and cools. When the temperature falls below the critical temperature, the vacuum remains in a metastable supercooled state; it does not immediately make the symmetry-breaking phase transition discussed above. During this stage of supercooled expansion, the energy density of the vacuum comes to dominate the energy density of radiation and matter. Friedman's theory predicts that the universe now expands at an exponential rate (because the expansion does not reduce the energy density of the vacuum). The exponential expansion ("inflation") enormously reduces both the average spatial curvature and the amplitude of any local irregularities in mass density that may have been present. It generates a universe whose average mass density is indistinguishable from the critical value mentioned at the end of Sec. 4.1.

The phase transition to the stable vacuum state corresponding to the now greatly reduced cosmic temperature occurs through the formation of bubbles of stable vacuum. Collisions between the walls of these bubbles release the energy stored in the initial, metastable vacuum state, causing the universe to reheat. These collisions also create magnetic monopoles, but, because of inflation, the space density of these monopoles is now acceptably low.

Unfortunately, the mechanism for "reheating" in this scenario—collisions between the walls of the stable-vacuum bubbles—creates an observationally unacceptable level of nonuniformity and anisotropy in the cosmic distribution of matter and energy (including the cosmic microwave background).

An alternative theory, called the "new" inflationary scenario, was put forward in 1982 by Andrei Linde and, independently, by A. Albrecht and P. J. Steinhardt. It envisions a gradual phase transition and a more uniform mode of release of the energy stored in the initial vacuum state. This scenario, however, can be made to work only with an implausible degree of fine-tuning of properties of the Higgs field; even then it encounters severe technical difficulties.

To overcome these difficulties, Linde (1990) has proposed a still more speculative scenario, "chaotic inflation," in which quantum fluctuations in the energy of the Higgs field play a key role. Such fluctuations become important (as we look backward in time) at the so-called Planck epoch, about 10^{-43} s after the nominal beginning of the cosmic expansion, when quantum fluctuations cause Einstein's theory of gravitation to break down. In the "chaotic inflation" scenario, these fluctuations in the energy of the Higgs field give rise to an infinite collection of distinct "miniuniverses" with a wide range of initial conditions and hence of fundamental properties, including perhaps the dimensionality of space-time and the values of basic physical constants. We happen to inhabit a miniuniverse whose initial conditions gave rise to a set of physical constants and a scenario of cosmic evolution hospitable to the emergence of life. Some writers offer the last statement as an answer to the question of why certain constants and parameters that characterize the universe (such as the ratio between the number of photons and the number of nucleons) have the values they do. This answer is known as the *anthropic principle.*

For a review of inflationary cosmology, see Linde (1990).

4.7 Origin and Growth of Density Fluctuations in the Fireball

The new inflationary scenario predicts that large-scale fluctuations in the mass density are generated during the inflationary phase. These fluctuations obey the cube-root-of-N law: The fluctuation in the number of particles in a region containing N particles on average is approximately proportional to the cube root of N. Eventually these fluctuations are supposed to evolve into the precursors of galaxies, galaxy clusters, and the large-scale sheet-and-bubble structure. But two difficulties have arisen with this theory. First, numerical simulations using either hot dark matter (massive neutrinos) or cold dark matter have so far failed to replicate the observed structure. Second, a coefficient in the theory that determines the amplitude of the fluctuations must be arbitrarily assigned a value 10^{12} times smaller than the value predicted by particle physics.

The theory has, however, had one spectacular success. It predicts that large-scale fluctuations in mass density are accompanied by fluctuations or ripples in the temperature of the cosmic microwave background (see Peebles, 1980). If the amplitude of the primordial density fluctuations were just large enough for the fluctuations to evolve into the large-scale structure we now observe, the fractional amplitude of the temperature ripples would be about 10^{-5}. The COBE measurements referred to in Sec. 3.7 support this prediction (Wright *et al.*, 1992). Moreover, the measured spectrum of the ripples, on angular scales greater than 7°, has the form predicted for density fluctuations that obey a cube-root-of-N law.

4.8 The Vacuum–Energy Problem

Quite apart from difficulties with the various inflationary scenarios, the enterprise of uniting particle physics with the fireball hypothesis encounters a formidable difficulty (Linde, 1990). If present ideas about particle physics are correct in their main outlines, the fireball hypothesis implies that the vacuum has undergone at least three phase transitions: the first broke the grand-unified symmetry of strong and electroweak interactions; the second broke the symmetry of the electromagnetic and weak interaction; in the third, the quark sea condensed into baryons and mesons. Each of these phase transitions caused the mass density of the vacuum to decrease. In units of grams per cubic centimeter, the estimated changes are respectively 10^{80}, 10^{25}, 10^{14}. The present mass density of the vacuum is at most about 10^{-29} g cm^{-3}; it could well be precisely 0 (apart from quantum fluctuations). Despite many strenuous and ingenious attempts, no convincing explanation has yet been offered for the present low value of the cosmic mass density, given the magnitude of its past changes.

4.9 A Cold Universe?

It was suggested by Layzer in 1952 that the hierarchy of self-gravitating systems, from planetary systems to galaxy clusters, might have been formed by a single repetitive process: gravitational clustering in an expanding universe. At a given stage in the process, clusters S_n are the "molecules" of an expanding cosmic gas. As the gas expands, it becomes less uniform. The clusters S_n congregate in clusters S_{n+1} that become the new "molecules." Because gravitation, the "intermolecular" interaction responsible for clustering, has no preferred scale, the process occurs repeatedly on successively larger scales. Thus small systems are formed earlier than large systems—protostars before protoclusters, protoclusters before protogalaxies, and so on.

In 1962, Ya. B. Zel'dovich argued that an initially cold universe composed mainly of hydrogen would solidify when its density fell to about one-tenth the density of water, and that the solid expanding medium would subsequently break up into large chunks. Zel'dovich abandoned this hypothesis in favor of the fireball hypothesis after the discovery of the cosmic microwave background in 1965, but it was incorporated by Layzer into the theory of gravitational clustering (Layzer, 1984). There does not yet exist a rigorous statistical theory of an expanding "gas" of gravitationally interacting "molecules," but in its present heuristic form the theory of gravitational clustering accounts semiquantitatively for the major features of the clustering hierarchy. For example, it predicts that the average binding energy per unit mass of clusters of mass M is proportional to $M^{1/3}$. Thus binary stars, rich globular clusters, and galaxies, whose masses are roughly in the ratios $1{:}10^6{:}10^{12}$, are predicted to have binding energies per unit mass in the ratios $1{:}10^2{:}10^4$, in satisfactory agreement with observation. The same theory also predicts the approximate value of the coefficient in this relation.

Gravitational clustering does not account, however, for cosmic structure on the very large scales, the sheet–bubble structure described in Sec. 3.3. It has recently been suggested (Layzer, 1992a) that density fluctuations present at the Planck epoch, the initial state of the cold universe, evolve into structures qualitatively similar to the observed sheet–bubble structure. As in the "new" inflationary theory, but for a different reason, the primordial large-scale density fluctuations are predicted to have the cube-root-of-N form mentioned in Sec. 4.8.

To account for the cosmic microwave background, Layzer and Ray Hively postulated in 1973 that 90% to 95% of the stars that formed early in the cosmic expansion had masses of order 10 to 15 solar masses. The light emitted by these stars during their 10-million-year lifetimes would have been transformed into approximately blackbody radiation by its interaction with solid grains formed from heavy elements synthesized in the massive stars and ejected during the explosive phase of their evolution. The observed energy density of the microwave background and the fact that its spectrum very accurately approximates that of a blackbody impose stringent constraints on this hypothesis. Wright (1992) has shown that these conditions can easily be met if a reasonable fraction of the iron manufactured in the massive stars condenses into "whiskers," elongated structures that thermalize starlight very effectively.

Because the stars that produce the cosmic microwave background form in a medium of fluctuating large-scale density, the resulting background radiation bears the imprint of these fluctuations. The amplitude and the spectrum of the predicted temperature ripples agree at large scales with the COBE measurements (Layzer, 1992b); as mentioned in Sec. 4.7, so do the amplitude and spectrum of the temperature ripples predicted by the "new" inflationary scenario. The two theories differ, however, in their predictions about the temperature-fluctuation spectrum at angular scales between a few degrees and a few arc minutes. As the sensitivity of observations in this region improves, they will refute one (or both) of the theories.

The cold scenario predicts that the nonluminous mass resides mainly in the collapsed cores and ejecta of supernovae. If 90% to 95% of the mass of a primordial galaxy resided in relatively short-lived massive stars, the remnants of these stars would now populate a spheroidal system comparable in extent with the primordial galaxy, in agreement with observation.

4.10 The Cold Universe and Particle Physics

The implications of the cold scenario for particle physics differ from those of hot scenarios in two major ways. First, the vacuum-energy problem does not arise in the cold model because a vacuum phase transition does not occur in a universe initially at zero temperature. Second, the cold scenario requires the existence of several levels of quark and lepton substructure between the present experimental limit, which corresponds to energies of a few hundred giga-electron-volts, and the Planck energy of 10^{19} GeV. This requirement is needed to give the coefficient in the cube-root-of-N law the "right" value—the value for which predictions about large-scale structure agree with observation.

INTRODUCTION

Gallium arsenide (GaAs) is the second most popular semiconductor material in use today [behind silicon (Si)] and is the material of choice for the highest-speed digital and microwave applications. The reasons are basically twofold:

1. The electrons move very fast in response to an applied electric field; and
2. the resistivity can be made either very low, permitting strong current conduction in devices, or very high, allowing "inert" platforms for integrated circuits.

These two properties have fostered a mature microwave industry, exploiting applications such as microwave communications and phased-array radar, and a budding digital industry, with a 16-Gflops supercomputer having all-GaAs logic due in the market in 1992 or 1993 and a smaller hybrid (GaAs/Si) machine already introduced in July 1991. However, it is more difficult to grow and process GaAs than Si, so that Si devices are cheaper

and thus completely control most of the present consumer markets (such as television). A developing market is optoelectronics, i.e., the joining of electronic and optical devices on a single chip. Here GaAs has a distinct advantage over Si because of inherent properties that make it a much more efficient emitter and absorber of light. Already, in fact, one of the chief uses of GaAs is as a substrate for light-emitting diodes (LEDs) and other discrete optical devices. But one can imagine more complicated applications in the future, such as transmitters and receivers with laser sources, detectors, amplifiers, modulators, demodulators, and logic elements all fabricated at the same time on one small piece of GaAs.

Because the commercial interest in GaAs depends upon its basic optical and electrical properties, it is necessary to consider these subjects in some detail. As with most useful semiconductors, these properties can be controlled by impurities and defects, which themselves are controlled by the growth conditions. For example, GaAs can be given a nearly metallic conductivity by heavily doping with Si, and a nearly insulating quality by doping with Cr (chromium) or by "doping" with a high concentration of a particular defect, As misplaced on a Ga site. To develop these concepts, we will first discuss the basic lattice properties and the electrical, optical, and thermal consequences of these properties. We will follow that discussion with a summary of some of the crystal-growth techniques, then a detailed development of the optical and electrical properties, and finally an enumeration of present and future applications. For the convenience of the reader, a summary of some of the more useful measured parameters associated with GaAs is given in Table 1. Much more detailed and critical summaries of these and other values can be found in the excellent review given by Blakemore (1982) and also in the volume *Properties of Gallium Arsenide*, involving a number of authors from the EMIS (Electronic Materials Information Service) group (1990).

Table 1. Properties of GaAs at 300 K.

Length of side of unit cube	5.65325 Å
Nearest-neighbor distance	2.44793 Å
Atomic density	4.4279×10^{22} cm^{-3}
Molecular weight	144.642 amu
Crystal density	5.3174 g/cm^3
Speed of sound	
Longitudinal wave, [100] direction	4.731×10^5 cm/s
Transverse wave, [100] direction	3.345×10^5 cm/s
Young's modulus	85.5×10^{10} dyn/cm^2
Poisson ratio ([100] direction)	0.31
Phonon energy (at the Γ point): LO phonon	36.1 meV
TO phonon	33.2 meV
Melting point	1513 K
Thermal expansion coefficient (linear)	5.73×10^{-6} K^{-1}
Debye temperature (thermal)	360 K
Specific heat (at constant pressure)	0.327 J/g·K
Dielectric constant: low frequency	12.85
high frequency	10.88
Refractive index (infrared)	3.299
Energy gap (direct)	1.423 eV
Effective mass (at Γ point): electron	$0.063m_0$
heavy hole	$0.50m_0$
light hole	$0.076m_0$
split-off hole	$0.145m_0$
Density of states (effective): conduction band	4.21×10^{17} cm^{-3}
valence band	9.51×10^{18} cm^{-3}
Carrier concentration (intrinsic)	2.25×10^6 cm^{-3}
Electrical conductivity (intrinsic)	3.0×10^{-9} Ω^{-1} cm^{-1}
Hall mobility (intrinsic): electrons	8500 cm^2/V·s
holes	450 cm^2/V·s

1. BASIC PROPERTIES

1.1 Lattice Structure

GaAs crystals do not appear in nature but can be grown by many different techniques, to be discussed later. The lattice is of the cubic sphalerite, or zinc-blende, type, which involves two face-centered cubic lattices, one consisting of Ga and the other of As, displaced from each other by one-quarter of a body diagonal. A unit cube is illustrated in Fig. 1. Note that each atom is surrounded by four atoms of the opposite kind sitting at the corners of a tetrahedron. Such an arrangement is very common for semiconductor materials. The size a of the unit cube, the nearest-neighbor distance, and several other relevant properties are listed in Table 1. An important feature of the GaAs lattice is relatively easy cleavage along the {110} family of planes. For ingots grown along the [100] direction, with wafers sliced perpendicular to that direction, the {110} cleavage planes are at right angles to each other, which facilitates cutting the wafer into smaller pieces. A weaker cleavage occurs along the {111} planes, but this property is normally of little consequence.

1.2 Defects and Impurities

Intrinsic (defect- and impurity-free) GaAs would have a room-temperature resistivity ρ of about 3×10^8 Ω cm. Such a material, by itself, would be of little use to the electronics industry. However, by doping with Si or other elements, ρ can be reduced to 10^{-3} Ω cm, which makes a very useful material indeed. Thus, impurities in semiconducting materials are extremely important because they allow modification and control of the electrical and optical properties. Defects are also important for the same reasons. Group II elements, such as Be, Mg, Zn, and Cd, generally substitute for a Ga atom, and act as "acceptors" (hole producers) because they bring one less electron than needed for bonding purposes and thus attempt to "accept" an electron from another source (e.g., the valence band or a donor impurity), leaving a hole in that source. Group VI elements, such as S, Se, and Te, generally substitute for As atoms, and act as "donors" since they bring an extra electron over that needed for bonding. Group IV elements, such as C, Si, Ge, and Sn, can go on either Ga or As sites, and thus can act as donors or acceptors, respectively. This behavior is termed "amphoteric." However, under the typical conditions being used for present-day GaAs crystal growth, C usually goes on the As site as an acceptor, and Si, Ge, and Sn on the Ga site as donors.

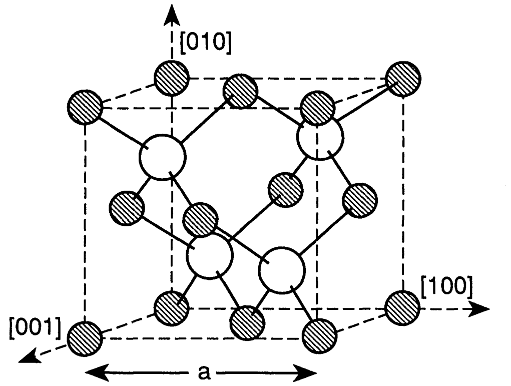

FIG. 1. Unit cube for GaAs, where a is the lattice constant. [From Blakemore (1982). Reproduced by permission of the American Institute of Physics.]

Typical background impurity concentrations range from 10^{14} cm^{-3} (2 parts per billion atomic, or 2 ppba) in epitaxial GaAs, to 10^{16} cm^{-3} (200 ppba) in bulk GaAs. The most commonly observed background elements are probably C as an acceptor and Si as a donor. The most common elements used for doping are C, Be, Zn, and Cd as acceptors, and Si, Sn, and Te as donors. Some of the principal considerations in doping are the solubility and the diffusion propensity under high-temperature processing conditions.

Defects can consist of missing atoms, called vacancies; atoms wedged in between other atoms, called interstitials; and atoms on the wrong sites, called antisites. By far the most important defect, and the only one identified so far in GaAs with any degree of certainty, is the arsenic antisite, i.e., As on a Ga site, or $\mathrm{As_{Ga}}$. It is said that this defect is the most studied of any in the history of semiconductors, and the reason for that is its importance in the production of semi-insulating GaAs, which is used as a substrate material for GaAs microwave devices as well as analog and digital integrated circuits (see Sec. 5). It is much more difficult to study defects than impurities, because defects are not responsive to any of the usual analytical techniques, such as mass spectroscopy. However, simple defects, such as vacancies, can be created by high-energy electron irradiation and thus fingerprinted with a fair degree of accuracy. For example, the arsenic vacancy V_{As} seems to be reasonably well identified by certain electrical characterization techniques. Optical and electrical signatures of several other defects have also been found, but identifications are uncertain. What is clear, however, is that defects can have either adverse or favorable effects on GaAs materials and devices, depending on the circumstances. The concentrations of electrically active defects typically range from 10^{13} cm^{-3} or less in epitaxial materials to 10^{16} cm^{-3} in bulk materials.

Besides the simple "point" defects described above, larger defects such as dislocations, precipitates, and voids can also exist. For example, bulk GaAs grown by the liquid-encapsulated Czochralski (LEC) method typically contains about 50 000 dislocations/cm^2 (counting only those which intersect the surface). Epitaxial GaAs has a much smaller dislocation density, but may have other imperfections. For example, molecular-beam epitaxial (MBE) layers can have from 10 to 1000 "oval" defects (small defects resulting from liquid Ga droplets) per cm^2 on the surface, depending on thickness and growth conditions. There is still a degree of controversy over how much these large defects may affect a device in close proximity to one of them. As an example, some studies have suggested that a metal-semiconductor field-effect transistor (MESFET) lying within about 30 μm of a dislocation will suffer a significant change in its threshold voltage. Such questions have great importance for integrated-circuit applications.

1.3 Lattice Motion

As with any solid, the atoms in GaAs can move and vibrate in directions and modes constrained by the lattice symmetry. The dynamics of the deformation and motion with respect to an external mechanical force are described by a tensor **c** with components c_{ij}, where this tensor is sometimes called the "elastic response tensor," and the components are variously called the "moduli of elasticity," the "elastic stiffness constants," or simply the "elastic constants." As an example, we would write the stress component X_x, which represents a force applied in the x direction (the capital letter) to a unit area of a plane whose normal also lies in the x direction (the subscript), as

$$X_x = c_{11}e_{xx} + c_{12}e_{yy} + c_{13}e_{zz} + c_{14}e_{yz} + c_{15}e_{zx} + c_{16}e_{xy}, \tag{1}$$

where **e** is the strain tensor. Similar equations could be written for Y_y, Z_z, Y_z, Z_x, and X_y. For the cubic lattice of GaAs several of the components vanish, and of the remaining ones only three, c_{11}, c_{12}, and c_{44}, are independent. These three components govern the speed of sound in any direction, since a sound wave results from the elastic response to an external force. For example, a wave propagating in a [100] direction with particle motion also in the same direction has a velocity $v_L = (c_{11}/\rho)^{1/2}$, where ρ is the crystal density. If the particle motion is in a (100) plane perpendicular to the direction of the motion, then $v_T = (c_{44}/\rho)^{1/2}$. Numerical values of v_L and v_T in this case are given in Table 1. For wave and particle motion in other directions, the equations are slightly more complicated.

Normally when we consider wave motion in a solid, we think of low-frequency sound waves, with frequencies $\nu \simeq 1\text{–}10^4$ Hz. In fact, however, in an equivalent one-dimensional GaAs lattice, the calculated ν can extend all the way up to approximately $[2ac_{11} \times (m_{As}^{-1} + m_{Ga}^{-1})/4\pi^2]^{1/2} \simeq 7.5 \times 10^{12}$ Hz, where a is the lattice constant. The density of states of the phonons (quantized lattice vibrations) as a function of frequency for GaAs is given in Fig. 2, and it is seen that there is a very strong peak near $\nu = 8 \times 10^{12}$ Hz, which is mainly due to optical phonons. For many experiments, the longitudinal-optical (LO) phonon at $\mathbf{k}=0$ in the Brillouin zone (Γ point), which has a frequency $\nu = 8.55 \times 10^{12}$ Hz (35.4 meV), is an important factor to be considered. For example, an electron or hole that attains a very high kinetic energy (becomes "hot"), by absorbing a light photon or being accelerated by an electric field, often gives off much of this excess energy by emitting optical phonons.

The lattice vibrations can also store energy. In the simplest ("classical") picture, each atom will have $\frac{1}{2}kT$ kinetic energy and $\frac{1}{2}kT$ of potential energy for each of its 3 degrees of freedom. Thus, for N atoms, the total energy U should be $3NkT$, and the specific heat $C = \partial U/\partial T = 3Nk$. Per unit mass we then would expect $C = 3k(2N_a/M) = 0.345$

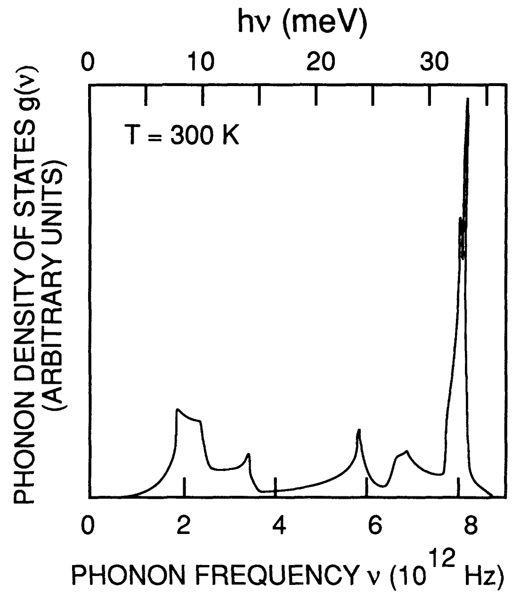

FIG. 2. Frequency dependence of the total spectral density of all lattice vibrational modes. [From Dolling and Cowley (1966). Reproduced by permission of the IOP Publishing Co.]

J/g·K, where N_a is Avogadro's number and M is the molecular weight. In fact, the specific heat at constant pressure C_p is about 0.327 J/g·K at 300 K and fairly well follows a Debye model, with a thermal Debye temperature $\Theta_D \simeq 360$ K, above about 100 K. It is interesting that this Θ_D corresponds to a frequency $k\Theta_D/h \simeq 8\times 10^{12}$ Hz, which is the most prominent frequency in the phonon density-of-states spectrum, Fig. 2.

If parts of a sample are at different temperatures, then heat will be transferred by the phonons from the hot areas to the cooler areas. The heat transferred across a unit area per unit time in a sample of length L is given by $Q=\kappa(T_1-T_2)/L$, where κ is the thermal conductivity and T_1 and T_2 are the temperatures at the respective ends of the sample. In classical theory, κ can be related to C by $\kappa=\rho Cvl/3$, where ρ is the density, v an average speed of sound, and l a phonon mean free path. Experimentally, $\kappa \simeq 0.55$ W/cm·K, in pure material at 300 K, which suggests a mean free path $l=200$–300 Å, depending on v. At low temperature, say 20 K, κ can approach 50 W/cm·K, and since C falls to about 0.02 J/g·K, l becomes very large, about 0.01 cm. Doping, even up to 10^{19} cm^{-3}, affects κ very little at 300 K, but begins to have a large effect below 50 K.

Anharmonic terms in the potential energy of the vibrating atoms are responsible for thermal expansion of the lattice with temperature. The linear expansion coefficient of GaAs is about 5.7×10^{-6} K^{-1} at 300 K and increases to about 7.2×10^{-6} K^{-1} at 1000 K.

1.4 Electron States

Lattice vibrations and the associated phonon modes are concerned with collective motions of the nuclear cores of the atoms, and the surrounding electrons are simply considered to move along with the cores. However, just as the collective motions of the nuclear cores (the lattice vibrations) can be described in terms of energy bands, so the interactions of the surrounding electrons with each other also lead to bands of energy separated by gaps, as shown in Fig. 3. The total density of states for all of the bands shown in Fig. 3 is plotted in Fig. 4. Here, the bands below $\mathscr{E}=0$ are called the valence bands, and are filled

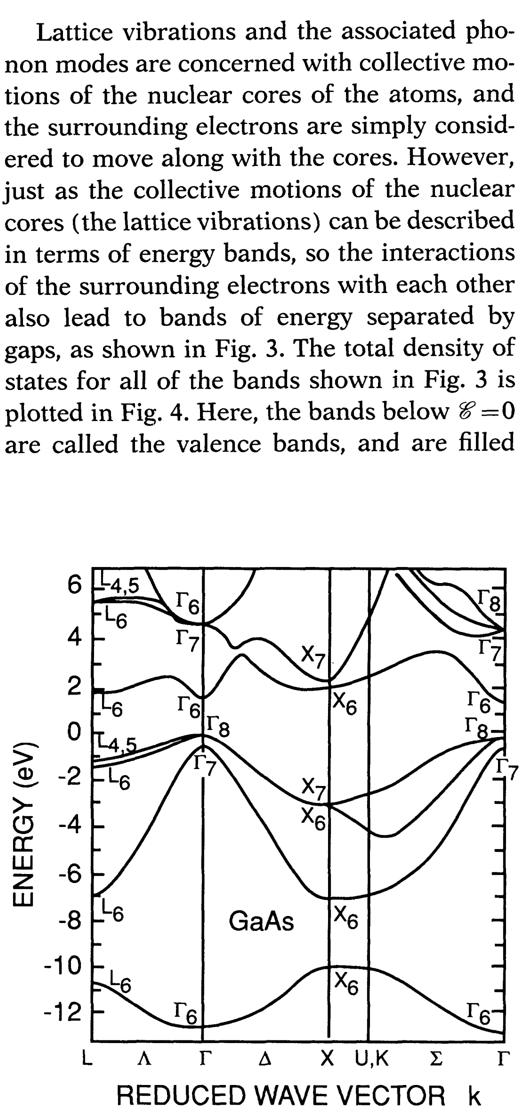

FIG. 3. Electron energy vs reduced wave vector for the four GaAs valence bands and the first four conduction bands. [From Chelikowsky and Cohen (1976). Reproduced by permission of the American Institute of Physics.]

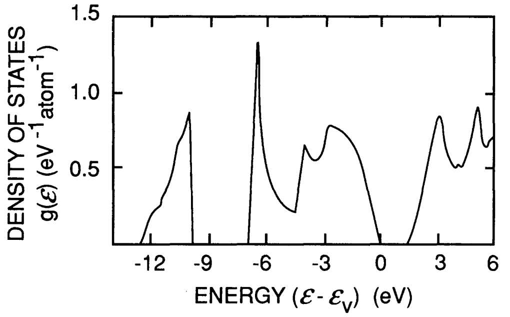

FIG. 4. Density of states for the lower part of the conduction band and for the four valence bands. [From Chelikowsky and Cohen (1976). Reproduced by permission of the American Institute of Physics.]

with electrons, while the bands above $\mathscr{E}=0$ are empty. (In this article, we will denote *general* energies by $\mathscr{E}$, in order to distinguish from electric field *E*, but *specific* energies by *E* with a subscript, which is a more common notation.) The lowest energy gap between filled and empty states occurs at the Γ point (k_x,k_y,k_z=0,0,0) in the Brillouin zone, and is "direct," i.e., the maxima of the Γ_8 valence band (Γ_{8V}) and the Γ_6 conduction band (Γ_{6C}) both occur at the same **k** value. The resultant band gap, 1.519 eV at $T=0$ K and 1.423 eV at $T=300$ K, is extremely important to the optical and electrical properties of GaAs, as will be shown later. The higher conduction bands, L_{6C} and X_{6C}, are of importance only at higher temperatures or for other situations in which the electrons are excited to high energies. Similarly, the Γ_7 valence band (the "split-off" band) normally has little influence on the optical and electrical properties.

The curvature in $\mathscr{E}$ vs **k** of the various bands is also very important because it influences both the density of states (Fig. 4) and the effective mass, which is given by $m^*=\hbar^2/(d^2\mathscr{E}/dk^2)$. Indeed, it is the strong curvature of the Γ_{6C} band which leads to a low effective mass ($m^*_{6C}=0.067m_0$ at $T=0$) and thus to high electron acceleration in an electric field. It is, in large part, the low effective electron mass, the relatively high band gap, and the direct nature of this gap that give GaAs many advantages over its chief rival, Si. However, there are also disadvantages, which will be discussed later.

2. CRYSTAL GROWTH

2.1 Bulk Growth

Since GaAs crystals are not found in nature, they must be grown by artificial means. The sizes of such crystals range from thin layers of a few angstroms (10^{-8} cm) thickness to large ingots more than 10 cm in length and 10 cm in diameter. We term the production of such ingots "bulk" growth and describe it in some detail below. [Also, it has been reviewed recently by AuCoin and Savage (1985).] The efficient, inexpensive growth of long, large-diameter GaAs ingots is crucial to the emerging GaAs integrated-circuit industry.

There are six major methods used to grow bulk GaAs:

1. horizontal Bridgman (HB);
2. vertical Bridgman (VB);
3. horizontal gradient-freeze (HGF);
4. vertical GF (VGF);
5. low-pressure liquid-encapsulated Czochralski (LP-LEC); and
6. high-pressure LEC (HP-LEC).

A large problem with GaAs crystal growth is that the As vapor pressure at elevated temperatures is much higher than that of Ga, so that As tends to evaporate from the growing crystal. The Bridgman and gradient-freeze techniques solve that problem by putting excess As into a closed tube containing the melt and growing crystal, whereas the LEC method encapsulates the melt with liquid B_2O_3, and further adds a high pressure of inert gas in order to hold in the As. It should be pointed out that this partial-pressure difference of the constituent elements is a problem not encountered in the growth of an elemental semiconductor such as Si. Thus, simpler techniques are available for Si growth, and, e.g., inexpensive 20-cm-diam Si wafers are readily available today.

2.1.1 Liquid-Encapsulated Czochralski Growth. The high-pressure LEC technique is presently the dominant method for producing semi-insulating (SI) GaAs, which is used as the basic substrate material for many GaAs devices. An advantage of the HP-LEC process is that polycrystalline GaAs can first be synthesized from elemental Ga and As in the same reactor that is later used for the single-crystal growth. The synthesis takes place at about 700 °C, with a liquid B_2O_3 layer and 60 atm of inert gas to keep the As from escaping. Then the temperature is increased to the GaAs melting point, the pressure reduced to 2–4 atm, and crystal growth begun by inserting a GaAs seed through the B_2O_3 layer and into the melt. The temperature is lowered until solidification begins to occur on the seed, and the seed is then pulled, along with the attached crystal, through the B_2O_3 encapsulant at a rate of 1–10 mm/h. A typical product of this process, an ingot somewhat larger than 76 mm in diameter and weighing about 4 kg, is shown in Fig. 5. This ingot would next be ground to obtain a nearly uniform 76-mm diameter and then sliced into wafers, which, after polishing, would have a thickness of about 650 μm.

As can be seen in Fig. 6, the only limit to crystal size in the LEC technique is the diameter of the crucible holding the melt. In fact, 125-mm-diam crystals have already been grown, and one manufacturer states that 125-mm, 25-kg crystals will be the norm in a few years. A disadvantage of the HP-LEC method is the size and cost of the reactor, which must withstand 60 atm pressure. The LP-LEC method helps somewhat in this regard, but has the disadvantage that As must be injected from an exterior source to maintain the proper stoichiometry.

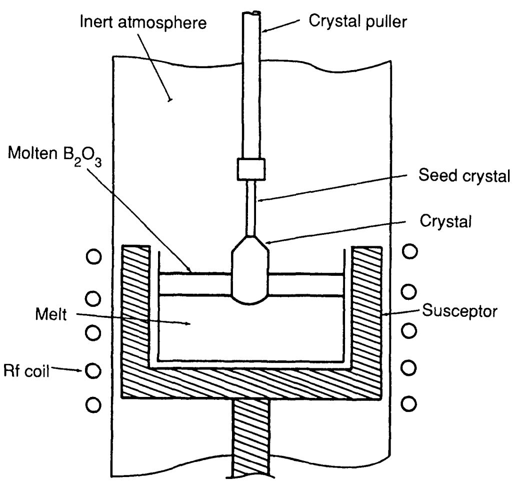

FIG. 6. Schematic of a liquid-encapsulated Czochralski crystal puller. [From AuCoin and Savage, (1985). Reproduced by permission of Howard W. Sams and Co.]

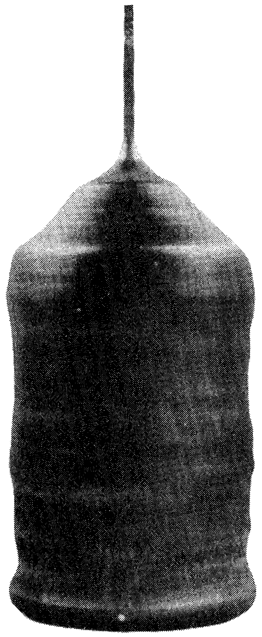

FIG. 5. A 4-kg undoped semi-insulating crystal of GaAs grown by the LEC method. (Courtesy D. E. Holmes.)

2.1.2 Bridgman and Gradient-Freeze Growth. Horizontal Bridgman and gradient-freeze reactors are much simpler and less expensive to set up than their LEC counterparts. As shown in Fig. 7, the seed and melt typically sit in a quartz boat, which itself is placed at one end of a sealed quartz ampoule with excess As at the other end to maintain stoichiometry. In the HGF variation, two (or more) furnaces produce a temperature profile (note that the right side is hotter, in Fig. 7), and the profile is slowly changed (cool zone moved to the right) to freeze the entire charge. In the HB variation, the furnace is moved, rather than the profile being electronically adjusted. In spite of their simplicity and the advantage of low dislocation density, these techniques have several disadvantages:

1. The crystals grow best in a ⟨111⟩ direction and so must be sliced at an angle to get the preferred (100) wafers;
2. because of that, and also because the tops of the crystals are flat to begin with, the wafers cannot be made round without wasting a significant amount of material; and
3. since the growth takes place in a quartz environment, Si is a common impurity and

makes the crystals *n*-type. To get semi-insulating material, Cr must be added, and that introduces a whole new set of problems for the subsequent device fabrication. Thus, HB and HGF wafers are usually used for applications such as solar cells, which do not need SI substrates.

All of the above problems can be circumvented by going to vertical growth in pyrolitic boron nitride (PBN) crucibles. The resulting crystals are round, have a ⟨100⟩ growth axis, are semi-insulating, and maintain the low dislocation density which is characteristic of the Bridgman and GF methods (because of low thermal gradients during growth). One obvious problem of the vertical growth techniques is that now the melt is touching all sides of the crucible, and it may wet or break the crucible (or crystal) because of expansion upon freezing. However, it appears that several American vendors have overcome these problems and are now marketing 76-mm-diam SI GaAs wafers produced by the VGF and VB methods. It will be interesting to see whether the VGF and VB methods will prove to be superior to the LEC technique for SI growth.

2.2 Epitaxial Growth

Although the starting material for GaAs devices is the substrate, typically 650 μm thick, the active (conductive) layer is usually much thinner, from 0.01 to 1 μm. Such thin conductive layers can be produced either by ion implantation or by epitaxial growth. Ion implantation is simple and cost-effective because the dopant (usually Si for *n*-type material, Be for *p*-type material) is implanted directly into the substrate. However, the dopant then has a nonflat profile (nearly Gaussian), and it may become further distorted during the high-temperature (~750–850 °C) anneal necessary to reduce lattice damage and move the ions onto substitutional lattice sites. Epitaxial growth of the active layer, on the other hand, can lead to very abrupt doping profiles, which are necessary for some devices.

2.2.1 Molecular-Beam Epitaxy. A schematic drawing of a molecular beam epitaxial (MBE) growth chamber is given in Fig. 8. Effusion cells, containing solid sources of Ga, As, and the various dopants, are heated until they produce the desired evaporation rate of

the atomic or molecular species. Because of the ultrahigh vacuum (10^{-11} Torr before growth, 10^{-6} Torr during growth), the various beams move almost without interaction before reaching the substrate surface. Gaseous sources, such as arsine, are also available and can be replenished much more easily. For characterization, built-in tools such as mass spectroscopy and reflection high-energy electron diffraction (RHEED) have proved very useful in setting the growth parameters precisely. Excellent single-crystal layers can be grown at substrate temperatures 200–600 °C, although the 200 °C material has an extremely high (and often very useful!) concentration (10^{20} cm^{-3}) of As antisites. Background impurity concentrations in the 10^{14}-cm^{-3} range can be routinely achieved, as can Si doping as high as 10^{19} cm^{-3}, and Be or C doping up to 10^{20} cm^{-3}. Coupled with the very precise thickness control (1 monolayer!), MBE has a versatility perhaps unmatched by any other technique. However, it also has several disadvantages:

1. high initial expense;
2. low growth rate (~ 1 μm/h);
3. long down time for source loading; and
4. difficulty in obtaining doping and thickness uniformity on large wafers.

Thus, MBE at present finds its primary application in growing very thin, complicated structures for discrete devices, although problems **3** and **4** above are being successfully addressed.

MBE growth and characterization have been recently reviewed by Sakaki (1989).

2.2.2 Metal-Organic Vapor-Phase Epitaxy. The major competing technology to MBE for thin layers is MOVPE (metal-organic vapor-phase epitaxy), also known as MOCVD (metal-organic chemical vapor deposition) and OMVPE (organometallic VPE). The apparatus is very simple, as illustrated in Fig. 9, and easy to set up, compared to an MBE system. In Fig. 9, the source gasses, typically trimethylgallium (TMGa) or triethylgallium (TEGa) and arsine (AsH_3), enter the chamber, are dispersed by a baffle, and then react over the substrate which is sitting on a susceptor held at 500–800 °C. The reaction products can be fairly complex and are not fully understood, but it is known that diffusion through a boundary gas layer at the susceptor surface is an important part of the process. This is in contrast to the MBE case in which the primary species essentially do not react until they reach the substrate surface and find each other through hopping processes. As compared with MBE, some of the advantages of MOVPE for GaAs growth are lower initial cost; higher growth rate (~ 10 μm/h); better thickness and doping uniformity on large wafers; and less down time for source replenishment. Some of the disadvantages are

1. the toxicity of arsine, which effectively raises the apparatus costs because of the necessity for safety devices; and
2. less precision in the control of very thin layers.

Attempts are being made to address problem **1** by finding new, safer gaseous sources of As, and problem **2** by working at low pressures, which allows the gas flow to be turned on and off quickly. In fact, by working at very low pressures, in a vacuum chamber, some of the advantages of MOVPE and MBE can be combined and a whole new discipline has developed, MOMBE (metal-organic MBE). It is likely that each of these three techniques, MBE, MOVPE, and MOMBE, will find particular applications in the future.

MOVPE growth of III-V compounds has been reviewed recently by Dapkus and Coleman (1989).

2.2.3 Vapor-Phase and Liquid-Phase Epitaxy. Two of the earliest and still viable techniques for growing GaAs layers are vapor-phase epitaxy (VPE) and liquid-phase epitaxy (LPE). The most common VPE system passes

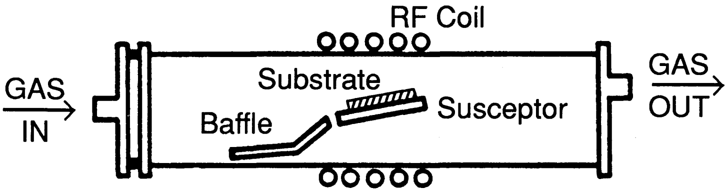

FIG. 9. Schematic of an MOVPE growth chamber. [From Coleman and Dapkus, (1985). Reproduced by permission of Howard W. Sams and Co.]

$AsCl_3$, carried by H_2, over a boat containing liquid Ga, and the reaction products, which are As_4 and GaCl, then flow further down the line and react to form GaAs on a substrate that is held at about 750 °C. In LPE, a supersaturated solution of As in Ga is placed in contact with a substrate and then slowly cooled, releasing the As and forming a layer of GaAs on top of the substrate. The advantages of VPE and LPE are simplicity of design; very high purity of the resulting layers (especially for VPE); and high growth rates (10–25 μm/h for VPE). The disadvantages are poor control of thin layers and poor uniformity over large areas. Although some clever solutions to these problems have been proposed and implemented, it is doubtful that VPE and LPE will be able to compete in producing thin, complex structures. However, VPE will continue to be used for applications requiring thick, high-quality layers, and LPE is still widely employed for optoelectronics applications involving ternary and quaternary alloys.

3. OPTICAL PROPERTIES

As stated earlier, GaAs has a direct energy gap that has a strong influence on its optical properties and in fact gives it a major advantage over Si for devices, such as lasers or photodetectors, which require absorption or emission of light. Furthermore, a whole range of wavelengths is available by forming ternaries such as $Al_xGa_{1-x}As$, and quaternaries such as $In_xGa_{1-x}As_yP_{1-y}$. Thus, the emerging optoelectronics industry is largely based on GaAs and other III-V compounds. In this section we will give a cursory review of the basic optical properties of GaAs. A good general account of optical properties in semiconductors can be found in the book by Pankove (1975).

3.1 Light Absorption

When light of intensity I_0 impinges upon a solid, some of it will be reflected, some absorbed, and the rest transmitted. The absorption should be an exponential process, and for a very thick sample (no light transmitted) we would expect that at a depth z into the material

$$I(z)=I_0(1-R)e^{-\alpha z}, \tag{2}$$

where R is the fractional reflectance and α is defined as the absorption coefficient. For thinner samples of thickness d, a fraction T will be transmitted, and after accounting for multiple internal reflections, T is given by

$$T=\frac{(1-R)^2e^{-\alpha d}}{1-R^2e^{-2\alpha d}}\,. \tag{3}$$

Transmission experiments based on Eq. (3) are widely used to determine α in semiconductor specimens. The absorption can arise from various processes, as enumerated below.

3.1.1 Band-to-Band, Exciton Absorption. A strong absorption takes place when the light energy $h\nu$ is sufficient to excite electrons from the valence band (VB) to the conduction band (CB) at the Γ point ($\mathbf{k}=0$). The absorption continues to increase above $h\nu=E_g$, as shown in Fig. 10, because the GaAs band structure (Fig. 3) allows many higher-energy transitions. The sharp peaks in Fig. 10 are due to exciton formation, i.e., bound states between the electrons and holes formed by the light. The excitons can either remain free or themselves become bound to donors and acceptors.

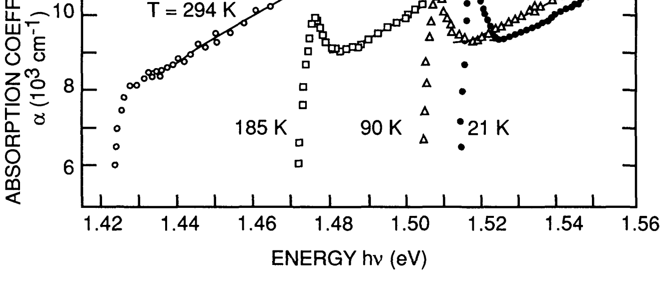

FIG. 10. Absorption coefficient vs photon energy for interband electronic transitions in GaAs at various temperatures. [From Sturge (1962). Reproduced by permission of the American Institute of Physics.]

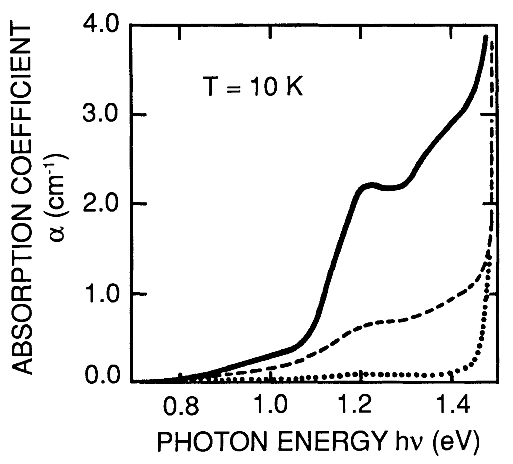

FIG. 11. Absorption coefficient vs photon energy for EL2/conduction-band electronic transitions in semi-insulating LEC GaAs. The dashed and dotted lines show photoquenching after white-light illumination for 1 and 10 min, respectively. [From Martin (1981). Reproduced by permission of the American Institute of Physics.]

Note that α quickly approaches $10^4\ \mathrm{cm}^{-1}$ for $h\nu > E_g$, which means that most of the light is absorbed within about 1 μm.

3.1.2 Band-to-Impurity or -Defect Absorption. An electron can be excited from a bound state of an impurity or defect to the conduction band if $h\nu > E_C - E_B$, where E_B is the energy of the bound electron. A good example of this process involves the famous defect EL2 (related to $\mathrm{As_{Ga}}$), as shown in Fig. 11. Since in SI GaAs, EL2 is only partially occupied, two excitation processes are possible: electrons to the CB from occupied states, and holes to the VB from unoccupied states. Then α is given by

$$\alpha(h\nu) = \sigma_n(h\nu)N^0_{\mathrm{EL2}} + \sigma_p(h\nu)N^+_{\mathrm{EL2}}, \qquad (4)$$

where σ_n and σ_p are the respective photoionization cross sections. Since σ_n and σ_p are known as functions of $h\nu$, both N^0_{EL2} and N^+_{EL2} can be determined by measuring α at two values of $h\nu$. Also, the Fermi energy can be determined from the fractional occupation.

3.1.3 Acceptor-to-Donor Absorption. An electron on an acceptor can be excited to a nearby donor, separated by distance r, if

$$h\nu = E_g - E_D - E_A + q^2/\epsilon r, \qquad (5)$$

where the last term is the Coulomb energy. Such transitions are commonly seen in GaAs if impurity concentrations are low, but usually in emission rather than absorption.

3.1.4 Free-Carrier Absorption. An electron or hole can make a transition to a higher state within the same band. Theoretically, it is expected that $\alpha \propto n\lambda^2$, where $\lambda = c/\nu$, but one set of data in GaAs suggests that $\alpha \simeq 7.5 \times 10^{-8}$ $n\lambda^3$ (if $\lambda > 4\ \mu\mathrm{m}$), for n and λ in the same unit system (Spitzer and Whelan, 1959). For example, if $n \simeq 10^{17}\ \mathrm{cm}^{-3}$ and $\lambda = 4 \times 10^{-4}$ cm, then $\alpha \simeq 0.5\ \mathrm{cm}^{-1}$, a rather small number. Thus, free-carrier absorption is usually not a problem in GaAs unless $n\lambda^3 > 10^7$ (e.g., n or $p > 10^{19}$ if $\lambda = 1\ \mu\mathrm{m}$).

3.1.5 Phonon Absorption. The phonon (lattice-vibration) bands can absorb light irradiation because the unequal charges on dissimilar atoms form dipoles. However, two or more phonons need to be involved in order to conserve momentum, since the photon momentum is very small. A portion of the lattice absorption spectrum is given in Fig. 12. For example, the strong peak at 64.8 meV is thought to be due to two TO (transverse optical) phonons, whereas much of the spectrum beyond that point is evidently due to three-phonon absorption.

3.1.6 Local Vibrational-Mode Absorption. Atoms that are light with respect to the host, such as Be, C, B, and Si in GaAs, can vibrate at high frequencies and be observed as relatively sharp peaks in the long-wavelength spectrum.

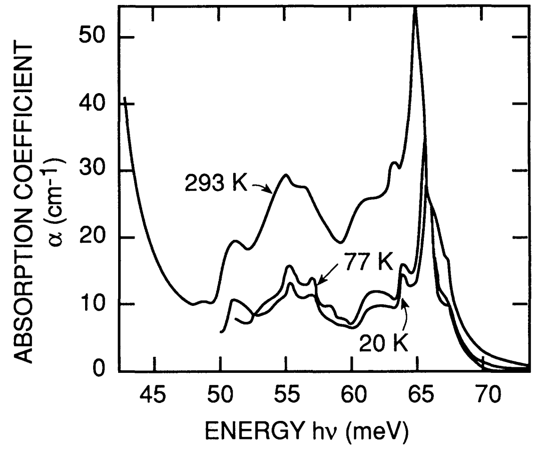

FIG. 12. Absorption coefficient vs photon energy for some of the lattice vibrational modes in GaAs. [From Cochran *et al.* (1961). Reproduced by permission of the American Institute of Physics.]

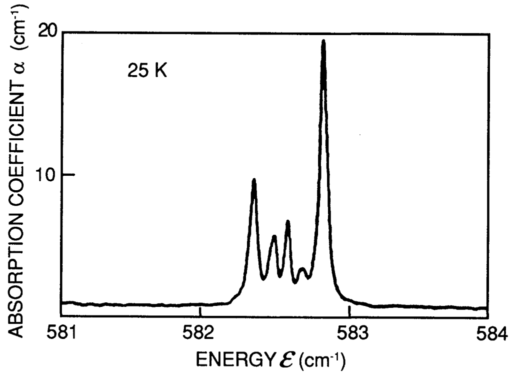

FIG. 13. Absorption coefficient vs photon energy for the carbon local-vibrational modes in GaAs. [From Theis *et al.* (1982). Reproduced by permission of the American Institute of Physics.]

From simple considerations, we would expect that $2\pi\nu \simeq (2k/m)^{1/2}$, where k is the force constant and m the mass of the impurity. Thus, for example, $^{11}B_{Ga}$ has an energy of 517 cm^{-1} (19.3 μm), and $^{10}B_{Ga}$, 540 cm^{-1} (18.5 μm), about the predicted ratio for the isotopes. Oxygen (interstitial) has lines near 730 cm^{-1}, $^{9}Be_{Ga}$ near 482 cm^{-1}, $^{28}Si_{Ga}$ near 384 cm^{-1}, and $^{12}C_{As}$ near 582 cm^{-1}. The local-vibrational-mode (LVM) spectrum of C, shown in Fig. 13, is especially interesting since it displays a nearest-neighbor isotope effect because the Ga atoms in the surrounding tetrahedron can be of either mass 69 or mass 71 (Theis *et al.*, 1982). The energy splittings, which can be fairly well predicted, are quite small, and require a high-resolution spectrometer to be observed. Note that the appearance of these splittings proves that C is on an As site, since if it were on a Ga site, the surrounding As atoms would all be of mass 75 and would produce no splitting. The LVM intensities of the above impurities can be used for concentration determinations, since the absorption cross sections are known. For this purpose, fortunately, a high-resolution instrument is not necessary.

3.2 Light Emission: Photoluminescence

The transitions involved in light absorption, described in Secs. 3.1.1–3.1.3, can also be responsible for light emission, if electrons or holes are in the excited states. However, for transitions involving band states the absorption process will have a much broader spectrum than the emission process, because absorption transitions can occur from any filled state to any empty state, whereas emission will occur primarily from a narrow, thermalized distribution of the excited carriers. Thus, sharp photoluminescence (PL) signals may be obtained from impurity concentrations as low as 10^{10} cm^{-3}, as long as extraneous broadening mechanisms are not present, and this capability makes PL extremely useful for semiconductor characterization.

Photoluminescence spectra representing four different samples (GaAs 1, 2, 3, and 4) are shown in Figs. 14 and 15 (Steiner *et al.*, 1989). Here X denotes either an exciton or an exciton-photon bound state known as a polariton; D denotes one of the hydrogenic donors, which are difficult to identify in GaAs because of very small energy separations between the various donor species; and the other symbols are obvious except for U which denotes an unknown band. Thus, the energy for the peak designated X is that resulting from the annihilation of a free exciton (or polariton), while the energy from the annihilation of an exciton bound to a neutral donor (D^0,X) is lower because of the binding energy. Conduction-band–to–acceptor transitions (Sec. 3.1.2) are represented by (e,C), and donor-acceptor-pair (DAP) transitions (Sec. 3.1.3) by (D^0,C),

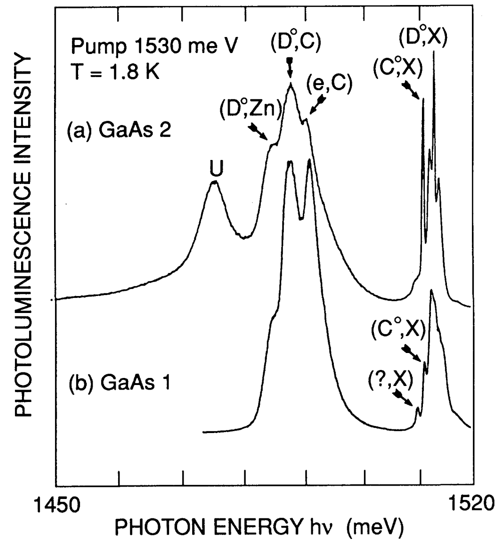

FIG. 14. Photoluminescence spectra in GaAs. [From Steiner *et al.* (1989). Reproduced by permission of the National Research Council of Canada.]

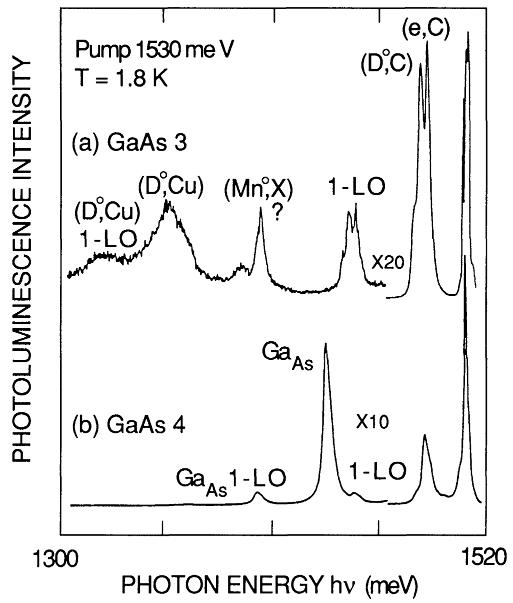

FIG. 15. Photoluminescence spectra in GaAs. [From Steiner *et al.* (1989). Reproduced by permission of the National Research Council of Canada.]

(D^0,Zn), and (D^0,Cu). The transition involving the defect Ga_{As} is also possibly of DAP nature. Furthermore, note that in several cases LO phonons are involved in the transitions. In general, PL spectra in GaAs nearly always show C, evidently a ubiquitous impurity, and in undoped SI GaAs a line at 0.68 eV due to the defect As_{Ga} is usually present.

Excited electrons and holes may also recombine through nonradiative (NR) channels which then diminish the overall PL intensity. Such channels are most effective if they involve a continuum or quasicontinuum of energy states between the initial excited state and final ground state, because then low-energy phonons can efficiently support the transitions through the chain of states. In some cases, higher-energy transitions can occur by the emission of several phonons at the same time, but this is a more unlikely process. Surfaces, or large defects, that involve a high density of dangling bonds can be efficient supporters of NR recombination. Thus, a high PL intensity often is more a result of good surface and bulk crystal quality rather than a high number of radiative recombination centers.

3.3 Modulated Reflectance: Photoreflectance

A disadvantage of PL measurements is that they must be carried out at very low temperatures, $T \lesssim 10$ K, in order to avoid kT broadening of the lines which involve a band, or even total loss of the lines for which the initial state is a shallow donor or acceptor. Furthermore, excitons are stable only at low temperatures in bulk material. Absorption (α) measurements at higher temperatures (see Fig. 10) still give a reasonably sharp response at the threshold energy (even though broadened by kT), but have little structure above the threshold, since the excitons are absent. The reflectance R, on the other hand, can give a sharper response because of its dependence on the index of refraction n, as shown below. For normal incidence of the light

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2}, \tag{6}$$

where $k = c\alpha/4\pi\nu$ and c is the speed of light. Near and below the band gap, $k \ll n$ so that $R \simeq (n-1)^2/(n+1)^2$. From the Kramers-Kronig relationship,

$$\begin{aligned} n(\mathcal{E}) - 1 &= \frac{ch}{2\pi^2}\, \mathrm{P} \int_0^\infty \frac{\alpha(\mathcal{E}')}{\mathcal{E}'^2 - \mathcal{E}^2}\, d\mathcal{E}' \\ &= \frac{ch}{4\pi^2}\, \mathrm{P} \int_0^\infty \ln\left(\frac{1}{\mathcal{E}'^2 - \mathcal{E}^2}\right) \\ &\quad \times \frac{d\alpha(\mathcal{E}')}{d\mathcal{E}'}\, d\mathcal{E}', \end{aligned} \tag{7}$$

where P denotes the Cauchy principal value of the integral. Since $\alpha(\mathcal{E})$ depends on the joint density of states, which is the highest near critical points—i.e., points at which $d[E_C(k) - E_V(k)]/dk = 0$—the derivative $d\alpha(\mathcal{E})/d\mathcal{E}$ will be a sharply varying function of $\mathcal{E}$. In the presence of an electric field E, α will become

$$\alpha(\mathcal{E},E) = \alpha(\mathcal{E},0) + \Delta\alpha(\mathcal{E},E) \tag{8}$$

and thus

$$\Delta n(\mathcal{E},E) = \frac{ch}{2\pi^2} \int_0^\infty \frac{\Delta\alpha(\mathcal{E}',E)}{\mathcal{E}'^2 - \mathcal{E}^2}\, d\mathcal{E}'. \tag{9}$$

When the field E is modulated, then Δn and thus R will also be modulated. An obvious way to modulate the field is to put a thin, transparent Schottky barrier on the sample and

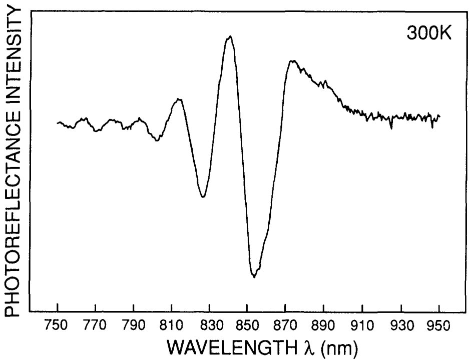

FIG. 16. Photoreflectance spectrum in a GaAs MBE layer.

apply an ac voltage. However, a far more convenient way is simply to change the built-in surface field by shining a modulated laser beam on the sample, since the free carriers produced will neutralize surface states and decrease the electric field. This phenomenon is called photoreflectance (PR). Besides obtaining information on the surface states, it is also possible to determine the bulk carrier density, since the initial electric field depends on this density. An example of PR spectra for a 1000-Å, undoped layer of MBE GaAs grown on a 2500-Å, *n*-type layer doped with 2×10^{17} cm^{-3} Si is shown in Fig. 16. The oscillations are a manifestation of the Franz-Keldysh effect, which is concerned with the behavior of the electronic wave function at a band edge in the presence of an electric field. The oscillations in this case can be easily analyzed to give a field $E=5\times10^4$ V/cm, very close to what was predicted from the expected surface potential, the doping in the active layer, and the thickness of the undoped layer. The photoreflectance technique has been reviewed by Pollak and Shen (1990) and Bottka *et al.* (1988).

4. ELECTRICAL PROPERTIES

4.1 Hall-Effect Measurements

The operation of virtually all GaAs devices involves the flow of charge carriers; therefore, the electrical properties of the material are very important. Ohm's law states simply that the current density $\mathbf{J}=\sigma\cdot\mathbf{E}$, where σ is the conductivity tensor. If the electric field **E** is applied in the x direction, and magnetic field **B** in the z direction, then for a large class of carrier scattering mechanisms (to be discussed later) it can be shown that (for electrons)

$$J_x=\frac{\sigma_{xx}^2+\sigma_{xy}^2}{\sigma_{xx}}E_x\bigg|_{B\to0}=\sigma_{xx}E_x=\frac{ne^2\langle\tau\rangle}{m^*}=ne\mu E_x, \tag{10}$$

$$R_{\mathrm{H}}=\frac{1}{B}\frac{\sigma_{xy}}{\sigma_{xx}^2+\sigma_{xy}^2}\bigg|_{B\to0}=-\frac{1}{ne}\frac{\langle\tau^2\rangle}{\langle\tau\rangle^2}=-\frac{r}{ne}, \tag{11}$$

where $\langle\tau\rangle$ is an average (over energy) of the momentum relaxation time, and the conductivity mobility μ is defined as $\mu=e\langle\tau\rangle/m^*$. (Note that the symbols σ and n should not be confused with those used in the previous section.) The quantity R_{H}, the Hall coefficient, is quite useful in all of semiconductor physics because it is very simply related to the carrier concentration n, and because it is easily measured: $R_{\mathrm{H}}=E_y/J_xB$. Another very useful quantity is $\sigma R_{\mathrm{H}}=-r\mu\equiv\mu_{\mathrm{H}}$, the Hall mobility, where we have redefined $\sigma_{xx}=\sigma$. A calculation of r vs T for electrons in relatively pure GaAs is shown in Fig. 17. It is clear that r deviates very little from unity in this case. In fact, at 296 K, for n ranging from 1×10^{12} to 1×10^{18} cm^{-3}, and compensation ratio N_I/n ranging from 1 to 10, r varies only between 1.02 and 1.26 (Look, 1989). For holes, r is more difficult to calculate and can be somewhat larger, although it is usually less than 2. In any case,

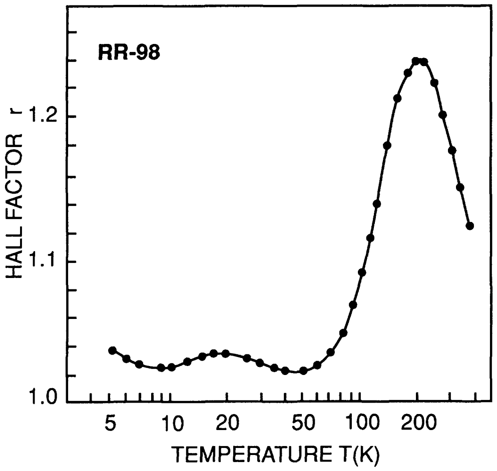

FIG. 17. Temperature dependence of the electron Hall factor *r* for a relatively pure, VPE GaAs layer. [From Look (1989). Reproduced by permission of John Wiley and Sons.]

Hall measurements give very useful approximations to n and μ and thus are widely used for their determinations. Below, we relate the quantities n and μ to materials parameters.

4.2 Electron and Hole Concentrations

A useful relationship in semiconductor analysis is the condition of charge balance:

$$n+\sum_i N_{Ai}^- = p+\sum_j N_{Dj}^+ , \tag{12}$$

where it is assumed here, for simplicity, that all acceptors either are neutral or have a single negative charge, and the same for donors except that the charge would be positive. More complex situations can be handled in a straightforward manner, although the equations can become tedious (Look, 1989). Typically, only one impurity or defect in the sample will be partially ionized, and all the others will be either neutral or fully ionized. If the partially ionized center is a donor, and if the sample is strongly n-type, then $n \ll p$ and Eq. (12) becomes

$$n+N_A^{\mathrm{net}} = N_D^+ = \frac{N_D}{1+(g_1/g_0)(n/N_C)e^{-\alpha/k}\exp(E_{D0}/kT)} , \tag{13}$$

where N_A^{net} is the total concentration of acceptors having energies below that of the donor N_D minus the total concentration of other donors having energies above that of N_D. Also, g_1/g_0 is a degeneracy factor, $E_D = E_{D0} - \alpha T$ is the temperature-dependent donor energy with respect to the conduction band (here the symbol α differs from that used in the previous section), and $N_C = 2(2\pi m^* kT)^{3/2}/h^3$ is an effective conduction-band density of states, which holds as long as the Fermi energy E_F is more than a few times kT below the conduction band. An example of fitting n vs T data by Eq. (13) is shown in Fig. 18. For example, the fit to sample RR-98, a VPE layer, has the parameters $N_D = 3.1\times10^{14}$ cm^{-3}, $N_A^{\mathrm{net}} = 2.5\times10^{13}$ cm^{-3}, $E_{D0} = 4.3$ meV, and $(g_0/g_1)\times\exp(\alpha/k) \simeq 1$. Here N_D and N_A are known to represent mainly Si and Zn, respectively, by comparison with PL experiments and other data. It is interesting that this particular N_A is the lowest acceptor concentration ever measured in GaAs, although numbers this low are more common in Si and Ge. Many other donors and acceptors in GaAs have been characterized in this way, with E_{D0} being the prime "fingerprinting" parameter. Some results are given in Table 2.

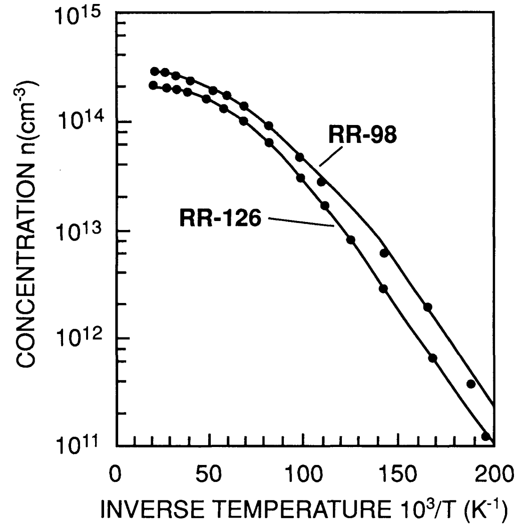

FIG. 18. Electron concentration vs inverse temperature for two VPE GaAs layers. Sample RR-98 has a very low compensation ratio. [From Look and Colter (1983). Reproduced by permission of the American Institute of Physics.]

4.3 Mobilities

Electrons or holes suddenly subjected to an electric field do not accelerate indefinitely, but suffer collisions, which eventually lead to a steady-state velocity (analogous to that of a skydiver freefalling through the air). The time required for the velocity (or momentum) to relax was designated τ in Sec. 4.1, and the mobility was shown to be $\mu = e\langle\tau\rangle/m^*$, where the brackets denote averaging over energy. An implicit assumption in the derivation leading to that form of μ is that the collisions are elastic, i.e., that the energy does not change as a result of the collision, even though the momentum does. If that is true, then at a given electron energy the total collision *rate* (τ^{-1}) should just be equal to the sum of the individual collision rates, i.e., $\tau^{-1} = \tau_1^{-1} + \tau_2^{-1} + \tau_3^{-1} + \cdots$. For many of the collision or scat-

Table 2. E_{D0} (donor) or E_{A0} (acceptor) values determined by Hall-effect measurements for various centers in GaAs

Species	Type	Energy (eV)
Si_{Ga}, Ge_{Ga}, Sn_{Ga}, S_{As}, Se_{As}, Te_{As}	Donor	$E_C-0.006$
Defects, V_{As}-related	Donor	$E_C-0.13$ to 0.20
Defect?	Donor	$E_C-0.43$
As_{Ga}	Donor, first level	$E_C-0.75$
	Donor, second level	$E_V+0.52$

tering mechanisms in GaAs, such as Coulomb scattering from ionized impurities or scattering involving low-energy acoustic phonons, that description is correct. However, at 296 K in GaAs the strongest scattering mechanism results from the absorption or emission of optical phonons, and the most important of these (the LO phonon) has an energy of 0.036 eV, greater than kT (0.025 eV). Thus, for optical-phonon scattering, τ would depend on both initial- and final-state energies, and thus would not be a useful description of the scattering process. Because of this problem, an accurate analysis of mobility in GaAs must involve a numerical solution of the Boltzmann transport equation. However, the *measurement* of mobility, as shown earlier, is easily accomplished by using the Hall effect: $\mu_H = R_H\sigma$.

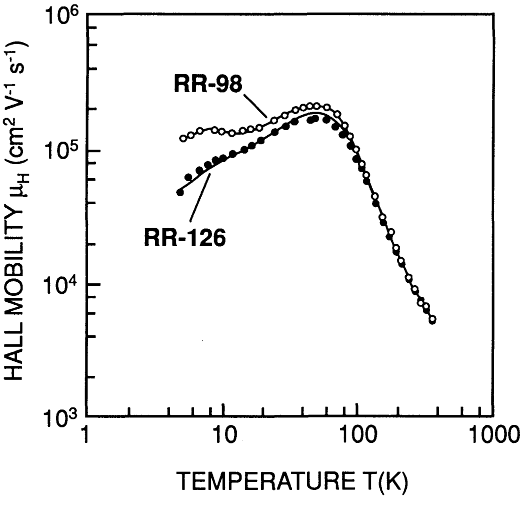

FIG. 19. Mobility vs temperature for the same two GaAs layers as shown in Fig. 18. [From Look and Colter (1983). Reproduced by permission of the American Institute of Physics.]

In Fig. 19 are shown μ vs T fits for the same two samples displayed in Fig. 18. Here the fit of N_A for sample RR-98 is 1.5×10^{13} cm^{-3}, rather than the 2.5×10^{13} cm^{-3} deduced (more accurately) from the n vs T data. Discrepancies of this magnitude are not unusual because of the complexity of mobility analysis.

Although sample RR-98 is quite pure, at low temperatures the ionized donors and acceptors still make their presences known, as shown in Fig. 20. The solid line is the theoretical μ vs T for a *completely* pure sample, and it is seen that μ should approach 7.3×10^6 cm^2/V·s at liquid-helium temperature, 4.2 K. In fact, a value of 1.2×10^7 cm^2/V·s has been measured at 0.35 K by separating the electron-producing ionized donors from the electrons themselves in an $Al_{0.35}Ga_{0.65}As$/GaAs heterostructure (Pfeiffer *et al.*, 1989). Such a value is in good agreement with the theory shown in Fig. 20.

As a figure of merit, μ(77 K) is much better than μ(296 K), because ionized impurities and defects are much stronger scattering centers at low temperatures. An empirical curve relating $\mu(77)$ to N_D+N_A in bulk material is shown in Fig. 21 (Wolfe *et al.*, 1970). Thus,

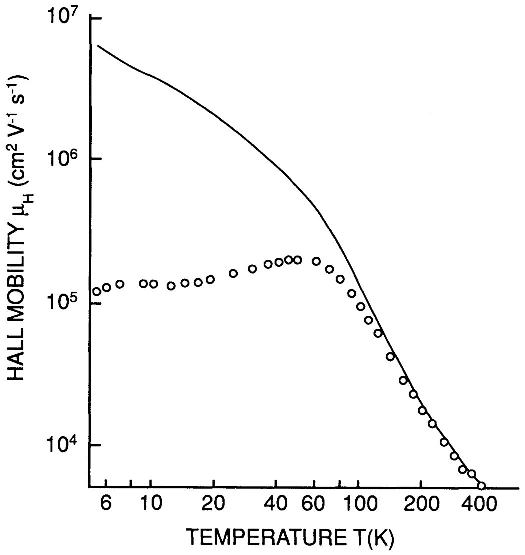

FIG. 20. The experimental Hall mobility (circles) vs temperature for a relatively pure, VPE GaAs layer. Also shown is the theoretical curve (solid line) for GaAs with no defect or impurity scattering. [From Look (1989). Reproduced by permission of John Wiley and Sons.]

any differentiation at this level of quality must be made on the basis of the *peak* mobility, which will occur at a lower temperature, the better the sample. As of this writing, the record peak mobilities, the temperatures at which they occur, and the references are as follows: VPE, 3.05×10^5 cm^2/V·s at 43 K, (Wolfe *et al.*, 1970); MOVPE, 3.35×10^5 cm^2/V·s at 38 K (Razeghi *et al.*, 1989); and MBE, 4.0×10^5 cm^2/V·s at $\simeq$35 K (Stanley *et al.*, 1991). For the VPE result, n vs T fitting gives $N_D = 4.6 \times 10^{13}$, $N_A = 3.0 \times 10^{13}$ cm^{-3}, and $E_{D0} = 5.57$ meV. Unfortunately, n vs T data were evidently not analyzed for the other two cases, but $n(77) \simeq N_D - N_A$ was about 3×10^{13} cm^{-3} in both cases. (None of these results have been corrected for Hall r factor.) Clearly, all of these techniques are presently capable of producing very pure GaAs layers although that was not the case for MBE and MOVPE until recently. It also should be realized that such high purities would almost certainly not be obtained in a production environment.

Before leaving the discussion of mobility it is important to note that the linear (Ohmic) relationship $v = \mu E$ does not hold to infinitely high field E, but in fact the electron velocity v goes through a peak at about $E \simeq 4$ kV/cm, and then settles to a relatively constant value near 1×10^7 cm/s. The reason for the peak is that electrons gain enough energy at $E \simeq 4$ kV/cm to transfer from the lowest $\mathscr{E}$ vs k valley (Γ) to the next higher valley (L), and the L valley has a lower mobility (because of a higher effective mass). This effect can be very important in the operation of high-speed devices (see Sec. 5) and in fact is the basis of one of them, the Gunn diode. Further discussion of the v vs E relationship can be found in Blakemore (1982).

5. APPLICATIONS

The general interest in GaAs began with the successful development of bulk crystal growth in the early 1950s, but greatly accelerated as novel devices emerged in the early 1960s. Today many different types of electronic, optical, and optoelectronic devices are based on GaAs, or at least use GaAs in some aspect. As yet, there is no large-scale consumer market, such as computers or television, to demand any of these devices in great numbers, but at least three such markets loom on the horizon: electronically scanned (phased-array) radar, direct satellite-to-home TV broadcasting, and collision-avoidance radar for automobiles. Other, smaller markets will keep the industry going, and perhaps slowly expanding, so that there is reason to develop existing devices further and design new ones. In this section,

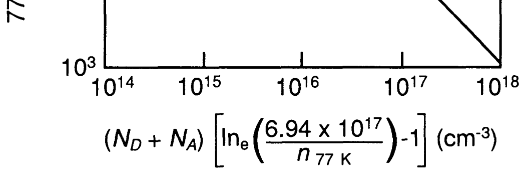

FIG. 21. The 77-K electron Hall mobility in GaAs vs an expression involving N_D, N_A, and n. [From Wolfe *et al.* (1970). Reproduced by permission of the American Institute of Physics.]

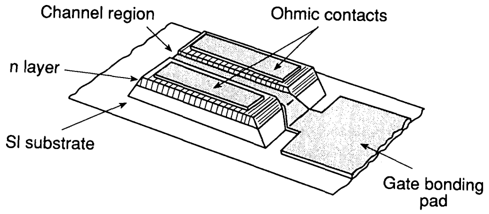

FIG. 22. Schematic of a typical MESFET. [From Arnold *et al.* (1989). Reproduced by permission of the IEE Publishing Dept.]

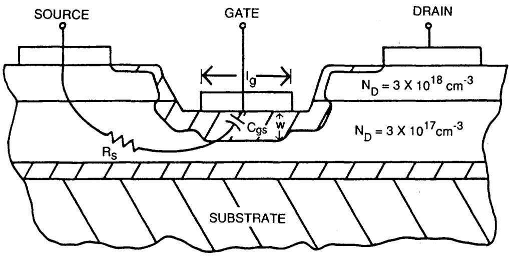
we will consider devices that are already in use or have the potential to be utilized in the near future.

5.1 Discrete Electronic Devices

5.1.1 Metal-Semiconductor Field-Effect Transistors. Without a doubt, the "workhorse" of present-day GaAs technology is the metal-semiconductor field-effect transistor (MESFET). A generic MESFET is shown in Fig. 22, although high-frequency versions usually have a somewhat different design. The *n* layer ("active" layer) may be produced directly by implantation of Si into the SI substrate, or by epitaxial growth with Si doping. The gate is recessed, in this design, to obtain the desired thickness of the channel under the gate, and thereby control the pinch-off or threshold voltage. Before application of the Ohmic and gate metal, the active layer is isolated from the active layers of other devices by a "mesa" etch that removes the conductive layer between devices. In this way, each device can operate independently, since in theory, currents should not be able to flow through the high-resistivity substrate. In actuality, the presence of "cross-talk" between closely spaced devices remains a major hindrance to the realization of high-density integrated circuits. One solution has been to insert a thin (~ 1 μm) layer of MBE GaAs, grown at 200 °C, between the substrate and the active layer.

A cross section of a typical MESFET is shown in Fig. 23. The active-layer regions with cross-hatching are depleted of free electrons, which are lost to surface states, substrate-interface states, or the gate metal. The device works by applying a negative voltage to the gate, thus drawing more free electrons to the metal and further reducing the thickness of the channel under the gate. The change in channel charge dQ resulting from the change of gate voltage dV_g depends on the gate-to-source capacitance C_{gs}; i.e., $dQ=C_{gs}dV_g=(\epsilon l_g Z/w)dV_g$ where ϵ is the dielectric constant, w is the thickness of the depletion region under the gate, l_g is the length of the gate (parallel to the current flow), and Z is the width of the gate (perpendicular to w and l_g). Also, the drain current I_D will change since $dI_D=nev(dw)Z=vdQ/l_g$, where v is the velocity of the electrons. For high drain voltages, the field near the drain will be very high and most of the electrons will be moving at the saturation velocity v_s (cf. Sec. 4.3). The primary operational characteristic of the MESFET is the intrinsic transconductance g_{m0} normalized to unit gate width. If $v \simeq v_s$, then



SOURCE

C_{gs}
w
R_s
SUBSTRATE

FIG. 23. Cross-sectional schematic of a typical MESFET. [From Goronkin *et al.*, (1985). Reproduced by permission of Howard W. Sams and Co.]

$$g_{m0}=\frac{dI_D}{dV_g}=C_{gs}\frac{v_s}{l_g}=\epsilon v_s\frac{Z}{w}\,. \tag{14}$$

Thus, it is very important to have a high saturation velocity v_s, large device width Z (perpendicular to plane of Fig. 23), and small depletion depth w. Unfortunately, too large a width Z limits the integration density, and too small a depth w can lead to gate leakage. Parasitic elements in the device will also limit its performance. One of the most harmful is the source resistance R_s, which comes from the source contact resistance and also from the "access" resistance due to the material between the source and gate. Because of R_s, the transconductance is reduced as follows:

$$g_m=\frac{g_{m0}}{1+g_{m0}R_s}\,. \tag{15}$$

Thus, for a normalized $g_{m0}=500$ mS/mm, a normalized R_s of 2 Ω mm will drop g_m in half. Therefore, much effort has been expended on reducing both the contact and access resistances. Of course, high mobility leads to low resistance, and, as discussed in Sec. 4.3, GaAs excels in this respect.

Another important operational parameter of MESFETs is the noise figure, defined as $NF=10\log_{10}F$ where

$$F=1+K_v\nu l_g[g_{m0}(R_g+R_s)]^{1/2}. \tag{16}$$

Here ν is the frequency of operation, R_g is the gate-metal resistance, and K_v is an undetermined constant on the order of unity. Although Eq. (16) is empirical, it has been shown to be representative of devices having a wide range of operating parameters. Thus, besides decreasing l_g and R_s, it is also of benefit to decrease R_g, usually by using a thick gate metal or *T*-shaped gate. Unfortunately, however, there is a trade-off between F and the transconductance g_{m0}, so that it is difficult to optimize gain and noise figure at the same time. Present technology allows l_g of 0.5 μm in production MESFETs, and down to 0.1 μm or even lower in laboratory devices. One of the best results (as of 1992) for an 0.5-μm gate-length MESFET is $NF=0.8$ dB along with an associated gain G_a of 6.3 dB at 16 GHz (Lau *et al.*, 1989). The K_v factor is 1.4 for this device.

The frequency response of MESFETs and other devices is usually measured in terms of f_T, the frequency at which the current gain descends to unity, and $f_{\max}$, the frequency at which the unilateral power gain is unity. Roughly speaking, f_T is more appropriate for low-noise applications, such as the front ends of amplifiers, and $f_{\max}$ for power applications. For a MESFET,

$$f_T=\frac{g_{m0}}{2\pi C_{gs}}=\frac{v_s}{2\pi l_g}, \tag{17}$$

$$f_{\max}=\frac{f_T}{2[(R_s+R_g+R_i)/R_{sd}+2\pi R_g C_{gd} f_T]^{1/2}}, \tag{18}$$

where R_i is a resistance in series with R_s and R_g in the usual equivalent circuit. Thus, the importance of using a material with high saturation velocity, such as GaAs, is obvious. Also important is the need to make the gate length as small as possible, but here there are trade-offs, since reproducibility, yield, and uniformity over the wafer will probably suffer. The best values of f_T reported (as of 1992) for a GaAs MESFET are $f_T=55$ GHz for $l_g=0.5$ μm, and $f_T=126$ GHz for $l_g=0.25$ μm (Feng *et al.*, 1990). By adding 18% In to the GaAs ($In_{0.18}Ga_{0.82}As$), values of $f_T=126$ GHz and $f_{\max}=232$ GHz are achieved for ion-implanted devices with $l_g=0.20$ μm.

5.1.2 Heterojunction Field-Effect Transistors. A limitation of MESFETs is that the free electrons providing the conduction will be scattered by the donors that supplied them. Such scattering diminishes the mobility μ, which increases R_s, and to a lesser extent reduces v_s. A glance at Eqs. (14)–(18) shows that v_s and R_s are prominent components of the figures of merit g_{m0}, g_m, NF, and f_T, so that it would be very helpful to reduce the donor scattering. This can be accomplished by a clever device pictured in Fig. 24, and variously known as the heterojunction FET (HFET), modulation-doped FET (MODFET), two-dimensional electron-gas FET (TEGFET), selectively doped heterojunction transistor (SDHT), or high-electron-mobility transistor (HEMT). The principal feature of this device is a heavily doped $Al_xGa_{1-x}As$ ($x\simeq0.2$–0.4) layer on top of an undoped GaAs layer (see review by Tu *et al.*, 1985). Since the lowest conduction band

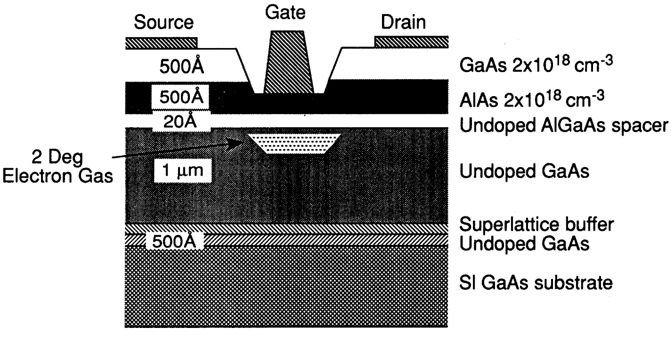

FIG. 24. Cross-sectional schematic of a heterojunction structure. [From Arnold *et al.* (1989). Reproduced by permission of the IEE Publishing Dept.]

in $Al_xGa_{1-x}As$ is higher in energy than that in GaAs, the electrons in the $Al_xGa_{1-x}As$ will transfer to the undoped GaAs, which should result in a higher μ (lower R_s) and higher v_s. Besides the "standard" $Al_xGa_{1-x}As/GaAs/$ GaAs substrate design, newer versions include $Al_xGa_{1-x}As/In_yGa_{1-y}As/GaAs$ substrate, and $Al_xIn_{1-x}As/In_yGa_{1-y}As/InP$ substrate. State-of-the-art results are $f_T=150$ GHz and $f_{max}=405$ GHz (corrected for gate-pad capacitance) for an 0.15-μm gate-length $In_{0.52}Al_{0.48}As/In_{0.53}Al_{0.47}As/InP$ device (Chao *et al.*, 1990); $NF=1.4$ dB with $G_a=6.6$ dB at 93 GHz for the same device; $f_T=120$ GHz, $f_{max}=290$ GHz, and $NF=2.1$ dB with $G_a=6.3$ dB at 94 GHz for an 0.1-μm gate-length $Al_{0.25}Ga_{0.75}As/In_{0.15}Ga_{0.85}As/GaAs$ device (Tan *et al.*, 1990).

An advantage of HFETs over MESFETs seems to be a substantially lower noise figure and higher gain at a given frequency. For example, the device mentioned above with $NF=1.4$ dB at 93 GHz had $NF=0.3$ dB and $G_a=17.2$ dB at 18 GHz, which are much better results than those reported for MESFETs in the previous section. Thus, HFETs should be superior for applications in which noise is a dominant consideration such as in radio astronomy. Also, the advantage of HFETs over MESFETs increases rapidly as temperature is lowered (e.g., the low-temperature mobility of HFETs is much higher), and so HFETs will be more likely used if cooling is practical. However, the economy of MESFET production will prevail in many of the less demanding applications.

5.1.3 Heterojunction Bipolar Transistors. Another candidate for certain digital and microwave applications is the heterojunction bipolar transistor (HBT), pictured in Fig. 25. A problem with regular bipolar designs is hole injection from the base into the emitter. This limits the doping in the base region, which leads to an unacceptably high base resistance R_b and low f_{max}, since

$$f_{max}=(f_T/8\pi R_b C_{bc})^{1/2}. \qquad (19)$$

Because $Al_xGa_{1-x}As$ has a lower valence band edge than GaAs, hole injection from a GaAs base to an $Al_xGa_{1-x}As$ emitter is reduced, and the GaAs base doping can be greatly increased, thus reducing R_b. State-of-the-art results for HBTs are $f_T=165$ GHz and $f_{max}=100$ GHz for a device with a 3.6×3.6-μm^2 InP emitter on an InGaAs base (Chen *et al.*, 1989); $f_T=65$ GHz and $f_{max}=218$ GHz for a 1×1-μm^2 $Al_{0.3}Ga_{0.7}As$ emitter on a GaAs base (Asbeck *et al.*, 1989). Clearly, there is a trade-off between f_T and f_{max}. Also, the noise figures, while better than those in Si bipolar designs, are much poorer than those in MESFETs or HFETs. For example, published results for a device having a 2×2-μm^2 emitter are $NF\simeq 4.6$ dB with $G_a=10.4$ dB at 16 GHz (Asbeck *et al.*, 1989). Thus, the HBT would probably not be used in low-noise microwave applications. Even for power microwave applications it has been suggested that the smaller emitter sizes necessary for high-frequency capabilities would make the thermal resistance unacceptably high; however, some useful power devices have been fabricated. Overall, the very high transconductances available (as high as 10,000 mS/mm reported) and correspondingly high current-drive capabilities, along with good threshold voltage control, make the HBT very attractive for digital applications.

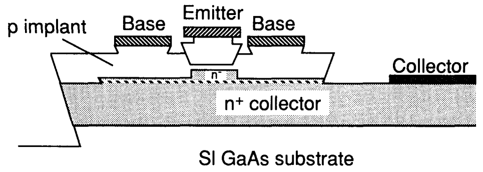

FIG. 25. Cross-sectional schematic of an HBT structure. [From Arnold *et al.* (1989). Reproduced by permission of the IEE Publishing Dept.]

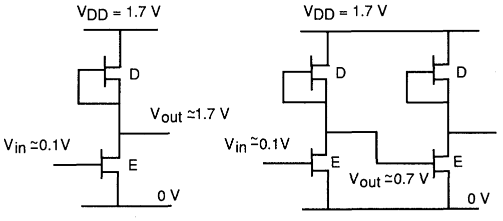
5.2 Integrated Circuits (ICs)

For digital logic and memory circuits there has long been a drive to put increasingly larger numbers of devices on the same chip in order to satisfy size, cost, and speed requirements. Although later in coming, the microwave field is now experiencing a similar drive, due mainly to size, cost, and reliability constraints. A microwave circuit consisting of transistors, capacitors, inductors, and resistors on the same chip is known as a monolithic microwave integrated circuit (MMIC). We will discuss GaAs-based digital ICs and MMICs, and make comparisons with the competitive Si technology.

5.2.1 Digital ICs. Because of its inherent speed advantages (cf. Sec. 4.3), it has long been forecast that GaAs would soon overtake Si as the material of choice for high-speed digital applications. The reason that this has not yet happened is perhaps best illustrated by considering the most ideal logic design. When thousands and even millions of devices are placed very close to each other on a small chip, the basic logic units should be as simple as possible, and should dissipate very little power. One such design is called direct-coupled FET logic (DCFL), and a simple DCFL inverter circuit is illustrated in Fig. 26. The lower ("switching") transistor is an enhancement ("E") mode MESFET, and the upper ("pull-up") transistor is a depletion ("D") mode device. For a typical logic "0" input voltage (less than the threshold voltage of ~0.2 V), the switching (E-mode) transistor will not conduct, and V_{out} will be held at $V_{DD}=1.7$ V since the pull-up D-mode transistor will conduct. However, in real life, the output will be connected to the gate of another switching transistor [Fig. 26(b)] which will then conduct and drop V_{out} to the Schottky barrier potential of a GaAs MESFET, about 0.7 *V* (logic "1" in this case). Further connections to other gates (more "fanout") will drop V_{out} even more, perhaps to about 0.6 *V* for a fanout of four. Thus, in this case the actual logic "1" is ~0.6 *V*, rather than 1.7 *V*. This example points out the first problem with GaAs MESFETs, the low maximum gate voltage (~0.7 V), which is an inherent feature of the GaAs Schottky barrier. In Si, a native oxide (SiO_2) is inserted between the semiconductor and metal [metal/oxide/semiconductor (MOS) device], which allows much higher voltages on the gate before conduction. Then logic "1" can be kept at a high value, and noise spikes or variations in device processing are not as critical, even for much higher fanouts; i.e., the "noise margin" is higher. Unfortunately, the GaAs native oxide is poor and introduces a large surface-state density, as do most other insulators on GaAs. Another problem is that a non-negligible current is drawn by the E-mode device, even in the off state (~0.1 *V*), so that not too many input transistors can be added in parallel (low "fanin"). Because of the small difference between the off voltage (~0.1 *V*) and the threshold voltage (0.2–0.3 *V*), the device uniformity must be controlled very precisely, and this has been a problem in the past. Recently, however, HFET threshold voltages have exhibited standard deviations of only 11 mV for E-HFETs and 14 mV for D-HFETs over a full 3-in. wafer.



(a) (b)

FIG. 26. Schematic of a logic circuit. [From Flynn *et al.* (1989). Reproduced by permission of the IEE Publishing Dept.]

A way to achieve higher allowable voltage swings between turnoff and turnon is to use depletion-mode technology throughout the design, and hold the gates at a high negative voltage in the off state. Two such logic designs are presently popular: buffered FET logic (BFL) and Schottky-diode FET logic (SDFL). Unfortunately, both of these schemes require a second power supply as well as level-shifting diodes to provide the proper voltages on the gates of the fanout transistors. Although increasing the noise margin, as well as fanin and fanout capabilities, these designs also greatly increase the total number of circuit elements required, and consequently the total power dissipation. Many digital MESFET, HFET, and HBT logic circuits are now being produced, and some of the more conservative and reliable designs have found their way into the computer marketplace. Convex Computer Corporation has introduced a new series of real-time computers that use both BiCMOS (bipolar complementary MOS) and GaAs logic circuits and have performance at the 800-Mflops level. Also, Cray Computer Corporation will soon introduce the Cray-3 Supercomputer, with up to 16 processors, giving a 16-Gflops capability. All of the logic functions in the Cray machine are performed by GaAs devices, which are designed around a conservative 1-μm gate-length, depletion-mode MESFET technology. The basic devices have 100-ps gate delays, while the circuits are clocked at 2 ns (500 MHz). Gate complexities range from 500 to 2000 gates, and more than 450 different logic types are employed.

Circuits with VLSI (very large scale integration) complexity are also being developed (see VLSI TECHNOLOGY). Honeywell has reported a 16×16 complex multiplier chip for digital signal processing applications. This unit uses 1-μm HFET technology implemented in a DCFL scheme, and consists of 4500 gates on an 7.8×8.5-mm^2 chip. Operated at 500 MHz, the unit can perform a full 16-bit complex multiplication every 8 ns.

For memory circuits, 4-K SRAMs (static random access memories) have been developed in both MESFET and HFET technology, with the latter having an 0.5-ns access time. Also, a 16-K HFET SRAM with an access time of 3.4 ns at 77 K has been produced. This unit has a total of 107 519 devices and is implemented in E/D DCFL technology, as are most of the HFET SRAM designs. With switching delays of less than 10 ps now available from HFET devices, it seems likely that GaAs memory devices will find use in some specialized applications in the future, even though their integration levels are still well below those of Si. A review of HFET LSI (large scale integration) technology has been given by Abe *et al.* (1989).

5.2.2 Microwave ICs (MMICs) One area in which GaAs already dominates Si is in microwave applications at frequencies above 1 GHz. As discussed in Sec. 5.1, f_T of greater than 100 GHz has already been demonstrated in all the basic technologies discussed here: MESFET, HFET, and HBT. Not only are these devices faster than any Si devices, but GaAs also has the enormous advantage of having readily available semi-insulating substrates, with $\rho > 10^7$ Ω cm at 296 K. Thus, MESFETs, MIM (metal/insulator/metal) capacitors, spiral inductors, transmission lines, resistors, air bridges, and via holes can all be fabricated on a single chip without having to worry about parasitic elements due to substrate conductivity. The resulting circuits are called MMICs (monolithic microwave integrated circuits) and are illustrated in Fig. 27. MMIC technology is impractical in Si, because stable Si substrates with $\rho > 10^4$ Ω cm, the minimum usable resistivity, are not available. The main advantages of MMIC circuits over discrete and hybrid circuits are in cost, size, and reliability.

Many MMIC circuits, covering a frequency range of dc to 115 GHz, have been designed and fabricated from single-function circuits such as small-signal and power amplifiers, switches, phase shifters, oscillators, and mixers, to multifunction circuits such as direct-broadcast-satellite receivers [with low-noise rf (radio-frequency) amplifiers, mixers, oscillators, and IF (intermediate frequency) amplifiers] and transmit/receive modules for phased-array radar (with low-noise and power amplifiers, phase shifters, and reciprocal switches). Other applications include electronic warfare instruments, decoy seekers, and smart munitions, in the military area; satellite transponders, mobile communication units, and position indicators, in the communications area; and cellular telephones, automotive anticollision devices, and high-definition TV, in the consumer area.

It is likely that MMIC will be the biggest driver of GaAs technology in the near future. At least 25 companies around the world have made significant contributions to MMIC designs since the first *X*-band amplifier was introduced by Plessey in 1974, and other companies are becoming involved each year. A major boost to MMIC technology in the United States is resulting from a 6-year (1988–1994), >$500M program, funded by the Defense Department. Although specifically intended for military applications, it will undoubtedly have an impact in the consumer

arena, also. Reviews of MMIC technology have been given by Arnold *et al.* (1989) and Pucel (1985).

5.3 Optical Devices

Because of its direct band gap, GaAs is an efficient emitter and detector of light, an advantage not enjoyed by Si (cf. Sec. 3.1.1). This property has led to many GaAs-based optical devices, including light-emitting diodes (LEDs), lasers, and various kinds of detectors. Although there are many present applications for such devices, such as bar-code readers, optical disks, and surveying instruments, and other potential applications such as all-optical computers and solar cells, the biggest impact, both now and in the future, will probably be in the communications and digital processing areas. Thus, we will concentrate on these areas in our examples below.

5.3.1 Sources. Light sources involving GaAs include LEDs and lasers, both emitting at a wavelength of about 0.85 μm (i.e., close to the band gap; cf. Sec. 1.4). This wavelength was ideal for minimum signal loss and wavelength dispersion of some of the early silica fibers, but present fiber technology has moved the loss minimum to 1.3 or 1.5 μm, and the dispersion minima to nearly the same wavelengths. At any of these wavelengths, a choice must be made between low-cost multimode fiber or the more expensive single-mode fiber, which have bandwidth-length products of about 200 MHz km and 100 GHz km, respectively. Thus, for short link lengths or low bit rates, the multimode, more lossy fiber can be used with an 0.85-μm GaAs laser or LED, whereas for longer links and higher bit rates, single-mode fiber with minimum loss at 1.3 or 1.55 μm is used with InGaAs or InGaAsP sources lattice-matched to InP. The material for most of these devices is grown by epitaxial techniques, usually LPE or MOVPE, since defects leading to nonradiative recombination must be kept at a minimum.

A simple implementation of a double-heterostructure injection laser is shown in Fig. 28. Although the carriers recombine and emit light in the cross-hatched GaAs region, the AlGaAs (actually $Al_{0.3}Ga_{0.7}As$) regions serve two important purposes: confinement of the injected carriers due to the band-gap discontinuities, and confinement of the optical field due to the index-of-refraction discontinuity. The result of the AlGaAs cladding layers is a greatly reduced current threshold for lasing.

5.3.2 Detectors. Optoelectronic detectors are of two basic types: photoconductors in which the light increases the majority-carrier concentration (usually electrons) and thus the drift current; and photodiodes, in which the electrons and holes which are created in (or diffuse into) the junction region are swept by the junction electron field. A very common detector for both signal processing and the optical communications areas is the reverse-biased *p-i-n* photodiode, in which a high-resistivity drift region of width *w* is placed between the *p* and *n* regions. This scheme effectively increases the junction width and thus the amount of light absorbed. It also decreases the junction capacitance, which decreases the R_LC time constant due to the load; however, it increases the transit time across the junction, which will be the speed-limiting feature if *w* is made too large. A schematic of a planar photodiode is shown in Fig. 29. Here the *p* region (AlGaAs) has a higher conduction-

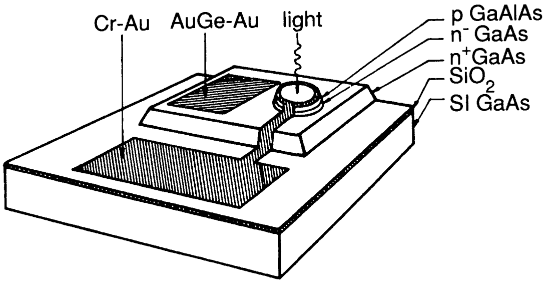

FIG. 29. Schematic of a planar photodiode. [From Bar-Chaim *et al.* (1983). Reproduced by permission of the American Institute of Physics.]

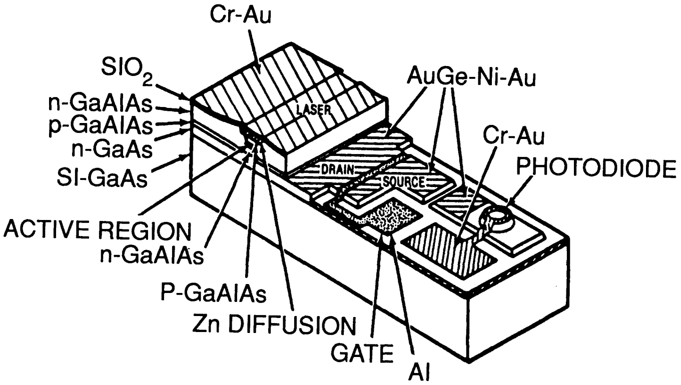

FIG. 30. Schematic of a monolithically integrated repeater circuit. (Courtesy A. Yariv).

band energy than the *n* region (GaAs) in order to "launch" the electrons into the drift space.

At very high reverse biases, the carriers in the drift region will pick up enough energy to create further electron-hole pairs by impact ionization. This process will "avalanche" and produce a very high optical gain. Avalanche detectors are used for applications in which noise is not a major consideration. A useful version of this detector has been designed around $Al_xGa_{1-x}As/GaAs$ superlattices.

For digital signal-processing applications, the fiber links are relatively short, so that the 0.85-μm minimum-loss fibers are not a limiting factor. Then, GaAs sources and detectors are ideally suited for most purposes. For optical communications, on the other hand, longer fibers are needed so that the higher-quality 1.3- and 1.55-μm minimum-loss fibers are normally used. In that case, the sources and detectors must be optimized for longer wavelengths, and are usually based on ternary materials, such as InGaAs, or quaternary materials, such as InGaAsP, lattice matched to InP. However, it must be noted that InP-based technology is not as mature, and it is also more difficult to grow ternaries and quaternaries than binaries.

5.3.3 Integrated Optics. Overall performance of a circuit can be greatly enhanced if several functions can be integrated on the same chip. In Fig. 30, we show a monolithically integrated repeater, consisting of a *p-i-n* detector, a MESFET, and a heterojunction laser diode. Here the *p*-AlGaAs layer serves as the window layer for the photodiode and as the current-confinement layer in the laser. Although this is a rather simple circuit, many OEICs (optoelectronic integrated circuits) nowadays have more than ten components, and it is likely that complexity will continue to increase in order to realize greater cost and speed advantages over hybrid circuits.

A good review of OEIC technology and applications has been given by Hirano (1987).

GLOSSARY

Acceptor: An impurity or defect in the crystal lattice that has the capability of taking an electron from the conduction band, the valence band, or a donor center (thus decreasing, increasing, or not changing the conductivity, respectively).

Donor: An impurity or defect in the crystal lattice that has the capability of donating an electron to the conduction band, the valence band, or an acceptor center.

Effective Mass: The mass that a free electron or hole in a crystal lattice "appears" to have when subjected to electric or magnetic forces.

Energy Gap: The energy difference between the highest point (in $\mathscr{E}$ vs **k** space) of the valence (filled) bands and the lowest point of the conduction (empty) bands.

Epitaxial Growth: Single-crystal growth on a substrate, usually of the same material, or material with a similar lattice constant.

Heterostructure: A crystal formed by the joining of two dissimilar materials, usually by epitaxial growth of one on the other.

Microwave: Referring to frequencies in the range 1 to 30 GHz.

MMIC (Monolithic Microwave Integrated Circuit): A circuit consisting of several microwave components, such as transistors, capacitors, and inductors, fabricated monolithically on the same chip.

Optoelectronic: Referring to the combining of optical components, such as lasers and detectors, and electronic components, such as oscillators and amplifiers, in the same circuit.

Phonons: Quantized lattice vibrations, having discrete, "particlelike" behavior.

Photons: Quantized light waves, having particlelike behavior.

Relaxation Time: The time required for randomization of electron or hole momentum through collisions (scattering). A different time is involved in energy relaxation.

List of Acronyms

BiCMOS	bipolar complementary metal/oxide/semiconductor
BFL	buffered FET logic
CB	conduction band
CMOS	complementary metal/oxide/semiconductor
DCFL	direct-coupled FET logic
GF	gradient freeze
HB	horizontal Bridgman
HBT	heterojunction bipolar transistor
HEMT	high electron mobility transistor
HFET	heterostructure field-effect transistor
HGF	horizontal gradient freeze
HP-LEC	high-pressure liquid-encapsulated Czochralski
IC	integrated circuit
IF	intermediate frequency
LEC	liquid-encapsulated Czochralski
LED	light-emitting diode
LO	longitudinal optical
LPE	liquid-phase epitaxy
LP-LEC	low-pressure liquid-encapsulated Czochralski
LSI	large-scale integration
LVM	local vibrational mode
MBE	molecular-beam epitaxy
MESFET	metal/semiconductor field-effect transistor
MIM	metal/insulator/metal
MMIC	monolothic microwave integrated circuit
MOCVD	metal-organic chemical vapor deposition
MODFET	modulation-doped field-effect transistor
MOMBE	metal-organic molecular beam epitaxy
MOS	metal/oxide/semiconductor
MOVPE	metal-organic vapor-phase epitaxy
NF	noise figure
NR	nonradiative
OEIC	optoelectronic integrated circuit
OMVPE	organometallic vapor-phase epitaxy
PBN	pyrolytic boron nitride
PL	photoluminescence
PR	photoreflectance
rf	radio frequency
RHEED	reflection high-energy electron diffraction
SDFL	Schottky diode FET logic
SDHT	selectively-doped heterostructure transistor
SI	semi-insulating
SRAM	static random access memory
TEGa	triethylgallium
TEGFET	two-dimensional electron gas field-effect transistor
TMGa	trimethylgallium
TO	transverse optical
VB	valence band
VB	vertical Bridgman
VGF	vertical gradient freeze
VLSI	very large scale integration
VPE	vapor-phase epitaxy

INTRODUCTION

What is Game Theory?

The theory of games is devoted to the analysis of individual and group decision making in situations involving a diversity of individual goals and differing levels of strategic control over the environment. It provides a mathematical theory of strategy as an extension of individual rational behavior. It is complementary to social psychology and other behavioral theories whose models of man presume limited rationality, constraints to calculation, and nonconscious behavior. Game theory examines the implications of the interactions of individually rational agents in situations involving more than one agent. It illustrates the relationship between individual and group rationality. Several simple intuitively plausible concepts concerning the extension of individual rationality to group rationality are shown to be false. The theory of games offers explanations and insights as to why this is so.

By limiting the model of the individual to rational man, the theory of games helps to sort out those aspects of behavior that require the introduction of psychological, sociopsychological, or sociological factors from those that can be explained by pure economic factors.

A Historical Sketch

Although several of the basic ideas concerning formal strategic analysis could be attributed as far back as the great classic of Sun Tzu (ca. 500 B.C.), modern game theory can be dated from the 1920s with the work of von Neumann (1928) on the two-person zero-sum game or game of pure opposition. Games such as chess, Go, or checkers are in this class. The gain to one player is attained only at the cost of a loss to the other. Although Borel (1924) had considered two-person zero-sum games, and considerably earlier Waldgrave had examined a simple game called "Le Her," the proof of the basic solution for a two-person zero-sum game—the minimax theorem (discussed in Sec. 2.1)—was von Neumann's seminal contribution.

Prior to von Neumann, Zermelo (1913) had proved (by backward induction) the first formal theorem in what is now known as game theory. However, this was an isolated result rather than the formal start of a new theory.

The result of Zermelo establishes that the outcome in a game of chess is strictly determined. Chess is a game of *perfect information*, which means that at every point in the game each individual knows precisely what has transpired (this contrasts with a game such as bridge or poker where the deal is a random move not disclosed to all). Starting at any end point of the game, as it is played sequentially the player who is called upon to move faces a one-person maximization problem if he selects the option to terminate the game with a win or draw. Thus we can replace the original game with a smaller game by removing the last set of choices and replacing them by the value of the optimal selection of the player who is called upon to move. This procedure can be repeated all the way back until the outcome of the game is determined at the start. To this day it has not been determined if chess is a win, loss, or draw for white, but we know that if people or machines could compute fast enough it would not be worth playing, like tic-tac-toe which is also a two-person zero-sum game with perfect information.

The work that launched game theory as a major discipline was the book *The Theory of Games and Economic Behavior* by von Neumann and Morgenstern (1944). Cournot (1897) and Edgeworth (1881) had recognized the importance of economic interaction among few agents, but Morgenstern was the first modern economist to realize the possibility of the construction of a general theory for the study of cross-purposes maximization. Morgenstern's collaboration with von Neumann resulted in the publication of the large and impressive book that introduced game theory as a scientific discipline of its own.

This book contained four logically separate contributions that the authors linked together. They were utility theory (see Sec. 1.8); the extensive form of a game (see Sec. 1.1); the theory of two-person zero-sum games (see Sec. 2.1); and a theory of cooperative games (see Sec. 1.3) based on a solution called the *stable set* (see Sec. 2.5.5), which reflects a form of social stability.

The 1950s saw the takeoff in the development of the mathematical aspects of theory of games and some applications. Nash (1951) defined the noncooperative equilibrium (see Secs. 2.2 and 2.3) and proved its existence for a broad class of games. Gillies (1953) and Shapley considered the core (see Sec. 2.5.1); Shapley (1953a) developed the value. Nash (1950,1953) wrote two seminal papers on two-person bargaining and fair division (see Sec. 3.1.2). Shapley (1953b) wrote a fundamental paper on stochastic games (see Sec. 1.4). Among the early applications Mayberry *et al.* (1953) applied Nash's results to duopoly and Shapley and Shubik (1954) applied the value to measure power in committee voting. As early as 1951 Nyblen applied game theory to macroeconomics and Harsanyi (1956) connected the work of Zeuthen (1930) with that of Nash in his early work on the development of a no-side-payment value (see Sec. 2.5.2). By the end of the 1950s the roots of game theory had been well established.

1. THE LANGUAGES OF GAME THEORY

A key contribution of the theory of games has been to provide several basically different abstractions together with special mathematical notation to study various aspects of multiperson optimization at various levels of detail. Each abstraction together with the mathematical notation used provides a language of discourse for a broad set of problems.

The three major representations of a game have been the extensive, the strategic (or normal), and the coalitional forms. The first provides microscopic detail concerning the moves, information conditions, and payoffs of the game; the strategic form suppresses much of this detail and describes a game only in terms of strategies and payoffs (see Sec. 1.2 below); the coalitional form goes to an even higher level of aggregation. The concern is with the joint gains of coalitions; thus there is no direct interest in details even about strategies. In this representation the game is portrayed by coalitions and the amounts they can achieve.

1.1 The Extensive Form

The basic description of a game in full process detail is provided by the *extensive form*. First developed by von Neumann and generalized by Kuhn (1953) for *n*-person games, the extensive form provides a precise language to describe choices, moves, information, and payoffs for any finite game.

Two simple examples of a game tree serve to illustrate the extensive form. A game in extensive form is represented by a rooted tree, which means that the tree has a distinguished node indicating where the game begins. In Figs. 1(a) and 1(b) the node is identified with the letter O. Each node of the game tree, except the terminal nodes, represents a choice point for one of the players (or Nature or chance, considered as an extra player, who when called upon to choose selects a move according to some given probability distribution). A move is represented by a branch of the tree. At each choice point the moves available to the player are indexed. In Figs. 1(a) and 1(b) player 1 selects his move first. His choice is to go left or right. These are indexed by 1 or 2. All choice points for each player are partitioned into information sets. These sets describe the state of insurance under which a player operates.

The game in Fig. 1(a) has perfect information. This means that at any point in the game the player whose choice it is knows exactly where he is. All his information sets contain only one element apiece. The game in Fig. 1(b) does not have perfect information. The information set for player 2 contains two nodes. This means that when player 2 selects his move, he does not know whether player 1 has selected left or right. Once the sequence of moves has reached a terminal point in the game tree the game is over and the numbers in parentheses at the bottom of each terminal node specify the payoffs to each player. The pair of numbers to the far left in Fig. 1 indicate that for the play of the game where each selects his first move the payoff is 1 to player 1 and −1 to player 2.

A (pure) strategy for a game in extensive form is a complete plan that tells the player how to select his move as a function of his current information at every point in the game. Given a strategy for each player these uniquely determine a path down the whole game tree and hence a play and an outcome.

A game of any complexity, such as chess, has myriads of strategies, many of which are redundant. But although it is not practical to enumerate all of the strategies in games involving more than three or four moves, the concept of a strategy as a complete contingent plan enables us to define precisely how contingent planning depends on information. This can be illustrated with the two simple examples. The game shown in Fig. 1(a) has two strategies for player 1. His moves and strategies coincide. He can select 1 or 2. Player 2, however, has four strategies because his choice

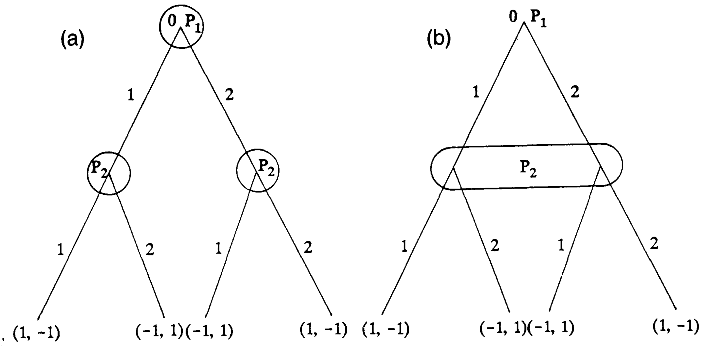

FIG. 1. Representations of a game in extensive form. (a) The case of perfect information. (b) The case of imperfect information.

of move is based upon contingent planning, which tells him what to do if player 1 selects 1 and what to do if player 1 selects 2. In each instance he can select one of two moves. In contrast in the game shown in Fig 1(b), when player 2 is called upon to select his move, he does not know what player 1's choice has been, and hence his choice is limited to selecting move 1 or 2 without conditioning the selection on what player 1 has done.

A mixed strategy for a player is a selection among his pure strategies according to some random distribution. We may regard each pure strategy as a complete book of instructions that one could give to an agent acting on one's behalf. A mixed strategy involves randomizing to decide which pure strategy to use.

1.2 The Strategic Form

The strategic (sometimes called the normal) form of a game is defined in terms of the players, their strategy sets, and their payoffs. Suppose that each player i has a set of strategies S_i, where we denote a specific strategy by s_i. Associated with each player i is a payoff function $P_i(s_1,s_2,\ldots,s_n)$. This describes the game in strategic form.

A two-player game can be illustrated simply in matrix form, or, more precisely, in bimatrix notation, i.e., in each cell there are two numbers, the first indicating the payoff to player 1 and the second to player 2. The two games illustrated in extensive form in Figs. 1(a) and 1(b) can be illustrated in strategic form in Tables 1(b) and 1(a).

The game with perfect information is displayed as a 2×4 matrix, as player 1 has two strategies (which coincide with his moves) but player 2 has four strategies as he has information which he can utilize for contingent planning. The numbers above the matrix are merely the names of the strategies and can be regarded as standing for the labels to four books of instructions.

1=(1,1;2,1), 2=(1,1;2,2), 3=(1,2;2,1), 4=(1,2;2,2)

1.3 The Coalitional Form

The coalitional form of a game is represented by its *characteristic function* if the game has transferable utility (referred to as TU). This means that when any group of players collaborate, whatever they earn, they are able to make transfers among themselves so that without loss of value they can transfer their joint gain among themselves in any way they choose. The characteristic function of an n-person game is a superadditive set function $v(S)$ defined on all of the 2^n-coalitions that can be formed from n players, where n is the number of players in the set N of all players. An additional economic assumption is that the set n is superadditive. This can be stated formally as

$$v(S \cup T) \geqslant v(S) + v(T). \tag{1}$$

The economic intuition behind this condition is that a coalition will not form unless there is the possibility of joint gain to the parties involved. A simple example of the characteristic function of a three-person game in coalitional form is shown below:

$$\begin{gathered} v(\{1\})=0,\quad v(\{2\})=0,\quad v(\{3\})=0, \\ v(\{1,2\})=1,\quad v(\{1,3\})=2,\quad v(\{2,3\})=3, \\ v(\{1,2,3\})=4. \end{gathered} \tag{2}$$

This is interpreted as follows: $v(\{i,j\})$ stands for the amount that can be obtained by the set of players whose names are i and j. Here we observe that any player by acting alone obtains nothing and that all three together obtain 4. An examination of the two-person coalitions shows that player 3 brings the most to any coalition of two.

Implicit in representation of the payoffs to any coalition by a single number is the idea that the coalition can divide the proceeds among themselves in any way the members see fit. In many situations the assumption that there is some perfect means of side payment among all players is not justified. The players may obtain payoffs as a result of the play of the game and may not be in a position to make side payments or adjustments to what each achieves. A game where there are no side payments is referred to as an NTU game (no transferable utility). It is represented by a characterizing function $V(S)$, where it is no longer possible to assign a single number to indicate the amount that a coalition S obtains, but instead a set of feasible efficient outcomes specifying what the coalition can achieve must be given. The analysis of NTU games is considerably more complex than TU games, but the NTU games have been used extensively in economic theory.

1.4 Other Structures

The notations developed in Secs. 1.1, 1.2, and 1.3 all involve a finite number of agents playing in a game with a given start and a finite end with the payoffs at the end. Many aspects of human cooperation and competition are not well modeled in this form. In general, for many situations there has been a yesterday, and history may matter. Furthermore, there may be a tomorrow, and the time at which the game ends may be indefinite.

In other instances the game under consideration might best be modeled with a continuous set of strategies, such as in a duel where two individuals are walking towards each other and each has to decide when to fire.

Another important class of games that are modeled naturally with continuous moves consists of games of pursuit, leading to differential games. The first book on differential games was by Isaacs (1965). Case (1979) applied differential games to some problems in economic competition. There is also a growing literature on other dynamic games; these include repeated games, stochastic games, games of survival, games of economic survival, and recursive games.

1.5 A Continuum of Agents

The original development of the theory of games by von Neumann and Morgenstern dealt with games with a finite set N of players. In applications it became desirable to consider both games with an infinite but countable set of players and games with a continuum of players. When studying mass economic and mass voting behavior, the modeling of these games is called for to examine the various forms of limiting behavior that might be encountered, as action in the market or at the ballot box involves millions of more or less anonymous individuals. One can consider an exchange economy with a baker, a butcher, and a candlestick maker, and then compare it with another economy where there are k individuals of each type, where we allow k to become arbitrarily large. A natural question to ask is, if we assume some form of behavior for the individual agent, does the behavior of the mass of agents approach a limit as k becomes large? As long as k is finite, although the power or possession of an individual in a replicated game shrinks relative to the game as a whole, nevertheless the player remains of measurable size. Shubik (1959a) considered the replications of a game, basing the idea on an interpretation of earlier work of Cournot and Edgeworth; Debreu and Scarf (1963) used replication in the study of the behavior of the core (Sec. 2.5.1).

The way we can capture the intuitive idea of an individual who is so small with respect to the market that he has no influence whatsoever on price is to consider a continuum of traders where each is of measure zero. Milnor and Shapley (1957) first considered *oceanic games* in the study of voting with a continuum of voters. Aumann (1964) considered cooperative markets with a continuum of traders. Dubey and Shapley (1980) considered games in strategic form and the noncooperative equilibrium solution with a continuum of traders. The idea of a continuum of economic agents plays a central role in understanding the concept of competition in an enterprise economy. It has enabled economists to formalize the remarks of Adam Smith on the "invisible hand."

1.6 Incomplete Information

The game-theory models described in Secs. 1.1–1.5 all have as an implicit assumption that the players know each other's preferences and strategy sets as part of the rules of the game. For example, although in chess it is reasonable to assume that each player knows the other's preferences concerning the outcome of the game, it is not likely that in a many-person trade each knows the valuations placed on all goods by the others. Harsanyi (1967,1968a,1968b) provided a means to take this lack of knowledge into account.

An n-player game with incomplete information in strategic form is described as follows. There are n players and each player i may be one of t_i types. There are n probability distributions $(p_1, p_2, \ldots, p_n)$ that can be used to determine each player type. At the start of the game all player types are determined and each player is informed privately of his type. The game is then played simultaneously by all the player types. Each player obtains a payoff that is determined by both the choice of all strategies and the selection of his type.

The Harsanyi formulation presents a way to model both incomplete information and beliefs about beliefs. Mertens and Zamir (1985) established that there is an equivalence between the Harsanyi formulation and consistent beliefs.

1.7 Common Knowledge

Although Harsanyi succeeded in modeling incomplete information in a situation in which all agents share a common prior, a "prior" being the *a priori* probability for the occurrence of an expected event, it is possible that knowledge about who knows what is not shared. Aumann (1976) has phrased it that a fact is common knowledge among the players if every player knows it, every player knows that every player knows it, and so on.

The importance of the role of common knowledge is illustrated in an example noted by Myerson (1991). A village has 100 couples. The men gather each day to praise their wives if they believe them to be faithful or to curse them if they believe otherwise. If a wife is unfaithful she and her lover tell all men in the village except her husband. In this village every wife has been unfaithful to her husband but each husband lives in the bliss of having no evidence about his wife. A visiting guru announces to all that there is an unfaithful wife in the village. One hundred days after the guru's visit all husbands curse their wives.

1.8 Utility Theory

Utility theory deals with the nature of the description of human preferences. A common error made in the discussion of game theory is that somehow the development of the theory of games depends upon a precise and unrealistic specification of measurable and comparable utility among all individuals—as though some soma pill or exchangeable utility existed. In fact, all that is needed for the logical basis of a theory of games is that each individual has some rule of choice when confronted with a set of alternatives. There is an enormous literature on preferences and utility [see, for example, Fishburn (1970)] that is complementary but incidental to many of the basic ideas of the theory of games.

2. SOLUTION CONCEPTS

2.1 The Zero-Sum Game and Maxmin

The seminal contribution of von Neumann was to show that for the class of two-person zero-sum games under reasonable conditions, the concept of rational behavior can be extended by means of the concept of individual rationality. The *security level* of player i is the greatest amount that he can guarantee for himself under all circumstances. This is the amount maxmin $P_i(s_1, s_2)$, where P_i is the payoff for player i, the s_i are the strategies of the players, and the term *maxmin* refers to the maximum that individual i can obtain on the assumption that j will select a strategy that minimizes i's payoff. An outcome to a game is called individually rational if each player obtains at least his security level. A game in which there is a single individually rational outcome is called *strictly determined.* An example in Table 2(a) shows a strictly determined two-person zero-sum game. The example in Table 2(b) shows the simple matching pennies game, which is not strictly determined.

Table 2. A game (a) with and (b) without a saddle point.

(a)

	1	2	min	
1	2	0	0	
2	3	1	1	max
max	3	1		
		min		

(b)

	1	2	min	
1	1	−1	−1	
2	−1	1	−1	max
max	1	1		
		min		

In Table 2(a), as the game is zero sum we do not need to place two entries in each cell; given the payoff to player 1 we know that the payoff to player 2 is the negative of this value. The matrix is bordered on the right by the values of the row minima, and it is bordered below by the column maxima. The row minima indicate the payoffs that player 1 can attain by playing strategies 1 or 2, assuming that player 2 minimizes player 1's payoff. The maximum entry in this column represents the best outcome that player 1 can guarantee for himself. There is a similar interpretation for the column maxima. The security level for player 1 is the maximum of the row minima, and the security level for player 2 is the minimum of the column maxima. In this instance we see that they coincide. A game that has this property is said to have a *saddle point* in pure strategies. A three-dimensional graph of the payoff surface to player 1 as a function of the two strategies would show the saddle point as the lowest mountain pass, i.e., it is shaped like a saddle. If both individuals are individually rational, they will each obtain the saddle-point value with no need to communicate except through their actions or selection of strategies.

The game shown in Table 2(b) is the strategic form of the game shown in Fig. 1(b); it can be interpreted as the familiar game of matching pennies. If player 1 matches player 2 he wins 1; if he fails to match he loses 1. When we border this matrix with the row minima and the column maxima, there is no coincidence of the maxmin with the minmax. von Neumann's theorem established that if we permit mixed strategies, i.e., the players are permitted to randomize over their pure strategies, then there will always be a coincidence of the maxmin of the expected values with the minmax of the expected values of the payoffs. In terms of this simple example, the way the game of matching pennies is usually played is that both sides toss their coins, i.e., employ random strategies simultaneously. Each player obtains an expected value of $\frac{1}{2}(1)+\frac{1}{2}(-1)=0$. This is the value to each in this symmetric, fair game.

The minimax theorem has had considerable influence outside of game theory alone. There is an intimate relationship between it and the duality theory in linear programming, where the mixed strategies have an interpretation in terms of shadow prices.

2.2 The Nonconstant Game and Noncooperative Equilibrium

The dominant solution concept for an n-person game in strategic form is the noncooperative equilibrium solution presented by Nash (1950,1951) but given over 100 years earlier in a more specialized form by Cournot.

Consider a set N of players with index $i=1,\ldots,n$. Player i selects a strategy s_i from his set S_i of pure strategies. $s=(s_1,s_2,\ldots,s_n)$ is a vector of strategies with one strategy for each player. We denote by s/s_i^* the set of strategies s with the ith element replaced by s_i^*.

The payoff to an individual i is a function of his strategy and the strategies of all others. We denote this as $P_i(s)$. A pure strategy noncooperative equilibrium is a vector of strategies $s^*=(s_1^*,s_2^*,\ldots,s_n^*)$ such that for each $i \in N$ and $s_i \in S_i$, s_i^* is an optimal response. Given the strategies of all other players no individual can improve his payoff by selecting a strategy s_i differing from s_i^*. This definition can be extended to include the use of mixed strategies by the players, where each selects a probability distribution over his set of pure strategies.

The basic idea behind the Nash equilibrium is one of self-fulfilling expectations. If each believes that the others are going to behave in certain ways, there will exist a mutually consistent set of expectations such that if each optimizes given his expectations, then the predictions of all will be fulfilled. Unfortunately, the equilibrium is a static concept, and little of any generality is known of the dynamics that might lead to a noncooperative equilibrium.

From the viewpoint of prediction it would be desirable if a game had a unique equilibrium point. Unfortunately this is often not so. Furthermore, in general, noncooperative equilibria do not lead to efficient outcomes [see Dubey (1986) and Dubey and Rogawsi (1990)]. Tables 1(a) and 1(b) provide examples of two simple 2×2 bimatrix games, where the first number in each cell is the payoff to the first player and the second number the payoff to the second.

In Table 3(a) there are two equilibrium points, one at (1,1) and another at (2,2). The first favors the first player and the second the second. They both face a problem in coordination: if each tries for the advantage they could easily both obtain nothing. Aumann

Table 3. (a) Battle of the sexes; (b) Prisoner's Dilemma.

(a)

	1	2
1	2,1	0,0
2	0,0	1,2

(b)

	1	2
1	5,5	−5,10
2	10,−5	0,0

(1987) has extended the idea of a noncooperative equilibrium to include the concept of a correlated equilibrium, where the individuals are willing to randomize jointly. Thus in this game they will flip to choose between strategies (1,1) and (2,2). There is a mixed-strategy noncooperative equilibrium point where each individual randomizes independently with probabilities for player 1 of $(\frac{2}{3},\frac{1}{3})$ and for player 2 $(\frac{2}{3},\frac{1}{3})$. The independent randomization results in an expected payoff to both of $(\frac{2}{3},\frac{2}{3})$, whereas the joint randomization gives them an expected payoff of $(\frac{3}{2},\frac{3}{2})$.

Table 3(b) illustrates a well-known game called the Prisoner's Dilemma. It provides a striking counterexample to the proposition of vector domination as a decision rule for the single individual. In one-person decision making, if an individual has several strategies and he faces several different states of Nature, then if one strategy has payoffs that dominate the payoffs obtained from another strategy under every state of Nature, it is both intuitively obvious and true that the first strategy will be selected over the second and will yield the player a higher payoff. This attractive rule does not generalize to two-person nonzero-sum games. We observe, if we examine just the payoffs to player 1 alone, that his second strategy dominates the first. He can observe that if player 2 selects his first (second) strategy player 1 obtains 10 (0); if instead player 1 uses his first strategy then he would obtain 5 (−5). But 10 is larger than 5 and 0 is larger than −5. If both players use this reasoning they both select their second strategies and end up with payoffs of (0,0), yet if they were able to collaborate they both could use their first strategy and obtain (5,5), which is strictly better for both. There has been considerable experimentation with this game and in the one-shot versions individuals do tend to select their second strategy. This particular game is utilized to show that individually rational behavior does not necessarily coincide with group rational behavior.

Another desirable property of a solution might be stability. Unfortunately, even games with unique equilibrium points do not necessarily have stability. Consider the game shown in Table 4. This 3×3 game has a unique mixed-strategy equilibrium point with a mix of $(\frac{1}{3},\frac{1}{3},\frac{1}{3})$, which yields an expected value of payoff to each player of 3. But by observing the matrix we see that if the players just blundered about the matrix sequentially using optimum response their expected value would be 4.5. Starting at any of the cells with a positive-entry optimum response leads to a six-cycle.

2.3 Noncooperative Equilibrium and the Extensive Form

Many of the applications of the noncooperative equilibrium solution have been to games in strategic form. One can also consider using this solution to a game in extensive form. When the extra detail of the extensive form is considered, several new and important problems that are obscured by the shorthand of the strategic form appear. In particular, Selten (1975) introduced the concept of a perfect equilibrium point. A perfect equilibrium has the property that it is an equilibrium not only in the game as a whole, but in every subgame. This can nontechnically be best illustrated with a simple example. Figure 2 shows a game in extensive form. It is a game with perfect information. At all points in the game the players know exactly where they are. There is no concealment of information. After player 1 has made his first choice, if he selects his second move then player 2 will be

Table 4. A game with a unique unstable equilibrium.

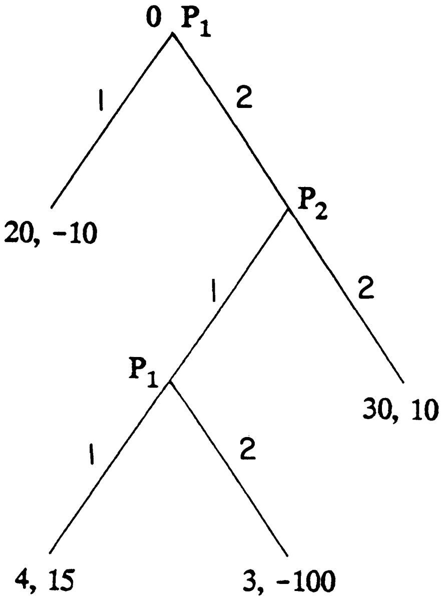

FIG. 2. A game with a perfect equilibrium and a threat.

called upon to choose his move. We could consider the rest of the tree as a separate game with its origin at player 2's choice point. This idea amounts to making an assumption that history does not matter. At any point in the game it is only the future that counts. This game has two equilibrium points. One is a perfect equilibrium and the other involves a threat by player 1 in which the history of the previous selection of moves matters. The equilibrium point in which player 1 selects move 1 and player 2 is prepared to select his move 1 is the perfect equilibrium and has a payoffs of (20, − 10). This can be calculated by backward induction. Suppose that the game had reached the second choice point for player 1; regarding this as a separate game, player 1 should choose move 1 and obtain 4. We can replace his choice point by the pair of payoffs (4,15). Player 2 is now faced with his choice. He will select his move 1 rather than move 2 as his payoff of 15 is better than a payoff of 10. We can replace his choice point by the payoff pair (4,15). Player 1 can now consider the game where by selecting 1 he obtains 20, or by selecting 2 he obtains 4. He selects 1 and the payoffs at this perfect equilibrium point are (10, − 10). A glance at the game tree shows that there is an outcome at which both players can improve. If both select their move 2 they obtain (30,10). This is also an equilibrium outcome, but its stability is maintained only by a threat strategy of the following variety. Player 1 announces "I will choose 2; if player 2 chooses 1, then I will choose 2 as my second choice." This can be interpreted as a threat in the sense that if player 1 were at his second choice point, his pure maximization of payoff, forgetting history, is to select move 1 and obtain 4; by selecting move 2 he obtains 3 but causes a loss of 100 to player 2. There is one viewpoint that individuals will not carry out unenforceable threats unless it is in one's immediate self-interest. Another viewpoint is that it is natural even in a one-play situation for player 1 to offer cooperation and to be prepared to back his words with his deeds if player 2 fails to cooperate.

Van Damme (1987) offers an excellent coverage of the many modifications to and variations of equilibrium-point theory for games in extensive form. Harsanyi and Selten (1987) present a monumental but controversial work arguing for a one-point equilibrium solution for all games.

2.4 Solutions to Games with Incomplete Information

The Harsanyi formulation of games with incomplete information permits an extension of the noncooperative solution to these games with the understanding of Bayesian rationality among the players. All players have personal probabilities about the types of player each other player might be, but their beliefs are all *consistent* in the sense that all personal probability distributions can be derived from a common *a priori* distribution, i.e., it is as though Nature randomizes from a known given set of *n* random variables and discloses what type each player is only to that player by revealing the value of his random variable.

Myerson (1991), in a recent book, provides a coverage of many of the more recent investigations of games with incomplete information.

2.5 Cooperative Games

The solutions to games in cooperative or coalitional form deal with concepts relevant to dividing joint gains among individuals who have agreed to act in concert to achieve an optimal product. There are several well-known solutions, each of which approaches this problem from a different point of view. Briefly, the core illustrates countervailing power; the value, fair division; the nucleolus, the minimization of the maximal amount that any coalition can claim; the bargaining set, a form of countervailing power between players; and the stable set, a form of social stability.

2.5.1 The Core. An *imputation* in an n-person cooperative (TU) game is a vector x of dimension n where each component x_i is the amount obtained by individual i. The sum of all x's adds up to $v(N)$, i.e., it exhausts the joint product. An imputation x dominates an imputation y via a coalition S if $x_i > y_i$ for all i in S. The *core* of an n-person game is the set of all undominated imputations. The core for the example of a three-person game in characteristic-function form shown in Sec. 1.3 is illustrated in Fig. 3. The corners of the triangle have coordinates (4,0,0), (0,4,0), and (0,0,4). Any point (a,a_2,a_3) in the triangle has coordinates that add to 4. Any point in the trapezoid delineated by $ACDE$ has the property that the sum of any two coordinates yields to a coalition of any two players more than they can obtain by themselves. This area is the core of the three-person game represented. The core need not always exist. For example, if the coalitions {1,2} and {1,3} each were able to obtain 3, the new game would have no imputation, giving all coalitions more than they could get by independent action. An interpretation of the core is that it is a set of imputations for which both societal and subgroup optimality is simultaneously satisfied.

FIG. 3. A three-person game in characteristic-function form. The trapezoid *ACDE* is the core; *V* is the value; *N* the nucleolus.

There has been considerable application of core theory to economics [see Hildenbrand, (1982)]. The connection between the core and superadditivity, which is at the basis of economic cooperation, has been studied by Wooders (1983).

2.5.2 The Value. The value of an n-person game in characteristic function form is a single-point solution arrived at by considering the combinatorics of all the ways that an individual could join a coalition of any size, calculating the marginal worth of his addition to the coalition, and then averaging over all of the contributions. It attaches a value or expected worth to every player.

Remarkably, Shapley (1953b) was able to derive the value from essentially four axioms:

1. Symmetry: If two players are identical (i.e., they make the same contribution to any coalition one or the other joins), they each obtain the same value.
2. Dummy player: If a player contributes nothing to the worth of every coalition he joins, his value is zero.
3. Efficiency: The sum of the values assigned to all players exhausts the available gain achieved by the coalition of all, i.e., it equals $v(N)$.
4. Additivity: If two separate games are considered jointly as though they were a single game, the sum of the values of the two games will equal the values of the new single game.

The specific formula derived by Shapley is as follows:

$$\varphi = \sum_{S \subset N} \sum_{i \in s} \frac{(n-s)!(s-1)!}{n!} [v(S) - v(S/i)], \tag{3}$$

where the term in the square brackets is the marginal contribution of player i to coalition S, and s is the number of players in S.

Aumann and Shapley (1974) in an important book have extended the analysis of the value from games with a finite number of players to games with a continuum of players.

2.5.3 The Nucleolus. The *excess* of a coalition S at imputation a is $V(S) - a(S)$, i.e., it is a measure of how much the coalition is giving up by accepting the imputation a rather than acting independently. The *nucleolus*, formulated by Schmeidler (1969), is that point which minimizes the maximum excess among all of the 2^n excesses for all coalitions. Intuitively, the excess is a measure of the dissatisfaction that a coalition might have for a specific imputation. The selection of the nucleolus minimizes the maximum dissatisfaction among all coalitions. Sobolev (1975) has provided axioms for the nucleolus. When the core is nonempty the nucleolus lies within it. In Fig. 3 it is denoted by N.

2.5.4 The Bargaining Set. A bargaining point is an imputation with the property that for each pair of players i,j any objection that might be raised by i against j can be met by a counter objection by j against i. An objection consists of a coalition S containing i but not j and an imputation feasible for S that is preferred to the given imputation by every member of S. A counter objection consists of another coalition T containing j but not i and an imputation that is (weakly) preferred to the objection of every member of T also in S and is (weakly) preferred to the original imputation by every member of T not in S. The bargaining set consists of those imputations such that to every objection there is a counter objection [see Aumann and Maschler (1964)]. The bargaining set exists in many minor variants all of which include the core. Peleg (1967) has proved that it is never empty (for side-payment games).

2.5.5 The Stable Set. The original solution for a game in coalitional form proposed by von Neumann and Morgenstern was the stable set. Formally, an imputation a dominates an imputation b if there is a coalition S such that all members of S are better off with b than with a and the coalition can enforce b. The core consists of all imputations none of which is dominated by another imputation. It has internal stability; no point in the core dominates any other. The stable set has this property, but it also has the extra property that together all points in a stable set are able to dominate any point outside. This is the property of external stability. Consider the three-person simple-majority voting game where any coalition of two or more obtains the prize of say, 1, while others obtain 0. The unique symmetric stable set consists of the three imputations $(\frac{1}{2},\frac{1}{2},0)$, $(\frac{1}{2},0,\frac{1}{2})$, and $(0,\frac{1}{2},\frac{1}{2})$. There are also other nonsymmetric stable sets to this game that appear to illustrate discriminatory behavior by two of the players against the third. von Neumann and Morgenstern stressed that the nonuniqueness of the stable sets and the complexity of the domination relationship reflected the many possible social structures of a society. The case for the stable set would be much stronger if it always was nonempty, as von Neumann conjectured. Unfortunately Lucas (1969) was able to show by means of a 10-person example that this was false. Shapley and Shubik (1969a) showed that the Lucas counterexample was by no means pathological, but could occur in an exchange economy.

There are several other solution concepts such as the kernel [Davis and Maschler (1965); Peleg (1987)] and variants of the core [see Shubik (1982)].

3. APPLICATIONS

The nature of the applications of game theory has ranged from qualitative advice giving and the construction of simple illustrative models (such as the Prisoners' Dilemma) in strategic analysis, through serving as an aid in theory construction in economics, political science, biology, and other disciplines, to the applied mathematical calculations of specific models in dueling theory and weapons evaluation [see, for example, Drescher (1961); Shubik (1983a)]. The last 30 years have seen considerable growth in the applications of game theory to economics, political science, biology, law, accounting, military science, ethics, and sociology, but little to engineering or physics, although this may change. Much attention has been given to mass behavior, but a key distinction between mass-people behavior and mass-particle behavior appears to be the different type of communication and information flows between individual particles or people. Neutrons do not appear to talk to each other; people do. However, polarization might be regarded as an analog to correlation of behavior caused by communication.

3.1 Economics

The major applications of game theory have been to economics. The monumental book of von Neumann and Morgenstern stressed the investigation of economic behavior. Furthermore, as the subject developed, the relationship between the early mathematical economics of Cournot and Edgeworth was recognized.

3.1.1 Competition among Few. One of the earliest problems in mathematical economics was the treatment of competition among the few. The extension of analysis from monopoly with one maximizing agent to duopoly with competition between two maximizing agents whose fates were intertwined represents a considerable advance. Cournot's analysis was clearly a special case of the noncooperative equilibrium solution put forward in full generality by Nash over a century later.

From the 1950s onward there has been a steady explosion in microeconomic applications to the study of oligopolistic competition and industrial organization. Unfortunately, economic dynamics gives no indication of being any easier than a three-, four-, or five-body problem in physics. Even limiting concern to competition between two firms, the dynamics depends delicately on the relative sizes of the firms, the choice of strategic variables, the sequencing of moves, and the state of information. Cournot and Bertrand (1883) both discussed simultaneous-move games, but one used quantity and the other price as the strategic variable. In contrast, Stackelberg (1952) considered sequential moves.

Even with the difficulties in the study of dynamics, considerable strides have been made in the study of competition among the few as is evinced by the books by Shubik (1959b), Friedman (1990), Tirole (1988), and others.

3.1.2 Fair Division; Bargaining. Underlying much economic thought is the concept of fair division. Is there such a thing as a just and equitable way to slice the economic pie? If there is, what is its relationship to the price system and a division arrived at competitively?

There is an extensive literature on bargaining and fair division between two parties. Zeuthen (1930) was an early precursor of the game-theoretic approach. The two basic papers by Nash (1950, 1953) were followed by the contributions of Shapley (1953b) and Harsanyi (1956,1963), extending the investigations of bargaining from two individuals to any number, covering both TU and NTU instances, and considering the possibility and the plausibility of the use of threats in bargaining. The axiomatic method has been used extensively, and Roth (1979) provides a detailed discussion of many of the variations in the axioms proposed as criteria for fair division. Other solutions proposed include those of Raiffa (1953), Kalai and Smorodinsky (1975), and Maschler and Perles (1981). Raiffa (1983), in a perceptive book dealing with teaching and experimentation in negotiation, provides valuable insights into the relationship between axioms and experiments in bargaining, as does Roth (1987).

3.1.3 Auctions. One of the earliest ways of disposing of goods at a price is some form of auction. Herodotus provides a description of an auction of brides in Babylonian times. A historical sketch of auctions has been provided by Shubik (1983b); Engelbreth-Wiggans (1980) and Milgrom and Weber (1982) have excellent surveys. The seminal paper is that of Vickery (1961). A simple example (that is related to both bargaining and auctions) serves to illustrate the nature of the game with incomplete information.

Two partners wish to break up a partnership. Each believes that the other values the business at somewhere between 0 and 1000 with all values equiprobable. They agree on a buy–sell agreement. They toss to see who makes the offer. Partner 1 knows that his value is C. He must make the offer to partner 2. If he bids aC his profit will be composed of two terms, the profit he makes if he buys or the profit if he sells:

$$(C-aC)\frac{ac}{1000}+\frac{1}{1000}\int_{y=aC}^{1000}(y-C)dy. \tag{4}$$

This amounts to

$$\frac{1}{1000}\left(\frac{3}{2}a(1-a)C^2+\frac{1000^2}{2}-1000C\right). \tag{5}$$

It can be shown that the optimal or expected most profitable bid is $a=\frac{1}{2}$. The partner will bid half of his true value. Suppose that $C=500$, then his profit is approximately 48.9. If he bids 500, his expected profit is zero.

3.1.4 Market Games and General Equilibrium. When we consider all games that can be represented in coalitional form by a characteristic function, only a small part will represent games arising from economies with a price system. Studying TU games, Shapley and Shubik (1969a,1976) defined a class of games called *totally balanced games* and showed that all exchange economies give rise to totally balanced games and *vice versa*. They also studied [Shapley and Shubik (1969b)] the relationship among the core, value, and competitive equilibrium for large market games. This was part of a program to show that many conceptually different solutions approached the same outcomes for large market games. The outcomes are the competitive equilibria. For market games the relationship of the limiting behavior of the core, nucleolus, value, and bargaining set to the competitive equilibria of an economy has been examined. A remarkable coincidence of solutions based on strikingly different assumptions is obtained for mass economic exchange.

3.1.5 Strategic Market Games and Money. One application of games in strategic and extensive form is to the theory of money and financial institutions. A Strategic Market Game [Shubik (1973); Shapley and Shubik (1977); and Dubey and Shubik (1978)] is a playable game whose rules provide a complete and consistent description of markets, price formation mechanisms, credit arrangements, and default procedures. A modern market may be regarded as an efficient aggregating–disaggregating device that operates on the actions of masses of anonymous individuals, accepting as inputs goods and money and producing as outputs prices and the redistribution of the goods and money. An example of an elementary price formation mechanism is as follows. Suppose that there are m sellers and n buyers of some good k. If all bid and offer simultaneously and if b^i_k is the amount of money offered by individual i for k and q^j_k is the amount of good k offered by j, then the price is given by

$$p_k = \sum_{i=1}^{m} b^i_k \left(\sum_{j=1}^{n} q^j_k \right)^{-1} . \tag{6}$$

There are many mechanisms for price formation. The one illustrated here is among the simplest. Others call for consideration of asymmetric information and sequential moves. By considering games with a continuum of traders, mass markets can be investigated. The properties of a mass market have been axiomatized [see Dubey *et al.* (1980)]. A key question to be asked is, under what conditions do efficient prices emerge in the economy? Market games are described in coalitional form; strategic market games are in strategic or extensive form. The former are preinstitutional; the latter, by the need to include a process description, provide elemental descriptions of market and financial institutions.

3.1.6 Accounting. The Shapley value is in essence a combinatoric averaging of the marginal contributions of each individual to the whole. As such it has direct application to some classical problems in accounting concerning the allocation of joint costs and incentive implications of such allocations. Shubik (1962) suggested this application of the value in order to examine the compatibility of accounting schemes that assign overheads to individual subunits with incentive schemes for the individual units. In other words, does the scheme of assigning profits and costs encourage individual units to behave in a manner compatible with the overall goals of the firm? The literature on applications of game theory to joint allocation has grown considerably. The books edited by Moriarty (1981) and Young (1985) provide many examples of application. Littlechild and Thompson (1977) apply this approach to aircraft landing fees; Young *et al.* (1982), to cost allocation in water resources development.

3.2 Political Science

Possibly the most direct and important application to political science has been in the theory of voting. The earliest application was the Shapley–Shubik (1954) power index, which is derived from the value in application to a class of games called *simple games*, which can be used to represent voting situations. In a simple game, the characteristic function takes on only two values, zero or one, which represent a motion lost or won.

3.2.1 Voting. It is reasonable to attribute the same *a priori* level of power or influence to each individual with one vote in a situation with a simple majority vote. If weighted voting is permitted, a natural question to ask is, how does an individual's power increase as his vote increases? If he has more than 50% of the vote he has complete control over the outcome. Thus we may ask, what is the nonlinear function that portrays the increase in power of the individual as his vote is increased? The index of power can be illustrated by two simple examples. Suppose first there is a simple majority game with five voters, each with a single vote. It can be denoted by (3:1,1,1,1,1), where the first number is the quota, i.e., the number of votes required for victory, and the other five numbers indicate the number of votes for each individual. As all individuals are identical their *a priori* power will be the same and can be denoted as $(\frac{1}{5},\frac{1}{5},\frac{1}{5},\frac{1}{5},\frac{1}{5})$. We now consider a slightly more complicated game. Suppose that there is the same number of votes with one fewer voter, and hence one of the voters has two votes. The game can be denoted by (3:2,1,1,1). The power of these voters can be calculated by considering each one's contribution to the 24 permutations of the order of voting which can take place. The tabulation below shows a way to represent all lineups. A dot placed over a vote indicates that that vote will be pivotal, i.e., by bringing this member into the coalition previously formed, he provides the margin that enables that coalition to control the outcome.

$2,\dot{1},1,1$	six ways
$1,\dot{2},1,1$	six ways
$1,1,\dot{2},1$	six ways
$1,1,\dot{1},2$	six ways

If the voter with two votes enters the coalition first there are 3! or six ways in which the three one-vote voters can enter. Similarly, there are six ways that each of the other patterns can form. The two-vote voter is pivotal in 12 of the 24 possibilities. The voting power of all four can be described by $(\frac{1}{2},\frac{1}{6},\frac{1}{6},\frac{1}{6})$. The index has been applied among others to the United Nation's security council and the electoral college [Mann and Shapley (1964)]. It is possible to design voting schemes where an individual with some votes may have no power whatsoever. In the weighted voting game (8:4,4,4,3) the voter with three votes is never pivotal in a winning coalition.

An interesting connection can be made with the power index and the Chow factor used in electrical engineering to measure redundancy and the probability of failure in networks. The concept of a winning coalition can be viewed as equivalent to asking when there are enough elements in a redundant system to keep it functioning [Dubey and Shapley (1980)]. There is also an alternative index suggested by Banzhaff (1965), which is discussed in Dubey and Shapley. The important concept of minimal winning coalition has been imaginatively applied to voting theory by Riker (1962).

The fully strategic aspects of voting require the study of games in extensive form. The basic work of Farquharson (1969) analyzed the logic of voting for candidates other than one's most preferred candidate. There is also a growing literature on special voting structures such as preference voting and proportional representation.

3.2.2 Deterrence Theory. Starting with the provocative work of Schelling (1960) and Ellsberg (1961), there has been a steady growth in game-theoretic application to international relations in general [see the exhaustive bibliography of O'Neill (1992)], and problems in the analysis of threats and nuclear warfare. Two recent examples of game-theoretic models concerned with nuclear threat and stability are Powell (1990) on nuclear deterrence theory and Bracken and Shubik (1991) on problems of stability in a multipolar nuclear world.

3.3 Biology

Since the early 1970s there has been a considerable growth in the application of game-theoretic models to biology. This work has as its major proponent Maynard Smith (1982). The central concept is the evolutionary stable strategy (ESS), which may be interpreted as a relative of the noncooperative equilibrium, where, however, the choice of strategy is interpreted genetically rather than as a conscious strategic choice. We may consider a population of animals with pairwise random encounters. Each animal is "coded" to be either aggressive or peaceful. The popu-

Table 5. A game with an evolutionary stable equilibrium.

	1	2
1	0,0	9,4
2	4,9	5,5

lation is split 50–50 between the two types. The payoffs shown in Table 5 may be regarded as the reproduction success of the two individuals after encounter. Thus, if an aggressive individual meets another aggressor, neither has offspring. If an aggressor meets a peaceful individual he will have 9 offspring and the other will have only 4. We can check that the 50–50 split of the population is in equilibrium. The population is stable. We assume that reproduction involves only the single animal and that the next generation is coded to follow the strategy of its parent. The fitness of each individual to reproduce is determined by its strategy and the strategy of the individual it encounters. The ESS is equivalent to a mixed strategy in the game, but is based on a frequency interpretation. Selten (1980), Crawford (1989), and others have considerably extended the original idea of Maynard Smith to include asymmetric conflicts, multispecies involvement, and the possibility of learning. It appears to be a safe bet that there will continue be a considerable growth in the application of game theory to biology in the next few years.

3.4 Other Applications

There is a growing literature of game-theoretic applications in the law as is evidenced by a forthcoming special issue of *The Cincinnati Law Review* devoted to game theory [Shubik (1992b)].

There is also work in agency theory. The simple nongame-theoretic view of organization has individuals arranged in various forms of hierarchial structure with the power of decision making flowing down from high to the lower ranks. The game-theoretic view takes into account that individuals often employ others whose goals and information differ from their own. Thus even though *A* may be superior to *B*, *B* may be in a position to withhold information from *A* in a manner that gives him considerable control over *A*. The agency problem takes this into account specifically. Papers in anthropology [Barth (1959)], sociology and philosophy [Rawls (1971)], and even biblical interpretation [Brams (1980)] have appeared.

4. MODELING, GAMING, AND EMPIRICAL VALIDATION

4.1 Experimental Gaming

Roth (1987), in a provocative discussion of laboratory experimentation in economics, has suggested three kinds of activities for those engaged in economic experimental gaming. They are "speaking to theorists," "searching for facts," and "whispering in the ears of princes." The third of these activities, from the viewpoint of society, is possibly the most immediately useful. In the United States the princes tend to be corporate executives, politicians, and generals or admirals. However, the topic of operational gaming merits a separate treatment.

Perhaps the most important item to keep in mind is the fundamental distinction between game theory and the approach of social psychology to the same problems. Underlying a considerable amount of game theory is the concept of *external symmetry*. Unless stated otherwise all players in game theory are treated as though they are intrinsically symmetric in all nonspecified attributes. They have the same perceptions and abilities to calculate and they have the same personalities. Much of game theory is devoted to deriving normative or behavioral solution concepts to games played by personality-free players in context-free environments. In particular, one of the impressive achievements of formal game theory has been to produce a menu of different solution concepts that suggest ingeniously reasoned sets of outcomes to nonsymmetric games played by externally symmetric players.

In contrast, the approach of the social psychologists has for the most part been to take symmetric games and observe the broad differences in play that can be attributed to nonsymmetric players. Personality, passion, and perception count and the social psychologist is interested to see how they count.

A detailed survey of the role of gaming relevant to the study of game theory is given by Shubik (1992a). One of the earliest experiments was that of Mosteller and Nogee (1951), devoted to measuring individual utility scales. The book by Siegal and Fouraker (1960) launched work on the study of bilateral monopoly and bargaining. Raiffa's (1983) imaginative work on the art and science of bargaining and negotiation and the experimental work of Roth (1987,1988) on bargaining indicate how this line of investigation has developed. Early work on competition among few players in a market setting was done by Hoggatt (1969), Friedman (1967,1969), Shubik *et al.* (1972), V. L. Smith (1965), and others. More recently V. L. Smith (1986), in collaboration with many others, has performed many experiments on auction markets, but with the emphasis more on the economics of many competitors than on the game-theoretic aspects of competition among the few.

There is now a vast literature on experimentation with matrix games where one of the major questions involves the validity of various forms of noncooperative equilibrium as a predictor of limiting behavior. The book by Rapaport *et al.* (1976) provides an excellent introduction to experimentation with matrix games.

4.2 Towards Dynamics and Bounded Rationality

The evidence from human experience and experimental gaming is overwhelming that in many contexts the personality-free rational calculator model of the human is a gross oversimplification. Work has begun on models of bounded rationality, where the individual's computational and perceptual abilities are limited. Formal theoretical work by Abreu and Rubinstein (1988) has considered games played by players modeled as simple automata with costly computation. Important works by Geanakoplos and Gray (1991) and by Baum (1991) have shown that for players with limited ability to compute, looking ahead further in a game such as chess is not the best strategy if the players do not have a perfect way of evaluating intermediate positions. These results may eventually have deep impact on the concept of long-range planning.

The work in gaming and in bounded rationality points towards a merging of the approaches towards the game-theoretic study of mass human economic and other behavior, not only by means of experimental games, but by mass simulations where each individual is represented as a behavioral particle in a mass stochastic environment. Thus it may well be that in the future at least part of the trend in game-theoretic research will be towards a statistical mechanics of human behavior, blending individual optimization with the many possibilities provided by human communication for correlated behavior.

GLOSSARY

Continuum of Players: A concept capturing the idea that a single player or a finite subset of players has negligible strategic influence. This enables the analyst to use measure-theory techniques, which are of considerable value in studying mass social behavior.

Equilibrium, Noncooperative: A solution concept for games that is based on individual optimization under the assumption of mutually consistent expectations. If all expect a certain outcome and each optimizes individually, based on this expectation, then the actions of all will result in their expectations being realized. Although equilibria exist for many games, little is known about the stability of these equilibria. The dynamics of adjustment calls for a theory of learning that is not covered by game theory.

Game, Market: A specialization of a game in coalitional form so that it reflects the basic economic model of trade and bargaining among individual owners where all coalitions are permitted and can form costlessly.

Game, Strategic Market: A specialization of a game in strategic form that reflects the basic economic model for anonymous trade utilizing a market mechanism.

Game, TU or NTU: A game is a TU (transferable utility) game if there exists a commodity for which all individuals have constant marginal utility regardless of the quantity they possess. It is a perfectly transferable store of wealth. The TU assumption is a good approximation for some economic situations where money more or less serves this purpose. For many situations the TU assumption is unreasonable and NTU (no transferable utility) games do not use this assumption. TU games are mathematically far more tractable than NTU games.

Information Set: The subset of alternatives that are distinguished by the player when he is called upon to move. If the player can always distinguish all of his alternatives he is said to be perfectly informed.

Prior: Term used in economics and statistics to denote the *a priori* probability distribution for the occurrence of an expected event.

Rooted Tree: A connected graph with no loops and a distinguished node (the root) which indicates the start of the game.

Strategy: A complete set of instructions as to how a player will select his moves under all contingencies. In general, even for most board games the number of strategies is hyperastronomical. Even with the largest computers an exhaustive investigation of all strategies is not feasible.

Value: A solution to a game in coalitional form that awards each player his expected marginal contribution to all coalitions on the assumption that all the ways in which he can be added to any coalition are equiprobable.

INTRODUCTION

Geodesy is traditionally defined as the science of studying the figure of the earth and its gravity field. Now that geodetic measurements have become very accurate and easily repeatable, the traditional definition must be extended to include temporal variations as well.

Although inquiry into the figure of the earth can be traced to antiquity, the recognized founder of scientific geodesy is Eratosthenes (276–195 B.C.) of Alexandria (Torge, 1980). Eratosthenes studied the rays of the sun at Alexandria and Syene (Assuan, today) at summer solstice noting that at Syene the rays entered a well in the vertical direction and at Alexandria (roughly on the same meridian) the rays were off the local vertical direction by about 1/50 of a circle. Using the estimated distance between Syene and Alexandria of 5000 stadia (1 Egyptian stade $=157.5$ m), he calculated the radius of the earth to be 6267 km. This is less than 2% lower than the actual mean radius of 6371 km.

Historically, other estimates differ by 3%–10% from the value known today. In 1669–1670, at the urging of the newly formed Academy of Sciences in Paris (1666), J. Picard carried out arc measurements on the meridian through Paris between Malvoisine and Amiens with the aid of a triangulation network. He was the first to use a telescope with

cross hairs. Picard's value for the Earth radius was good to +0.01%, which aided Newton in the verification of the law of gravitation which he formulated in 1665–1666.

From observations of pendulum motion (the period), one can infer an increase of gravity from the equator to the poles. Using such observations and their own works, Isaac Newton (1643–1727) and Christian Huygens (1629–1695) suggested Earth models flattened at the poles.

If we let the letter a stand for the equatorial radius and b the polar radius, the normalized deviation or flattening is defined as $f=(a-b)/a$. Today we know that $1/f=298.257$. Historically this value also was attempted to be found through meridian arc measurements. Depending on where the arc measurements were obtained, the determination of the flattening could have even the wrong sign (polar radius greater than equatorial). In 1743, A.C. Clairaut (1713–1765) synthesized the physical and geodetic concerns in a theorem named for him that permits the computation of flattening from two gravity measurements at different latitudes. However, the practical implementation of this theorem suffered until the twentieth century from the lack of precise and well-distributed gravity measurements and the inability to reduce these data to the Earth ellipsoid.

Historically, the task of determining the figure of the Earth was, for simplicity, subdivided into two almost independent tasks: horizontal surveys for determination of latitudes and longitudes and vertical surveys for determination of heights. The reference surface for horizontal surveys is a suitable but otherwise arbitrary rotational ellipsoid. The heights, however, are referred to an equipotential surface or mean sea level (which later will be called the geoid). The use of different reference surfaces for horizontal and for vertical coordinates makes the accurate computations of three-dimensional Cartesian coordinates impossible, unless the separation between the mean sea level and the reference ellipsoid is known accurately. The ability to compute Cartesian coordinates is of importance because modern survey methods, such as those using artificial satellites, provide such coordinates and their comparison and compatibility with older surveys is essential.

Geodesy can be subdivided into the following groups: geometric geodesy, gravimetric geodesy, and space geodesy. Geometric geodesy deals with the measuring and computational methods that are applicable in the surveys of large areas, thus beyond the scope of plane surveying, and with the geometric determination of the size and shape of the reference ellipsoid. The geometric effort results in horizontal coordinates (geodetic latitude and longitude) referred to a suitable reference ellipsoid, and in heights above sea level. These results are mainly based on distance, direction measurements, and height differences. Gravimetric geodesy deals with the determination of the gravity equipotential surface most closely approximating mean sea level (known as the geoid) as a graphical depiction of the gravity field of the Earth, and with related problems. Geodetic astronomy provides the link between the "arbitrary" geometric reference system and the real world (nature) and thus serves to control the distorting effects of arbitrariness. This is achieved by attempting to keep the directions that are referred to the arbitrarily chosen reference ellipsoid close to "natural" directions determined from astronomical observations. Space geodesy provides local, regional, and global geodetic control through three-dimensional coordinates and vectors determined mostly from observations on artificial satellites and other space techniques. Since the orbits of satellites are affected by, among other things, the gravity field of the Earth, these observations also provide a means to improve our knowledge of this field.

In the following, these areas of study along with geophysical implications are described in varying detail.

1. GEOMETRIC GEODESY

1.1 Preview

If a whole country is to be surveyed, a network of control points evenly distributed over the entire country is set up and the mutual positions of the stations are determined on an ellipsoid that fits well the Earth (mean sea level) over the area in question. The mutual positions of the control points are given by their coordinates in a reference system especially set up for the area (geodetic datum). *A* datum may cover the area of only a given country or of several ones. For exam-

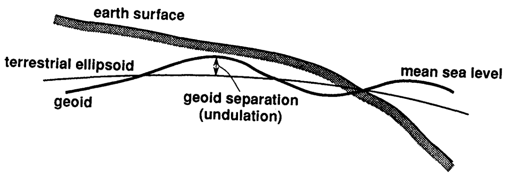

FIG. 1. Geoid and terrestrial ellipsoid generally do not deviate from each other by more than about 100 m.

ple, the North American Datum of 1983 covers Canada, Greenland, Mexico, and the United States. In order to determine the coordinates of control points, the procedure has been as follows.

Initially, points of the first-order network, separated by distances of generally 20 to 50 km, are selected. Their connecting lines with adjacent points should form, as nearly as possible, equilateral triangles. Then all angles (triangulation) or all distances (trilateration) or their combinations in the individual triangles are measured. The inevitable measuring discrepancies are eliminated in a least-squares adjustment. In order to determine the length of the triangle sides, i.e., the scale, the length of at least one side *must* be measured.

In order to understand how the position of the control points on the ellipsoid can be derived from triangulation or trilateration (or ultra-accurate traversing), the ellipsoid will have to be described in some detail. The actual shape of the Earth approximated by the geoid is defined as the surface that is everywhere perpendicular to the plumb line (direction of gravity) and that, over the oceans, nearly coincides with the undisturbed mean surface of the oceans. The geoid is a complicated surface that cannot be described by a closed mathematical expression (see also Sec. 2.2). Therefore a region or area such as a nation or continent is approximated by a best-fitting rotational ellipsoid (terrestrial ellipsoid or spheroid) from which the mean sea level seldom deviates by more than 100 m (see Figs. 1 and 2). The position of a terrain point on the ellipsoid may be thought of as its projection (along its plumb line to the geoid and then) along the ellipsoidal normal to the ellipsoid.

To orient the network on the ellipsoid, one needs the astronomic (sometimes called the geographic) latitude and longitude of at least one control point, and the angle subtended by one triangle side and the astronomic meridian (*astronomic azimuth*). The determination of these astronomic quantities is the task of geodetic astronomy. Since the angle between the true plumb line and the ellipsoidal normal (deflection of the vertical) is always significant (Fig. 3), astronomic latitude, longitude, and azimuth are measured at several evenly

distributed locations. Because the deflection of the vertical is dependent on the position and orientation of the ellipsoid, the best-fitting reference ellipsoid for the area can be determined from the condition that the sum of squares of the deflections of the vertical attains a minimum.

If the network is oriented on the ellipsoid, then all triangle sides (angles) can be computed from the base line and the adjusted angles (side lengths). From the triangles the geodetic coordinates of all control points can then be calculated.

Since the geodetic coordinates (latitude, longitude) are not desirable for computations in subsequent lower-order surveying, they are usually transformed into two-dimensional plane coordinates. The transformation to the plane is necessary because the end result of the survey, the map, is a plane figure, and also because calculations in the plane are much simpler than on the ellipsoid. This transformation procedure (map projection) causes some distortions that can be mathematically expressed and thus accommodated if necessary (see CARTOGRAPHY AND GEOGRAPHIC INFORMATION SYSTEMS).

1.2 Computations on the Ellipsoid

1.2.1 Geodetic Coordinates and the Geodetic Datums. The points projected on the reference ellipsoid are defined either by their geodetic latitude and longitude or by their orthogonal ellipsoidal coordinates, but mostly by the former (Fig. 4). The geodetic latitude of a point P is the angle φ subtended by the ellipsoidal normal at P and the equator. The geodetic longitude of P is the angle λ subtended by the meridian plane through P (the plane through P and the rotation axis) and a zero or prime meridian plane of a selected point Q (e.g., Greenwich). The orthogonal ellipsoidal coordinates x,y are geodesic arcs (shortest distances between points) that define the position of P with respect to an arbitrary origin P_0. The meridian through P_0 at the geodetic longitude λ_0 serves as the y axis. The abscissa x is the PF portion of the geodesic through P, perpendicular to the meridian λ_0. The ordinate is the length of the meridian arc P_0F.

the normal section p_0. The plane containing the normal at P and the point P_0 intersects the ellipsoid along the normal section p. Since the ellipsoidal normals at P and P_0 usually do not intersect each other (exceptions: P and P_0 are on the same meridian or parallel), the two normal sections, p and p_0, are not identical. Thus, either one has to decide which normal section should be used for the calculations, or the uniquely defined geodesic between P and P_0, usually located between the normal sections, must be used.

1.2.2 Plane Coordinates. The geodetic coordinates also must be mapped onto a plane to provide plane coordinates for lower-order surveys and mapping. The most commonly used conformal projections of the ellipsoid to the plane are the transverse Mercator and the Lambert conic projections (see CARTOGRAPHY AND GEOGRAPHIC INFORMATION SYSTEMS).

In the transverse Mercator projection, points on the ellipsoid are projected onto a cylinder of elliptic base whose axis in the ellipsoidal equator passes through its center. The orientation of the cylinder is such that it is secant or tangent to a certain central meridian. Sectors of 1.5°–3.0° on both sides of the central meridian can be mapped onto the cylinder without exceedingly large scale distortions. The cylinder then is turned to the next zone (3°–6°) and the zone around the new central meridian is projected. Since the cylinder fits the ellipsoid along the central meridians, this projection is advantageous in the mapping of areas of long north–south extensions.

In the Lambert conic projection, points on the ellipsoid are projected onto a cone of circular base whose axis coincides with the rotation axis of the ellipsoid. The cone is set either tangent to the ellipsoid along a standard parallel or in a secant position with two standard parallels. Since the cone fits the area well along a single parallel or between the two standard parallels, it is advantageous in the mapping of areas of long east–west extensions.

The transverse Mercator is used in some 22 states in the United States, and also by many in Europe, Africa, and Australia. The Lambert projection is used by 30 states and by a number of Central and South American countries. Some states in the United States use both projections. Other projections could also be used in certain cases. For example, the stereographic projection could be employed to advantage for a small circular area (e.g., the polar regions).

2. DETERMINATION OF THE REFERENCE SURFACES AND GRAVIMETRIC GEODESY

As mentioned earlier, height measurements are referred to the geoid and planimetric measurements to a rotational ellipsoid, which in the area of the survey fits the geoid best. The three interrelated problems of geodesy treated in this section are

1. determination of the best-fitting ellipsoid,
2. determination of the geoid, and
3. relationships between spirit levelling and the geoid.

2.1 Geometric Methods

2.1.1 Geometric Determination of the Reference Ellipsoid. Figure 5 shows a meridian section of the reference ellipsoid. Two meridian arcs m and m' are shown with terminal points at latitudes φ_1, φ_2, φ'_1, and φ'_2. There exists a known functional relationship between these quantities and the semiaxes a and b of the meridian ellipse. If the lengths of two meridian arcs are measured and the geodetic latitudes at the ends are determined

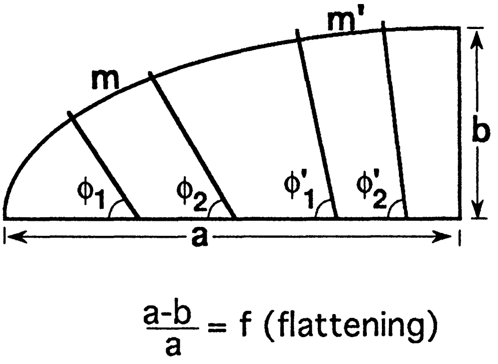

FIG. 5. Determination of the reference ellipsoid from two arc measurements.

(e.g., from astronomic latitude observations, assuming the first time around that there are no deflections of the vertical), one can obtain two equations from which the two unknowns *a* and *b* can be computed. The larger the difference in latitude, the more accurate will be *a* and *b*. In practice, the lengths of the several hundreds of kilometers long meridian arcs are measured indirectly by a chain of triangles and a base line. The shape of the triangulation chain is determined by measuring all angles, and the scale is derived from the base line and the base extension network.

A number of arc measurements were carried out in the eighteenth and nineteenth centuries according to the above principle. Several ellipsoids were derived. One of the best known ellipsoid determinations was made by Bessel in 1841. He used a total of 10 arc measurements: seven in Europe, two in eastern India, and one in Peru. In the adjustment he assumed the measured distances to be free of errors and derived the ellipsoid parameters in such a way that, along the arc, the differences between the astronomic and geodetic latitudes became minimum. The Bessel ellipsoid is still used although it is known today that the semimajor axis is too short by almost 1 km (6,377,397 m versus the current value of 6,378,137 m; and $1/f=299.15$ vs 298.257).

In the above-described method to determine the ellipsoid, the various arc measurements are considered independent, and the resulting ellipsoid(s) will fit well only the arc(s) used in the measurements. Better results can be obtained by the so-called area method. This method uses connected triangle chains or large networks where, in many points, the astronomical latitude, longitude, and azimuth are measured. The parameters of the best-fitting ellipsoid are then determined as follows: First measure and adjust all triangles of the network using the technique of least-squares adjustments. Then compute preliminary geodetic latitudes and longitudes on an approximate geodetic datum (an approximate ellipsoid, on which geodetic latitude and longitude of the initial point, as well as an initial azimuth, are defined arbitrarily, but within certain limits). The thus determined geodetic latitudes and longitudes, and the azimuths obtained from the adjustment, will deviate from the measured astronomical latitudes, longitudes (deflection of the vertical), and azimuths by small amounts, but systematically. Now change the approximate datum by changing the dimensions of the ellipsoid and shift and rotate the network by changing the initial point's geodetic latitude, longitude, and azimuth such that the new deflections of the vertical should become smaller and randomly distributed over the area. Here the area in consideration could be as small as an individual nation or as large as a continent. This gives an ellipsoid whose normals will coincide with the directions of the plumb lines as well as possible, and thus one which fits the geoid better. The deflections of the vertical are not observation errors, but are physical quantities. They are the result of the deviation of the level surface (geoid) from a rotational ellipsoid. The next section deals with how one can determine the deflection values.

2.2 Gravimetric Geodesy

2.2.1 Equipotential (Level) Surfaces and Gravity. Figure 6 shows some level surfaces of the Earth. They are by definition orthogonal to the plumb lines. Shifting masses along such a surface requires no work; thus the potential of the Earth's gravity field is constant on each of them. In contrast, moving a mass from one surface to another requires work that is independent of the path taken. If the potential of a certain equipotential surface is denoted by *W* (the work required to bring a unit mass from infinity to the surface in the gravity field), and one moves the unit mass from this surface to a somewhat lower equi-

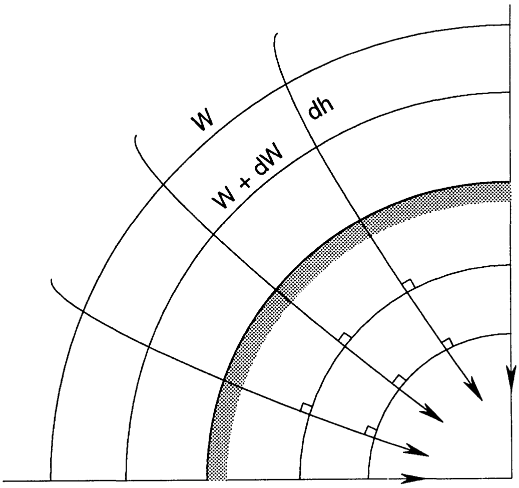

FIG. 6. Equipotential (level) surfaces in the Earth's gravity field and plumb lines.

potential surface $W+dW$, then $dW=-gdh$, where g denotes the gravity and dh the normal distance between the two equipotential surfaces. Thus, the gravity is the derivative of the potential with respect to the normal (plumb line). In an arbitrary orthogonal coordinate system the potential at point $P(x,y,z)$ is given by $W=W(x,y,z)$. The equation of the equipotential surface through P is $W(x,y,z)=\text{const.}$

These are the fundamental relations between gravity, its potential, and the equipotential surfaces. Since the gravity is measurable, it can be assumed that measurement of gravity permits the determination of the shape of equipotential surfaces and, since the geoid is an equipotential surface, also the determination of the shape of the geoid.

2.2.2 Normal Gravity and Gravity Anomaly. In an orthogonal coordinate system with its origin at the center of mass of the Earth, and the z axis coinciding with the rotation axis of the Earth, the potential at an external point P (x,y,z) is

$$W=G\int \frac{dm}{r}+\frac{\omega^2}{2}\,(x^2+y^2),$$

where G is the Newtonian gravitational constant, dm is the element of the Earth's mass, r is the distance of the mass element from P, and ω is the rotational speed of the Earth. If this equation is equal to a constant, one has the equation of the equipotential surface through P, or, with x,y,z as variables, the equation of any equipotential surface in the gravity field of the Earth. Unfortunately, the equation is not solvable in this form since we know neither the density distribution nor the shape of the surface over which the integration has to be carried out. Alternatively, the gravity potential at P is decomposed to two parts: U, the normal potential, and T, the disturbing potential. The normal potential is defined as the potential at P due to the attraction of a rotational equipotential ellipsoid (spheroid) that (ideally) has the same mass as the Earth and the same potential as the geoid. The center of this level ellipsoid is located at the center of mass of the Earth. Thus $W=U+T$.

The above equation is valid only for level surfaces located entirely outside the physical surface of the Earth. However, experience has shown that it is still usable in the proximity of the ocean surface, *i.e.*, for the geoid ($W=W_g$) and for its corresponding level ellipsoid, the terrestrial ellipsoid or spheroid ($U=W_g$), which approximates the geoid very well.

The normal gravity on the surface of the terrestrial ellipsoid (currently adopted parameters $a=6\,378\,137$ m, $1/f=298.257$, $GM=3\,986\,005\times10^8$ m^3/s^2, $\omega=7.292\,115\times10^{-5}$ rad/s) can be calculated rigorously from closed-form formulas if the geodetic latitude of the station is known.

The disturbing potential $T=W-U$ can be represented by the gravity anomaly $\Delta g=g-\gamma$, where g is the gravity reduced to the geoid, and γ the normal gravity on the terrestrial ellipsoid, both located on the plumb line of the observing station. The reduction of the measured gravity to the geoid is done using assumptions regarding the density of the masses out of the geoid.

2.2.3 Determination of the Geoid from Gravity Measurements. With the help of the gravity anomalies the distance between the geoid and the terrestrial ellipsoid (geoid undulations) can be determined. According to the formula of Stokes (spherical approximation) derived more than 100 years ago,

$$N=\frac{1}{4\pi}\frac{R}{\gamma}\int_\sigma \Delta g S(\psi)d\sigma,$$

where N=geoidal undulation, R=mean Earth radius, Δg=average gravity anomaly in the area element $d\sigma$, γ=average gravity of the Earth, $d\sigma$=differential area element, ψ=angular distance on the sphere between the area element and the computation point, and

$$S(\psi)=\frac{1}{\sin(\psi/2)}-6\sin\frac{\psi}{2}+1-5\cos\psi$$
$$-3\cos\ln\left(\sin\frac{\psi}{2}+\sin^2\frac{\psi}{2}\right)$$

(Stokes's function).

The integration must be carried out over the entire surface of the Earth. However, for political and practical reasons, gravity anomalies are not available all over the Earth. This fact complicates the calculations of the geoid enormously. In order to obtain gravity infor-

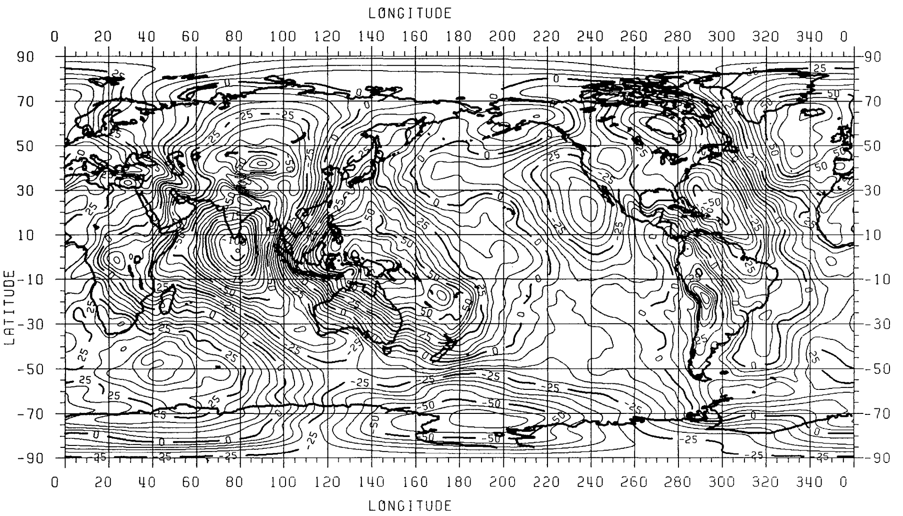

FIG. 7. Ohio State University 91A gravity model geoid heights (meters) relative to the GRS 80 reference ellipsoid (courtesy of Richard H. Rapp, Dept. of Geodetic Science and Surveying, Ohio State Univ.)

mation over unsurveyed areas, such as the polar regions, the orbital perturbations of a large number of satellites are analyzed and isostatic theories are used. Over the oceans, gravity anomalies are predicted or deduced from sea surface heights observed by altimetry satellites.

The geoid determination is, at present, possible to an accuracy of about 20 cm to 1 m. A global gravimetric geoid is shown in Fig. 7.

Differentiation of Stokes's equation with respect to a meridional and a parallel length increment yields the north-south and east-west components of the deflections of the vertical respectively.

2.2.4 Leveling, Orthometric Heights, and the Geoid. Once the geoid is determined, geometric levelling, starting from the geoid, is used to give the height of points located on the Earth's surface. For example, to determine the height of location *B* in Fig. 8, by geometric levelling starting at location *A*, the height differences dh_1, dh_2 between the level surfaces at subsequent rod positions are measured. Since the height of *B* is defined as the length of its plumb line down to the geoid (orthometric height), one actually should measure the quantities dh_1', dh_2',.... Because the work to proceed from one level surface to the other is the same for either location, one has the following relation between *dh* and the corresponding dh': $g\,dh = g'\,dh'$, where *g* is the mean gravity along the distance *dh*, and *g'* the mean along dh'. It follows that Σdh, the leveled height (difference) of *B*, is slightly different from $\Sigma dh'$, the correct orthometric height (difference) of *B*. Hence, a correction to the measured height, called the orthometric correction, should be applied in order to get the correct orthometric height. This correction is a function of the gravity values (*g*) along the path on the Earth's surface from location *A* to location *B* (see Fig. 8) and along the plumb line (*g'*) at location *B*. The latter can only be estimated on the basis of models of the structure of the Earth's crust. Therefore, in precision levelling, the gravity along the level lines is measured by means of a gravimeter. If a gravimeter is not available, as an approximation gravity values based on the reference ellipsoid (normal gravity) are used.

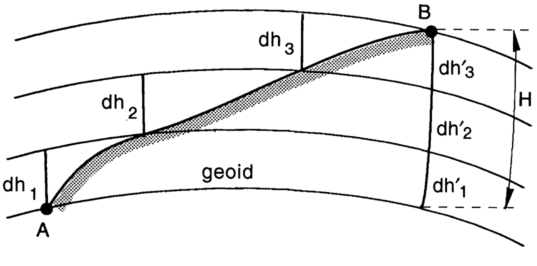

FIG. 8. The effect of the convergence of the level surfaces on geometric levelling.

3. MODERN CARTESIAN THREE-DIMENSIONAL GEODESY

3.1 Preview

The techniques described in the previous sections were developed either for horizontal (latitude, longitude) or for vertical positioning (height above sea level). These coordinates cannot be combined into three-dimensional ones of the same accuracy, because the geoid-ellipsoid separation component of the vertical coordinate (the geoid undulation) is not known with the same accuracy as either the horizontal coordinates or the height above sea level. This, together with the fact that the direct applicability of most traditional techniques is limited by the line of sight, i.e., by the curvature of the Earth, made the development of other technologies, not hampered by these problems, desirable for a number of traditional and heretofore not attempted geodetic applications. Satellite, radio astronomic, and inertial survey techniques are the ones that seem to be most suitable for such purposes. In the following these techniques together with some applications are described.

As the rapidly emerging industrial technology develops, more precise geodetic information can be achieved. For some areas of the world there still is little or no observational material. For these areas, additional or new surveys are required to relate one datum to another more precisely and to develop a standard world reference system that will satisfy future needs. Space technology is providing useful techniques for such surveys.

The theoretical use of artificial Earth satellites for obtaining geodetic information has been studied for some time. Scientific papers advocating the use of satellites for geodetic purposes have been published since 1956, and geodetic purposes were outlined for data obtained from Project Vanguard, the first U.S. satellite of geodetic significance, during the 1958–59 International Geophysical Year (Kozai, 1959; Kaula, 1966).

Many techniques and a great deal of knowledge were ultimately derived from this project. With this information, the constant growth of space technology, and the development of electronic measuring devices, it has become possible to plan and develop other satellites specifically equipped for geodetic purposes.

The feasibility of using pulsed lasers to range to artificial Earth satellites was first demonstrated in 1964 with the returns from the first satellites with laser retroreflectors. Since that time many reflector-equipped satellites have been launched and tracked. Two satellites, Starlette (France) launched in February of 1975 and LAGEOS (U.S.) in May of 1976, were specifically designed for precise laser tracking and Earth dynamic studies. Present-day lasers have demonstrated accuracies of 2–50 cm for a single range and about 5–10 parts in 10^9 in distance precision over baselines of 900–3000 km.

Our natural satellite, the moon, has also become a target for precise distance measurements, after lunar laser reflectors had been deposited on its surface.

Interferometric observations of signals from extragalactic radio sources (quasars) are also useful geodetic tools. The most widely used technique, very long-baseline interferometry (VLBI), was first developed in the 1960s for studies of source structure and size. The technique has been applied since to several other fields such as radio astrometry and relativity studies as well as to geodesy and geophysics. With interferometry, angular resolution is achieved by comparing signals from two widely separated antennas. The limiting factor on the resolution is the distance between the antennas and the size of the antenna. Earlier interferometers needed a physical communication link (e.g., cable) to transmit signals from one antenna to the other; therefore, the extent of antenna separation was naturally limited. This problem was solved by the development of VLBI, where the real communication link is bypassed by the use of highly stable atomic clocks at each radio telescope. The clocks are used to control the recordings of the radio signals on digital type tape recorders. These tapes then are transported to a common location where in essence the event is replayed and signals are compared by a computer. Because of the volume of the signals received and the complexity of the operation, the computer requirements are extensive.

In addition to the techniques mentioned above, three-dimensional coordinates may also be obtained by inertial survey systems. The principle of these systems, first developed for navigation, is that changes in position can be determined by the second integral of acceleration. Accelerometers measure specific force, which is the combined effect of acceleration and gravity: therefore gravity must be known (measured or calculated) to obtain acceleration. The orientation of the specific force is determined by gyroscopes. A computer keeps track of the orientation with respect to the reference frame of interest and performs the integration in the coordinates. The end product is two- or three-dimensional relative coordinates, depending on the number and direction of accelerations measured. The systems designed for geodetic use are mounted either in ground vehicles or in helicopters. Because of the cost of the observing equipment, vehicle, and computer operations, the use of these techniques so far has been mostly limited to government agencies and a few commercial organizations. The introduction of ring-laser gyros and fiber optic technology will aid in making available more precise, less expensive inertial systems.

3.2 Satellite Geodesy

3.2.1 Introduction. The scientific purpose of satellite observations falls into either dynamic or geometric categories. The dynamic purpose of satellite tracking is to observe positions and motions of satellites as a function of time, with sufficient accuracy for developing a theory of motion capable of predicting future positions at least as accurately as they can be observed. In order to make these predictions, an extensive theory of the motion, the precise knowledge of the physical parameters defining the force fields in which the satellite moves, and the accurate geocentric position of the observer are needed. Since, at least initially, the physical parameters and the tracking station positions are not known adequately, even when the theory of motion is sufficiently extensive, the observed positions and motions of the satellite will differ from the predicted ones. From these differences, corrections to the assumed parameters and station coordinates may be calculated, generally by means of a least-squares adjustment procedure.

In the area of celestial mechanics, a branch of classical mechanics, many improvements on the theory of motion have been developed during the centuries. The best mathematical minds of humanity devoted their energy to this problem, but mostly in connection with planetary motions. The circumstances of an artificial Earth satellite are different from those of an ordinary planet in two main respects: its orbit is much closer to the Earth than the orbit of any planet with respect to its primary, and it moves, at least partially, in an atmosphere while the natural satellites move practically in a vacuum. The first fact implies that the motion of an artificial satellite is significantly affected by the asymmetries of the Earth's gravitational field and by its temporal variations (e.g., tides), and therefore it could be used to determine the parameters defining this field. These parameters in turn may yield information on the shape, the mass distribution, and the dynamic behavior of the Earth. The second fact opens up possibilities to determine the structure of the atmosphere and to provide an insight to its behavior. There are also other phenomena that will influence the motion, such as the attraction of the sun and the moon, radiation pressure emanating from the sun, lunar and solar tidal distortions, and effects of the magnetic field of the Earth.

For principal geodetic results, the observables are the difference between transmitted and received frequencies [called the Doppler frequency after the Austrian Christian Doppler (1803–1853) who first demonstrated the principle using sound waves], range, or direction components (e.g., right ascension and declination), either observed individually or in certain combinations. Sometimes the instrumentation will collect integrated Doppler values that can be related to range changes. Receivers designed to track signals from the Global Positioning System (GPS) satellites can measure Doppler, phase delay, or advance of the carrier when compared to the phase of the receiver's oscillator, and pseudorange, which is the speed of light multiplied by the difference between transmit time based on the satellite's clock and received time based on the receiver's clock.

3.2.2 Principal Methods

3.2.2.1 General Dynamic Method. In the simplest case, when a spherical satellite moves around its spherical primary, affected only by the latter's attraction, the resulting normal orbit may be defined by six parameters, E_i ($i=1, 2, \ldots, 6$). These parameters may be selected according to various theoretical and computational criteria. From the didactic point of view, the simplest set is the classical Keplerian elements (Fig. 9), which define the orientation of the plane of the orbit in space (two parameters), the size, shape, and orientation of the Keplerian ellipse in that plane (three parameters), and finally, the position of the satellite at some given epoch (one parameter). In the gravitational force field of the spherical primary, five of these elements are constant and the satellite moves in its defined orbit in accordance with the laws of Kepler. As mentioned, the circumstances of a near-Earth artificial satellite are different from the above, the main consequence being that the orbital elements will no longer be time invariant, or, in other words, their derivatives with respect to time, $\dot{E}_i$, will not be zero. The variation of a given element from some reference epoch T_0 to the epoch of utilization T can symbolically be described by the equation

$$E_i = E_i^0 + \int_{T_0}^{T} \dot{E}_i dT,$$

where E_i^0 is the element in question at the epoch T_0 and E_i is that at T. The integral represents the perturbation of the element E_i. The function $\dot{E}_i$ is the rate of change of the element E_i due to all perturbing forces (nonspherical part of the Earth's attraction, atmospheric drag, etc.) and as such is a function of several hundred parameters, P_j ($j=1,2,\ldots,n$), defining these forces. For example, an adequate description of the Earth's gravitational field may require as many as 500, the atmospheric drag 10, and the radiation pressure 5 force parameters. The integral may be solved analytically (method of general perturbations) or numerically (method of special perturbations).

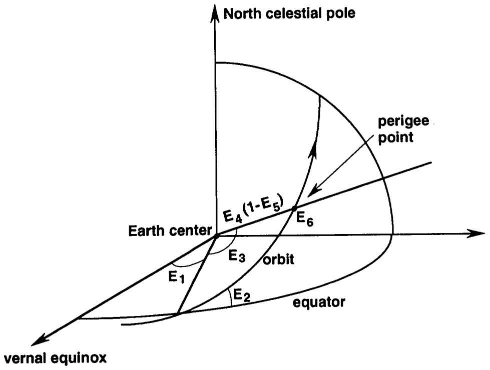

FIG. 9. Keplerian orbital elements: Right ascension of the node (E_1), inclination (E_2), argument of perigee (E_3), semi-diameter of the elliptic orbit (E_4), eccentricity of the ellipse (E_5), time of perigee passage (E_6).

Once the orbital elements are thus computed at the epoch T, they can be readily converted into positional and velocity components of the satellite and referenced to some well-defined coordinate system. If the parameters defining the observer's position in this coordinate system, S_k ($k=1,2,3$), are also known, then the observables can be calculated, i.e., predicted. To refer the positions of the satellite and the observer to the same (usually Earth-fixed) coordinate system, the precise knowledge of the Earth's rotation (precession, nutation, polar motion, and time) is also required.

Provided that the theory of motion is correct and that the observations have been freed of systematic errors, the differences between the computed, C_l ($l=1,2,\ldots,m$), and the observed, O_l, values of the observables will be due to the erroneous geocentric coordinates of the observer S_k and the erroneous orbital elements at epoch T_0 that are included along with the parameters describing the force field in the vector components P_j. Assuming that both the differences $O_l - C_l$ and the errors dP_j, dS_k are differentially small, then the following type of relations may be established:

$$O_l - C_l = \sum_j \frac{\partial C_l}{\partial P_j} dP_j + \sum_k \frac{\partial C_l}{\partial S_k} dS_k ,$$

where

$$\frac{\partial C_l}{\partial P_j} = \frac{\partial C_l}{\partial E_i} \frac{\partial E_i}{\partial P_j} ,$$

E_i being an orbital element at the instant of observation.

If the above equation is regarded as an observational equation, then the quantities dP_j and dS_k are the unknown corrections to the assumed parameters and station coordinates, respectively, and $\partial C_l/\partial P_j$ and $\partial C_l/\partial S_k$ are coefficients, representing the variations of the observables with respect to P_j and S_k, computed from the prediction mathematics. The left side of the equation, $O_l - C_l$, is the known difference between the observation and its predicted value. In order to obtain a satisfactory solution, the number of observations m must greatly exceed the number of unknown parameters n plus the station unknowns $p \times k$ (p is the number of stations), and a least-squares adjustment is performed in the traditional sense. To perform such a calculation is a formidable task, considering that recent solutions, for example, included data from over 30 satellites observed over two- to four-week periods from as many as 50–100 stations. Thus, the unknowns may include 150–300 components of positions in addition to about 2000 harmonic coefficients of the Earth's gravity field, about 90 tidal coefficients, thousands of orbital constants (e.g., E_i^0), possibly Earth rotation parameters, etc. Such general solutions, because of the high cost of solving the large number of equations, are performed infrequently, and only by a few organizations having access to large computers.

3.2.2.2 Partial Dynamic Method. Once the results of a general solution, such as the one outlined above, are available, additional stations can be added on at a much smaller cost. In such partial solutions, positions of observing stations are obtained from least-squares adjustments, where the Earth's gravity field and the positions of many of the stations are held at values determined in the preceding general solution. Usually a separate computer program is used for this purpose because program efficiency is greater when the objectives are more limited. In these solutions a shorter time span of data (two to five days) may be used, which will also reduce the effect of some errors in the force field. The unknowns in such a solution, in addition to the coordinates of the new stations, include the six initial orbital constants E_i^0, usually a drag (scaling) parameter, and maybe components of the pole position. In other words, in such solutions most perturbations are treated as known phenomena that can be calculated from the parameters determined in the general solution.

3.2.2.3 Short-Arc, Point-Positioning, and Translocation Methods. Two special cases of the partial solution are the so-called short-arc and the point-positioning methods. In the former, the data are limited generally to satellite passes of 10–30-min lengths. These relatively inexpensive solutions contain as unknowns only six initial orbital parameters per pass and the coordinates of the participating stations. The method is limited to relative positioning with respect to a reference station whose coordinates are held to their estimated (not necessarily geocentric) values. Because of the shortness of the arc, the perturbation models may be simpler than in the partial solutions; for example, the gravity field may be satisfactorily described by as few as 50–75 parameters, depending mainly on the length of the arc and the altitude of the satellite. The relative station positions obtained from short-arc solutions are considered generally free of orbital (or other) biases equally affecting stations observing the same arcs.

In the point-positioning method the data span is several days long for Doppler satellites and less than that for GPS satellites, and the orbital elements are held to the values obtained from a precise satellite trajectory (ephemeris). Thus, the only unknowns in the solution are the coordinates of the observing stations and their clock offsets or frequency drifts. The satellite ephemeris is generated and made available by some organization that keeps continuous track of the satellites in question. A prime example of this method is positioning by use of instruments that measure the range difference between a ground station and two satellite positions by means of integrating the Doppler shift of radio transmissions from the Navy Navigational Satellites (NNS). Precise ephemerides of these satellites are generated, from which satisfactory orbital elements may be obtained for the instants of the observations. Predicted, and therefore less accurate, elements are also generated and injected into the satellite's memory, which in turn are retransmitted and can be used with certain types of receivers. In this latter case it is advisable to observe the satellite passes from at least two stations simultaneously and to solve only for relative positions that, similarly to the short-arc case, will be less affected by the biases in the orbital elements than the positions themselves. This mode of operation is termed translocation.

3.2.3 Applications of Satellite-Derived Geodetic Parameters. For the geodesist it is important to know the positions of a large number of well-distributed stations, especially if these positions are determined accurately in some homogeneous way and are referred to a well-defined and accessible coordinate system. Even with the present modest accuracies, several immediate applications come to mind. In addition to the most obvious one, namely, to aid in the accurate determination of orbits, some of the most important geodetic applications are as follows:

1. The gravity harmonic coefficients obtained from general dynamic solutions provide an accurate long-wavelength representation of the Earth's gravity field, and hence the geoid. This long-wavelength information is combined with gravity anomaly data, obtained from terrestrial gravity observations (over the continents) and satellite altimetry data (over the oceans), to give the most accurate global geoid known at present.
2. Three parameters—*GM*, the geocentric gravitational constant, a, the equatorial radius of the Earth, and J_2, the second zonal harmonic of the gravity field—together with ω, the rotation rate of the Earth, contain enough information to define the size and shape of a best-fitting geocentric equipotential Earth ellipsoid (spheroid). The orientation of this ellipsoid is also defined through satellite observations, as well as astrogeodetic ones, and maintained by some international agencies, such as the International Earth Rotation Service (IERS). This ellipsoid serves as a global Geodetic Reference System and is modified from time to time (e.g., GRS67 and GRS80) by the International Association of Geodesy. The values are published each quadrennium in its *Geodesist's Handbook*, as a special edition of the journal *Bulletin Géodésique*.
3. An independent geodetic datum can be related to others by determining transformation parameters between them and a common satellite system. The problem of estimating datum transformation parameters is very often an ill-conditioned one. Therefore a careful analysis is needed in order to minimize the correlations between the estimated transformation parameters.
4. Possible distortions within a geodetic network can be detected by inspecting the residuals after systematic components arising from the above transformation are removed. These distortions may be due to various errors that are partly observational and partly computational in nature. This application presumes that the satellite-determined positions are more accurate and homogeneous than those established by ground surveys.
5. A primary geodetic network can be strengthened by incorporating accurate satellite (Doppler, laser, or GPS) positions in the adjustment process.
6. Mapping control can be established in unsurveyed areas.
7. Geodynamic activity can be monitored. Some of the geodetic space techniques have the fundamental capability of accurately monitoring the motion in space of a point on the Earth's surface or the capability of measuring the changes in the distance between two or more points. The present capabilities make it possible to measure with unprecedented accuracies certain important geodynamic phenomena, such as tectonic plate motions, deformations around fault zones, Earth tide displacements, temporal changes in the Earth's gravity due to the post-glacial rebound, sea surface variability and apparent positional changes due to polar motion, and variations in the rotational rate of the Earth. Some of these phenomena have been measured and monitored in the past by means of traditional instrumentation. Prime examples are the polar motion and Earth rotation efforts coordinated by the International Polar Motion Service (IPMS) and the Bureau International de l'Heure (BIH), based on optical astronomic techniques such as use of zenith telescopes and astrolabes. Doppler satellite techniques also provided information on the motion of the pole. These techniques allow the determination of polar motion to an accuracy of 50–100 cm and of Earth rotation to 0.7–1 ms over two to five days averaging time (Mueller and Zerbini, 1989).

   The most accurate measurements of geodynamic phenomena are obtained by the very long-baseline interferometers, the lunar laser rangers, the satellite laser rangers, and, recently, the GPS satellites. These systems have already demonstrated the following accuracies: plate and fault motions, 1–2 cm/yr or better; polar motion, 2–3 cm over 12 h averaging; and Earth rotational rate, 0.05 ms over 12 h averaging.
8. A Terrestrial Reference Frame for Earth Dynamics may be established. The expected increase in observational accuracy and the resulting increase in the resolution of geophysical phenomena requires a redefinition of many of the concepts used in the more traditional analysis described ear-

lier, in which, with the possible exception of the Earth tides phenomena, the Earth was assumed to be a rigid body. It is the departures from rigidity that are interesting and are to be studied in suitable reference systems needing definition. The realization of such a reference system must necessarily use observations from the Earth, and it could be defined through the adopted coordinates of super control stations, determined with high precision from laser observations to satellites or to the moon, VLBI observations, and GPS phase observations. The following criteria seem desirable for such a coordinate system:

- **a.** The system should be as nearly invariant as possible with respect to changes in the number, distribution, and data acquisition rates of observing stations in different parts of the world.
- **b.** The system should facilitate the rapid determination of sudden changes in the position or motion of individual stations, as well as sudden changes in polar motion and the rotation of the Earth.
- **c.** The system should be approximately fixed with respect to the mantle (should rotate with the Earth) in some average sense.

These criteria lead to the choice of a coordinate system in which our previous knowledge of the motion of the stations with respect to each other and to the mantle is used to model the station motions due to plate movements, etc. Such a coordinate system conceptually would be similar to that used by astronomers in the fundamental star catalogs, where the adopted coordinates of stars together with their relative motions define the frame of reference. To maintain such a system the International Earth Rotation Service (IERS) was established in 1988 in Paris, France; its responsibilities include coordinating the continuing observations at the fundamental stations and issuing directives on changes in the adopted coordinates and motion parameters or models, when the need for such changes arises from the data analyses. An international terrestrial reference frame is then realized through the coordinates of the fundamental stations at some reference epoch.

3.2.4 Special Satellite Geodetic Techniques

3.2.4.1 Global Positioning System (GPS). The GPS has been designed to provide for passive, all-weather, precise navigation from any location on or near the Earth at any time. The GPS satellites will be operated by the U.S. Air Force for the U.S. Department of Defense. When fully operational, the GPS constellation of satellites will consist of 21 (and three spare) satellites, equally spaced in three orbit planes, with 12-h periods. This will allow visibility of at least four satellites in good geometry for any point on Earth. The GPS satellites will employ precise atomic frequency standards to assure high oscillator stability and precise time information. Each satellite will broadcast on two L-band frequencies, L_1 (1575.42 MHz) and L_2 (1227.60 MHz), which will allow elimination of first-order ionospheric refraction. Additional information will be modulated onto these L-band frequencies for the following purposes: to identify each satellite uniquely; to provide for measurement of the signal travel time to the receiver by measuring the phase shift required to correlate the codes to receiver-generated codes; and to allow restriction of the use of the system if desired. The master control station is located at Colorado Springs, Colorado, where all operational tracking data are collected, with precise orbital information (predictions) then being made. This information is then loaded into the satellite memory at least once per day as the broadcast message for the satellite. The three major observables of the GPS satellites are pseudorange, phase difference, and phase difference rate (Doppler). The pseudorange is basically a range observation from the receiver to the GPS satellite, but since the receiver's clock and the satellite's clock are not synchronized, this range will be contaminated with clock errors. Resection of ranges to four different satellites will provide the three-dimensional position of the receiver as well as an estimate of the receiver clock offset to GPS system time. This will be the primary method for navigation. The differences between phase observables from different stations to different satellites will be free of most of the systematic errors affecting the original observables, such as the clock errors of the satellites and receivers, and hence these differences are the primary geodetic observables. The Doppler observable is the weakest and the least used in geodesy but will be useful if velocity estimates are required.

The GPS observations have already demonstrated accuracies approaching one part in 10^9 in measuring distances of a few thousand kilometers, and are used heavily in monitoring crustal deformations.

3.2.4.2 Satellite Altimetry. A short burst of electromagnetic waves is directed downward from the satellite, and the return signal, reflected from the sea surface, is monitored by a fast-response instrument. The resulting signal's delay time and shape are then used to determine the vertical distance from the satellite to the ocean surface and back to the detector. If the satellite's position is known from other tracking data, the sea surface height can be determined. If the geoid is also known, the separation of the sea surface and the geoid can be determined, a phenomenon called the sea surface topography, which is of great interest to oceanographers. Altimeters with a precision of approximately 50–100 cm have flown on Skylab and GEOS3. An improved altimeter with 10-cm precision operated successfully on the SEASAT 1 satellite for a few months until the spacecraft failed in October 1978. The most ambitious TOPEX ocean sensing satellite, with sub-10-cm altimeter, was launched in summer, 1992.

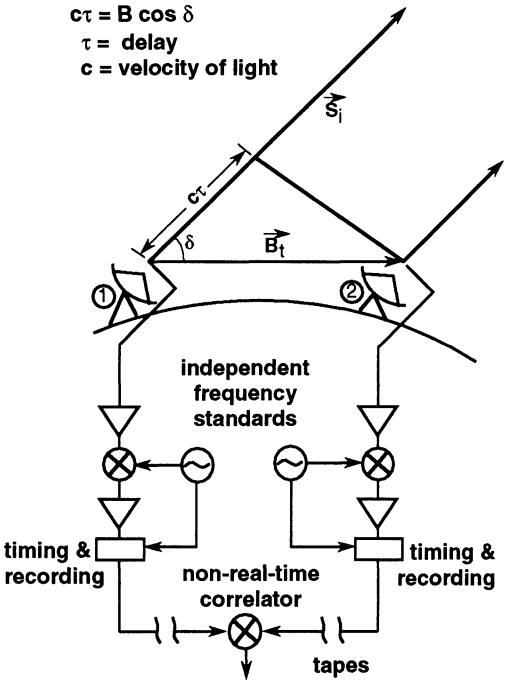
3.2.5 Lunar Laser Ranging (LLR). The goal of LLR is to use ranges to the moon observed from some stations on the Earth in order to improve the knowledge of the lunar orbit and of the positions of the lunar reflectors as well as the observing stations. Also, it is desired to study gravitational theory and the rotation of the moon by analysis of position deviations of the moon remaining after modeling known parameters. Retroreflectors were placed on the moon by the crews of Apollo 11, 14, and 15. Two other reflectors were placed by the Soviet Lunar 17 and 21 missions. Laser ranging to most of these reflectors began shortly after each of these missions, and is still continuing. The arrangement of the four working reflectors on the moon is a quadrilateral with sides of about 1000 km, a good length for the study of lunar rotation.

Although the great majority of lunar ranging observations to date have been made at only one observatory (McDonald Observatory, at Fort Davis, Texas), a remarkable number of accomplishments have been made by the lunar laser ranging program, which are not elaborated here.

3.3 Very Long-Baseline Interferometry

3.3.1 Introduction. The primary very long-baseline interferometer (VLBI) observable for geodetic and astrometric studies is the time interval between the arrival of a radio signal at one end of the interferometer and its arrival at the other end. This interval is called the delay, and its time derivative is the delay rate observable. From a sufficient set of these data as functions of time, the geometry of the interferometer baseline and the position of the observed radio sources can be determined.

3.3.2 Basic Instrumentation. The basic geometry of a VLBI interferometer is shown in Fig. 10. Each observing station receives and records independently the signals from a radio source. The time of arrival of the signals in



very long baseline interferometry (VLBI)

FIG. 10. Basic geometry of radio source interferometry.

terms of the local clocks is also recorded. In the simplest case the signal from the source is a single plane wave and the observing sites are fixed in space. The difference in recorded arrival time (τ) is then a direct measure, in light-time ($c\tau$), of the component of the interferometer baseline in the direction of the source ($B\cos\delta$). Measuring delays from sources located on orthogonal planes in space completely determines the baseline length and orientation. Two additional factors must now be taken into account. As the Earth rotates in space, the projected baseline in the direction of the source changes with time, introducing the delay rate observable. As the stations move, the signals recorded by each station are Doppler shifted. These effects must be removed before the recordings can be correlated to determine the delay observable.

VLBI instrumentation can be divided into the following main components: antenna, receiver, frequency standard, and recorder.

Antennas used for VLBI have varied in size from the 305-m bowl at Arecibo, Puerto Rico, to a 4-m dish of the Jet Propulsion Laboratory. The sites have been distributed geographically as widely as Australia and the Crimea.

Commercial rubidium and cesium beam clocks and hydrogen masers have been used as VLBI frequency standards. Rubidium clocks have fractional frequency stabilities of parts in 10^{11} while hydrogen masers can be two or more orders of magnitude better. Two time scales are important. Over periods of a few minutes frequency stability must be adequate to provide sufficient integration time for extracting the VLBI observables. Over periods from several hours to a day, the frequency standard must function as a stable clock for recording signal arrival time.

3.3.3 Applications. VLBI delay observations are composed of three components. The first component is due to the geometry of the station locations and source location, as illustrated in Fig. 10. This component contains all of the information about the geodetic and astrometric parameters that are of interest. The second component is due to instrumental effects, principally clock errors. The third component is due to effects of the propagation medium (e.g., the atmosphere and the ionosphere). Only the geometric component is considered here.

From Fig. 10 we see that the geometric delay τ can be written in vector form as

$$\tau c = -\mathbf{B}_t \cdot \mathbf{R}\mathbf{S}_i ,$$

where $\mathbf{S}_i$ is the unit vector in the direction of the radio source in an inertial coordinate system, $\mathbf{B}_t$ is the vector separation of the receiving stations, usually modeled in an Earth-fixed coordinate system, $\mathbf{R}$ is a transformation matrix that accounts for the rotations of the Earth in space, c is the speed of light, and τ is the time delay observable. Hence, $\mathbf{R}$ will contain parameters of the precision, nutation, and polar motion of the Earth. The vector $\mathbf{S}_i$ is a function of the right ascension and declination of the radio source, while the vector $\mathbf{B}_t$ has Δx, Δy, and Δz as components.

If sufficient observations are taken, one can solve for all the above-mentioned parameters in a well-defined Earth-fixed and celestial coordinate systems. The estimated parameters may include baseline components, nutation parameters and polar motion, radio source right ascensions and declinations, and clock drifts and drift rates.

If the observations made are delay rates rather than delays, a slightly different situation emerges. It is not possible with delay rates alone to estimate all of the parameters of geodetic and astrometric interest. The polar component of the baseline cannot be estimated, and, in addition, at least one of the baseline coordinates or source coordinates must be determined by some other means.

4. CONCLUDING REMARKS

With the introduction of artificial satellites in the late 1950s, the geodetic sciences have been under continuous and rapid change. Today the impacts of very high-quality measurement systems such as lasers, very long-baseline interferometry, precise absolute gravimeters, satellite-based altimetry, and the Global Positioning System (GPS) are bringing allied sciences such as geophysics, oceanography, remote sensing and photogrammetry, and navigation into much closer contact. For example, one would not consider using traditional measurements such as angles and distances from theodolites and electronic distance-measuring devices to establish a modern national geodetic network as was done as recently as 1987. Today the increased precision with greatly reduced costs of GPS, strengthened by satellite laser ranging and/or VLBI, would be almost the exclusive techniques employed. Real-time millimeter measurements are being collected in search of earthquake and volcanic precursors. Similar measures of ice-sheet thicknesses and sea-level monitoring along with precise satellite altimetry are opening up new vistas for studying energy transfers between oceans and the atmosphere, ocean circulation, climate, and internal Earth structure.

GLOSSARY

Anomaly, Gravity: The difference between the gravity on a geop (defined below) and the normal gravity on the corresponding spherop (defined below). The gravity anomaly is generated by masses deviating from those of the normal Earth. The effects of these disturbing masses on the gravity anomaly are given by the principal equation of gravimetric geodesy. The sign of the anomaly is in the sense observed minus normal. In the conventional theories the geop used is the geoid (defined below).

Clairaut's Theorem: An expression for the variation of the normal gravity on the Earth spherop, which is the basis of standard gravity formulas such as the international gravity formula. It also establishes the relationship between normal gravity and flattening of the Earth spherop that makes it possible to compute the flattening from surface gravity observations.

Deflection of the Vertical: *Absolute deflection* is the angle at a point on the geoid between the normal to the geoid at this point and the normal to the Earth spherop at the corresponding point. It may be determined from gravity values evenly distributed over the whole of the Earth surface.

Doppler Effect: The change of frequency of sound, light, or radio waves with the relative velocity of the source and the observer: if the source and observer are moving closer together, the observed frequency is higher than the transmitted frequency.

Ellipsoid, Best-Fitting: A reference ellipsoid whose size, shape, and orientation have been determined from the condition that it should fit best to the geoid or to parts of it. The criteria for best fit vary. Usually it is required that the square sum of the astrogeodetic deflections (or their deviations from the absolute deflections) or of the geoid undulations, extended for the area in question, should be a minimum.

Ellipsoid, Level: An equipotential surface of ellipsoidal shape. If the Earth were a rotating fluid of uniform density, its shape would be a rotational ellipsoid.

Ellipsoid, Reference: Any one of arbitrarily selected ellipsoids used in geodetic calculations to represent the Earth (International ellipsoid, Clarke's ellipsoid of 1866, GRS 80, and so forth).

Ellipsoid, Rotational: The figure generated by rotating an ellipse about its minor axis. It is defined by two parameters (two semidiameters or one semidiameter and the flattening, and so forth). Also called *ellipsoid of revolution.*

Flattening (Rotational Ellipsoid or Ellipse): The ratio of the difference between the major and minor semidiameters to the major semidiameter.

Flattening, Gravitational: The ratio of the difference between the polar and equatorial normal gravities to the equatorial normal gravity.

Geographic Position: The geographic position of a terrestrial point is its position relative to a geodetic reference surface, which is used in mapping as a substitute for the actual shape of the Earth. The most often used reference surfaces are an ellipsoid and a geopotential surface. The position usually is given in curvilinear coordinates, such as latitude, longitude, and height above the reference surface. It is customary to distinguish between ellipsoidal (geodetic) and gravitational (astronomic) coordinates depending upon whether the ellipsoid or the geopotential surface, respectively, is used as a reference surface.

Geoid: That equipotential surface of the Earth's gravity potential (geop) that most nearly coincides with the undisturbed mean sea level.

Geop: An equipotential surface in the gravity field of the Earth. On such a surface the geopotential is a constant and the gravity vector is perpendicular to it at every point. Also called *geopotential surface.*

Geopotential: The gravity potential of the actual Earth. The sum of the gravitational (attraction) potential and the potential of the centrifugal force. A function describing the variation of the geopotential in space. The function whose partial derivative in any direction gives the gravity component in that direction.

Gravity: The resultant of gravitation and the centrifugal force caused by the rotation of the Earth. The vertical gradient of the geopotential. It may be determined by methods such as reversing pendulum, long pendulum, upward projected ball, free fall, free and nonfree fall, and so forth. Also called *absolute gravity.*

Gravity, Normal: The gravity caused by the mass attraction of the normal Earth (defined below) combined with the centrifugal force due to its rotation. The normal gradient of the spheropotential.

Height, Orthometric: The distance between the geop through the station in question and the geoid, measured along the plumb line of the station.

Latitude, Geodetic: The angle between the ellipsoidal normal to the point in question and the equatorial plane of a reference ellipsoid. Positive in the Northern Hemisphere.

Longitude, Geodetic: The angle between the geodetic meridian plane of the observer and that of an arbitrary point near Greenwich. It is measured in the equatorial plane of the reference ellipsoid and numbered usually from the point near Greenwich. It is determined, however, by means of triangulation, trilateration, or similar methods from the geodetic meridian plane of the initial point of the geodetic datum to which it refers. Also called *geocentric longitude.*

Meridian, Geodetic: A curve (ellipse) on the reference ellipsoid that contains points of equal geodetic longitude.

Normal Earth: A mass such that its external bounding equipotential surface is the spherop (defined below), and its gravity is given by the prescribed gravity formula.

Spheroid: The spherop that possesses, in the normal gravity field of the Earth, the same constant of potential as the geoid in the true gravity field.

Spherop: An equipotential surface in the normal gravity field of the Earth. On such a surface the spheropotential (defined below) is constant. The normal gravity is perpendicular to it at every point. It may be shown that, neglecting terms smaller than the second power of the flattening, the surface of a spherop is identical to that of a rotational ellipsoid. Also called *spheropotential surface.*

Spheropotential: The potential function of the normal gravity. It may be defined either as the external gravity potential of a level ellipsoid approximating the Earth, or as a function consisting of the first few terms of some expansion of the geopotential.

INTRODUCTION

Four sources contribute to the electromagnetic field observed near Earth and at its surface: electric currents in the core, permanent magnetization in the crust or upper lithosphere, the dynamo action of moving, conducting seawater in Earth's main field, and "external" electric currents above Earth (in the ionosphere and magnetosphere) and their induced components inside Earth. The core, or main, field is by far the strongest of the sources. Because the core field must diffuse through Earth's mantle, this field yields information both on the region of its generation and on the electrical conductivity of the mantle. Studies of the external currents provide information on the vast plasma-filled space that surrounds the planet. Analyses of the induced electric current components yield further information on the conductivity structure of Earth's crust and mantle or on ocean currents.

1. EARTH'S INTERNAL MAGNETIC FIELD

1.1 Introduction

The science of geomagnetism began in 1600 with publication of the book *De Magnete* by a British physician, William Gilbert, in which he concluded that Earth itself is a great magnet. The fact that the geomagnetic field causes a compass to point in a particular direction was known to the early Chinese, an observation that illustrates that the magnetic field is a vector. If a magnetized needle is perfectly balanced on a pivot so that it is free to rotate about a horizontal axis, it will be

---

nearly horizontal near Earth's equator, be nearly vertical near Earth's poles, and be inclined relative to the horizontal elsewhere, consistent with a dipolar form.

Except during magnetic storms (see Sec. 2) and in highly anomalous areas of the Earth's surface, about 99% of the magnetic field at the Earth's surface arises from electric currents in the conducting liquid core. About 90% of that field from the core takes the form of a magnetic dipole that can be modeled as lying at the Earth's center. In 1980 the model dipole was inclined at 11.2° to the axis of Earth's rotation in the direction of 289.3° E longitude. (A slightly more accurate dipole representation could be obtained by translating the inclined dipole from the center of the Earth in the general direction of the western Pacific. This is called an "eccentric dipole field," and in 1980 the dipole would have been displaced about 450 km from the Earth's center.) The position of the north pole of the model dipole (latitude 78.8° N, longitude 289.3° E) is called the geomagnetic north pole. The two locations in the northern and southern hemispheres where the field is exactly vertical are called the dip poles. The dip poles must be determined by *in situ* measurements, and in 1984 the north dip pole was measured at 77.0° N, 258.7° E. The dip poles and the dipole poles are not colocated, and each has a corresponding equator. Both sets of poles change position with time. There may also be local dip poles found near strongly magnetized mineral deposits in Earth's crust.

The temporal change of the field from the core is often referred to as a secular variation, though that term is most often used to refer only to the first time derivative of the change. Changes through geologic time are studied using measured magnetic properties of rocks, which also provide evidence that the field polarity occasionally reverses.

The main geomagnetic field (described by **B**, the magnetic induction or flux density, rather than **H**, the magnetic intensity) is described by Maxwell's equations. Within volumes where the current density is negligible **B** is curl-free and can be represented as the gradient of a scalar potential:

$$\mathbf{B}=-\nabla V, \tag{1}$$

$$\nabla^2 V=0. \tag{2}$$

1.2 Gauss's Representation of the Field

A solution to Eq. (2) for the geomagnetic field was first found by Gauss in the form of a spherical-harmonic expansion,

$$\begin{aligned} V=a \sum_{n=1}^{\infty} \sum_{m=0}^{n} \{ & (a/r)^n [g_n^m(t)\cos m\phi \\ & + h_n^m(t)\sin m\phi] \\ & + (r/a)^{n+1}[q_n^m(t)\cos m\phi \\ & + s_n^m(t)\sin m\phi]\} P_n^m(\cos\theta). \end{aligned} \tag{3}$$

Here a is the radius of the Earth, r is the radial distance from the center of the Earth, θ is the colatitude, ϕ is east longitude, $P_n^m(\theta,\phi)$ are the associated Legendre functions of degree n and order m, and g_n^m, h_n^m, q_n^m, and s_n^m are functions of time alone. P_n^m are Schmidt normalized so that

$$\int_0^\pi P_n^m P_n^{m'} \sin\theta \, d\theta = \delta_{nm'\delta_{mm'}} 4/(2n+1).$$

Terms in a/r describe fields originating within the Earth, and terms in r/a describe fields originating outside the Earth—i.e., in the ionosphere, magnetosphere, etc. If **B** is known everywhere on the spherical surface $r=a$ at the time t, then the Gauss coefficients, the g_n^m, h_n^m, q_n^m, and s_n^m, can be determined exactly.

1.3 Length Scales

At Earth's surface the strength of the dominant dipole field is about 6×10^4 nT at the poles and 3×10^4 nT at the equator. The remainder of the field has a complicated spatial pattern. A quantitative summary of the importance of the various horizontal wavelengths at Earth's surface can be obtained by considering separately the fields for various spherical harmonic degrees n. The strength of the "signal" in **B** at the wavelengths corresponding to a given degree n in Eq. (3) can be measured by averaging $|\mathbf{B}_n|^2$ over the Earth's surface:

$$\langle |\mathbf{B}_n|^2 \rangle = (n+1) \sum_{m=0}^{n} [(g_n^m)^2 + (h_n^m)^2]. \tag{4}$$

Figure 1, from Cain *et al.* (1989), shows the observed $\langle |\mathbf{B}_n|^2 \rangle$ as a function of n for low n.

The usual interpretation of Fig. 1 is that at the surface of Earth $\mathbf{B}_n$ comes principally from the core for $1 \leqslant n \leqslant 12$, principally from

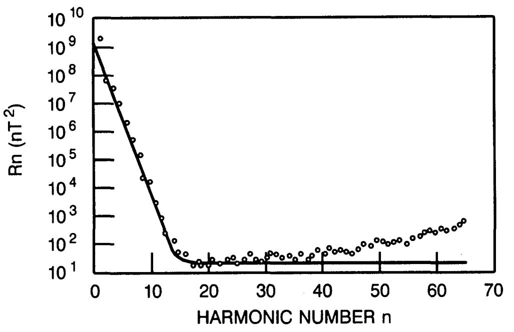

FIG. 1. Total mean square contributions to the vector field by all harmonics of degree n. Units are nT^2. Solid line is a fit to the data omitting a random noise component. Random noise is the cause of the rise in the data for $n > 40$. From Cain *et al.* (1989).

the crust (called "anomaly fields") for $n > 16$, and with both sources contributing for $13 \leqslant n \leqslant 15$. With existing satellite data, the crustal portion of the spectrum can be extended to an n of at least 50, which corresponds to a spatial wavelength of about 800 km. It is more convenient to use a characteristic size in kilometers for the anomaly fields, where the characteristic sizes are taken to be the distance between the half-amplitude contours of an anomaly. Aeromagnetic and shipborne magnetic surveys can typically map anomalies of characteristic size ranging from <1 to >100 km (see GEOPHYSICS).

1.4 Time Scales

Measurements of the remanent magnetization of ancient rocks suggest that the geomagnetic field strength has not changed by more than a factor of 3 to 4 over the last 3 billion years, except that it drops by a factor of 5 or more during geomagnetic reversals. Existing data indicate that the field may not become 0 during a reversal and that these reversals have occurred with increasing frequency during the past 70 million years, with a current average rate of about six per million years. The occurrence pattern of reversals appears to be random rather than periodic. For example, the typical occurrence period between the last few reversals has been of the order of 170 000 years, but the last complete reversal occurred over 700 000 years ago. During an individual reversal, the intensity of **B** may become anomalously low for about 10 000 years or less, and the reversal of its direction is typically completed in about 4000 years. Archeological evidence (magnetization of baked hearths and pots) indicates that the field intensity 2000 years ago at some sites was 50% higher than it is at present. In the last century the model dipole field intensity has been decreasing at a variable rate, averaging about 0.05% per year.

The secular variation $\partial_t \mathbf{B}$ is of the order of 60 nT/y. It varies greatly with position and with time. About 25% of the energy in $\partial_t \mathbf{B}$ at Earth's surface can be removed by subtracting from $\partial_t \mathbf{B}$ the field obtained by rotating the **B** pattern rigidly and steadily westward at about 0.2 deg/y. It is now believed that the secular variation is produced by fluid motions in the upper core of the Earth and that these motions may include a general westward rotation plus large spatially variable components. Figure 2 shows the variable rate of change of the main dipole term, g_1^0, in Eq. (3). Also shown in Fig. 2 is the change in length of day in milliseconds. There is a strong correlation between the two quantities with the length of day change leading the dipole change by about 13

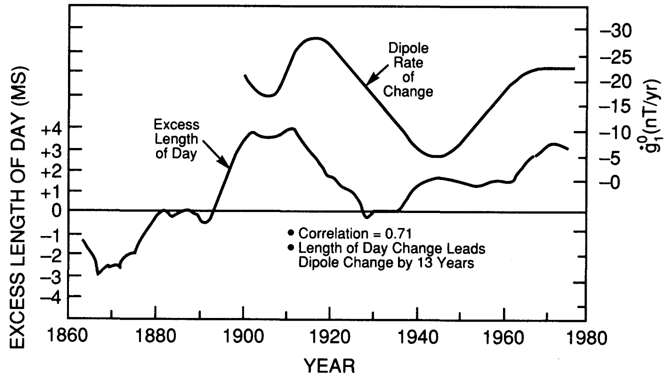

FIG. 2. Rate of change of axial dipole, $\dot{g}_1^0$, in nT/y and change of length of day in milliseconds from 1860 to 1980.

years. This correlation and lead–lag relationship is most likely related to electromagnetic coupling between the core and the mantle.

1.5 Origin of the Main (Core) Field

That portion of the magnetic field **B** at the Earth's surface that originates in the core is produced by electric currents driven by a self-sustaining dynamo process; fluid flowing across magnetic lines of force generates emf's that drive the electric currents that maintain **B**. The relationship between the fluid velocity and the magnetic field is expressed by the dynamo equation

$$\partial_t \mathbf{B} = (1/\sigma\mu_0)\nabla^2\mathbf{B} + \nabla\times(\mathbf{v}\times\mathbf{B}). \tag{5}$$

where σ is the conductivity, μ_0 the permeability, and **v** the fluid velocity. The two terms on the right-hand side of the equation describe diffusion and convection, respectively. When σ is very high, as in the liquid core, convection dominates diffusion. For most purposes the diffusion term can be ignored, and the magnetic field can be considered "frozen in" to the fluid; i.e., the field moves with the fluid. In a dynamo, energy from some source causes fluid flow, **v**, in some initial magnetic field such that, through the processes embodied in Eq. (5), the magnetic field grows or is sustained. **B** can be conveniently decomposed into toroidal ($\mathbf{B}_T$) and poloidal ($\mathbf{B}_P$) components, where $\mathbf{B}_T$ is any field of the form $\mathbf{B}_T = -\mathbf{r}\times\nabla t$ and $\mathbf{B}_P$ is any field of the form $-\nabla\times(\mathbf{r}\times\nabla p)$, with t and p any scalar functions of position. Toroidal fields have only an azimuthal component. Poloidal fields have components in meridional planes; e.g., dipole fields. Following Parker (1979), the fundamental physical processes that are responsible for generating toroidal fields from poloidal fields and vice versa are assumed to be differential rotation of the outer-core fluid and the cyclonic motion of convective upwelling in the outer core.

The angular velocity of the core is presumed to decrease with distance from the spin axis, as evidenced, for example, by the geomagnetic westward drift. This nonuniform rotation causes a shear in the lines of force of any poloidal (e.g., dipole) magnetic field, stretching the field in the azimuthal direction. Thus an azimuthal, or toroidal, field will be generated from a poloidal field. One suggestion is that this process reaches its limit when the Lorentz force balances the Coriolis forces of the convective motions, in which case the toroidal field could easily exceed 10^{-3} T. If the Coriolis forces are balanced by the fluid pressure, then the toroidal field could be much smaller. The dipole field today has a strength of only about 10^{-5} T at the core–mantle boundary. Because toroidal fields require meridional electrical currents, these magnetic fields cannot extend outside the core into the nonconducting mantle and are therefore unobservable at the surface of Earth. What may be the largest portion of the magnetic field of our planet is therefore undetectable to us.

Similarly, cyclonic motion of localized convective upwelling provides a mechanism for generating poloidal fields from toroidal fields. In this case, as a local packet of fluid upwells to form a convection cell, it carries with it the lines of force of the azimuthal field, forming a bulge in the field. Since the Earth is spinning, such fluid upwelling is cyclonic. This means that the bulge rotates as it rises. The net result is a small patch of field with a longitudinal component as well as an azimuthal component. The averaging together of many such cells is thought to be the principal means of generating toroidal fields from poloidal fields.

The core is not perfectly conducting and such a process, left to itself, would damp out in a few tens of thousands of years. An energy source is required to drive the convection of the core fluid. Some have suggested that radiogenic sources in the core could furnish the necessary energy, but this is disputed by others. The inner core (see EARTH, INTERIOR STRUCTURE OF THE) is formed by freezing of part or all of the liquid in the outer core, a process that could also provide the necessary heat source. The most popular current notion is that, at the inner-core boundary, the fluid of the outer core separates into a heavy fraction, which freezes to form the solid inner core, and a lighter fraction, which remains in the outer core. This lighter fraction is buoyant and drives the outer-core convection. In this scheme, the ultimate source of energy is the gravitational energy of the Earth, hence the term "gravitationally powered dynamo" for this generation mechanism.

1.6 Origin of the Crustal Field

As it forms, a rock generally acquires a magnetization along the direction of the ambient field. The strength and permanence of the magnetization depend upon the mineralogy of the rock and upon the strength of the ambient field. Examination of this magnetization in rock samples in the laboratory provides information on the geomagnetic field at the time the rock was formed. Ferrimagnetic materials lose their magnetization when heated above a critical temperature, called the Curie temperature, typically about 600 °C for magnetite. Some ferrimagnetic rocks when cooled to below their Curie points acquire a relatively strong and stable field. This is the dominant process (thermal remanant magnetization—TRM) that gives the lineated magnetic anomalies found on the ocean floor. These lineated magnetization reversals resulted as the ocean floor cooled at and near midocean spreading centers, and thus are records of the process of sea-floor spreading. Rocks can also acquire a viscous magnetization (VM) in which the acquired induced magnetization intensity is proportional to the length of time a rock spends in the ambient field. VM has been thought to be of particular importance in the lower crust of the Earth.

Spatial variations in the anomaly field reflect differences in near-surface magnetization of the rocks. Magnetization variations occur not only from variations in the amount of magnetic minerals but also from variations in topography and in the depth to the Curie isotherm. Variations in magnetization content reflect the past history of the rock: the chemistry of the rock source and the processes by which it was formed, the thermal and mechanical history of the rock formation, and alteration due to diagenesis and metamorphism. Figure 3 shows a relative magnetization map of the United States derived from satellite magnetic anomaly data, with some of the geologic and tectonic features indicated for comparison. 2. EARTH'S VARIABLE MAGNETIC FIELD

2.1 Introduction

The magnetic field of the Earth, if measured with sensitive instruments on the surface of or in the space around the planet, is found to vary on time scales from months to days to fractions of a second. The amplitudes of these variations can range typically from a percent or so to as little as one part in a million or less of the background field magnitude. These changes arise from electrical currents flowing in the space environment around the Earth, particularly in the ionosphere (*q.v.*) (altitudes of around 100 to 150 km) and in the magnetosphere (*q.v.*).

2.2 Magnetosphere and Ionosphere

In a steady-state perspective, the dominant current systems in the overall magnetosphere can be illustrated as shown in Fig. 4. Currents with densities ~25–150 mA/m^2 flow along the Earth's day-side magnetopause (typically located at ~$10R_E$ from Earth's center) and provide for the separation of the Earth magnetic-field–dominated regime from that of the interplanetary medium (consisting of the solar wind and interplanetary magnetic field). On the night side, in the plasma sheet of Earth's magnetotail (which begins at distances of the order of ~$10R_E$ behind the Earth), currents of density typically ~10 to 80 nA/m^2 (total magnetotail current ~10^8 A) flow dawn to dusk through the center of the magnetotail and close around its boundary. During geomagnetic disturbances, a ring current of order 10^6–10^7 A (~1–10 nA/m^2) grows from near the Earthward edge of the magnetotail current sheet, approaches closer to Earth, and, in large enough geomagnetic storms, completely encircles the planet. This ring

current can be connected to the ionosphere, particularly the auroral current system, through magnetic-field–aligned currents (a feature that indicates that geomagnetic field lines are not always equipotentials, as might be thought from simple considerations).

The dominant current systems in Earth's ionosphere are illustrated in Fig. 5. Day-side ionosphere currents are produced primarily by enhanced ionization caused by the fluxes of ultraviolet radiation from the sun. These currents, as well as those on the day-side magnetopause, produce variations in day-side magnetic fields. These day-side ionospheric currents have seasonal dependences (because of the tilt of the Earth's rotation axis) and a dependence on the phase of the approximately 11-year solar sunspot cycle. The most intense of these daytime currents—the equatorial electrojets—flow within a few degrees of the magnetic equator. Night-side auroral currents, with intensities of the order of 10^6 A or more and latitudinal extents of 100 km or more, flow in the ionosphere at latitudes near 65°. These ionospheric auroral currents are connected, through magnetic-field–aligned currents, to the Earthward edge of the magnetotail current sheet. The auroral current system appears as an essentially continuous oval band of illumination in the high upper atmosphere—the ionosphere—encircling each geomagnetic pole. The day-side portions of these auroral currents are connected, again via field-aligned currents, to the currents flowing on the day-side magnetopause. Occasionally single or multiple, approximately sun-aligned, auroral arcs stretch across the polar caps. The relationships of such arcs to magnetosphere current systems remain somewhat uncertain.

2.3 Variations in Magnetosphere–Ionosphere Current Systems

The solar wind, the continued outflow into the interplanetary medium of the 10^6-K solar corona, provides the energy for the complex plasma environment surrounding the Earth. Variations in the solar-wind flow speed, plasma number density, and interplanetary magnetic field strength and direction all can perturb, often severely, the geospace environment. These occurrences are called geomagnetic storms. For example, a large enough increase

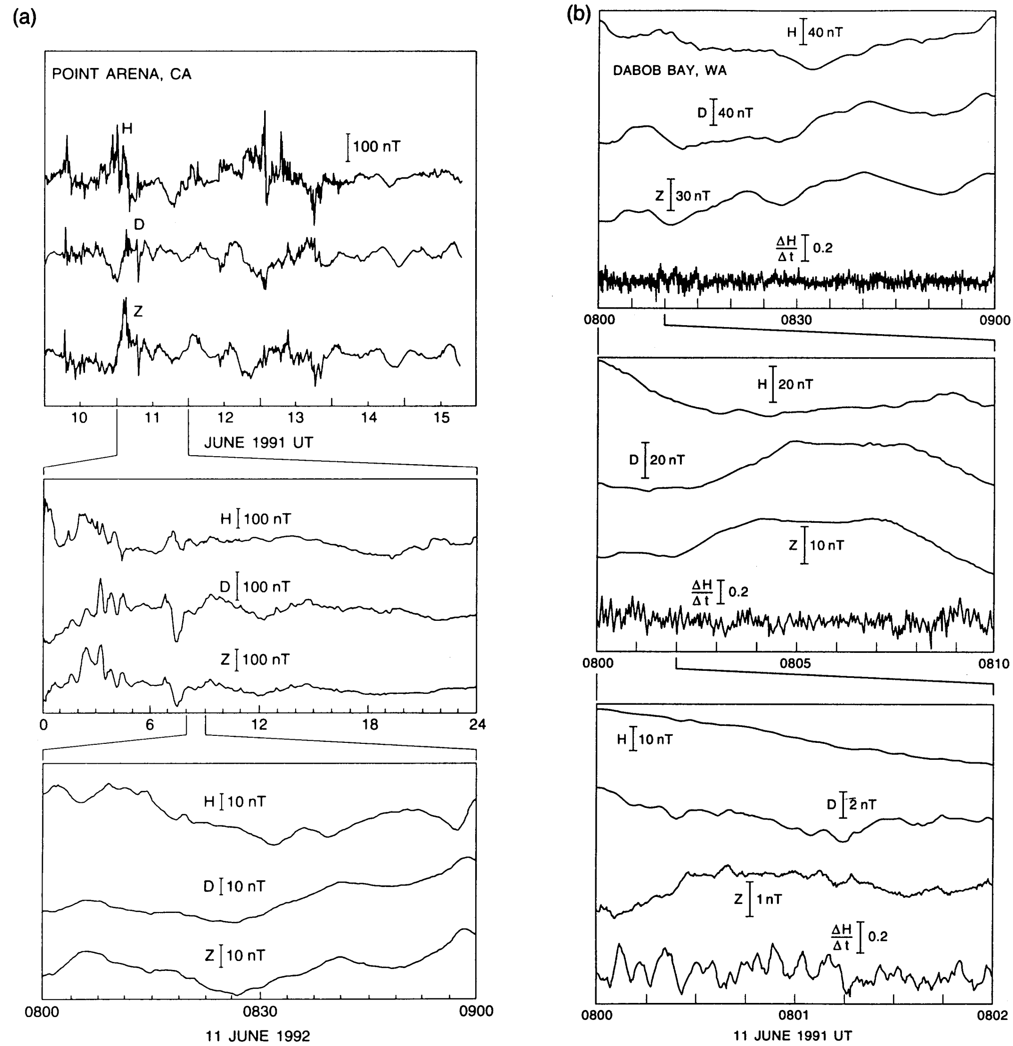

FIG. 6. (a) Time–intensity traces of geomagnetic fluctuations measured at increasing sensitivity and time resolution, days to hours, at Point Arena, CA, a mid-geomagnetic-latitude location on the west coast of the United States. The magnetic field is measured in three orthogonal geomagnetic components: *H* (south–north), *D* (west–east), *Z* (vertical). (b) Time-intensity traces of geomagnetic fluctuations measured at increasing sensitivity and time resolution, hours to seconds, at Dabob Bay, WA, a mid-geomagnetic-latitude location on the west coast of the United States.

in the pressure of the solar-wind flow can push the magnetopause substantially closer to Earth than normal, and not infrequently within the orbit of a geosynchronous satellite ($\sim 6.6R_E$). When this happens, the effective field at this location will have a direction and magnitude approximately opposite to that of the geomagnetic dipole. At the time of such solar-wind disturbances, the ionospheric auroral currents are considerably enhanced and shift equatorward from their usual locations; in some extreme cases, aurorae have been reported as far south as Hawaii. During such very large geomagnetic storms, the ring current becomes greatly enhanced and produces a decrease of as much as a fraction of a percent in the intensity of the main magnetic field as measured at a near-equatorial location on the Earth's surface.

In more usual circumstances, less intense variations in the solar-wind pressure and changes in the interplanetary field direction can produce geomagnetic disturbances (substorms) that last on the order of 1 to 3 h. One

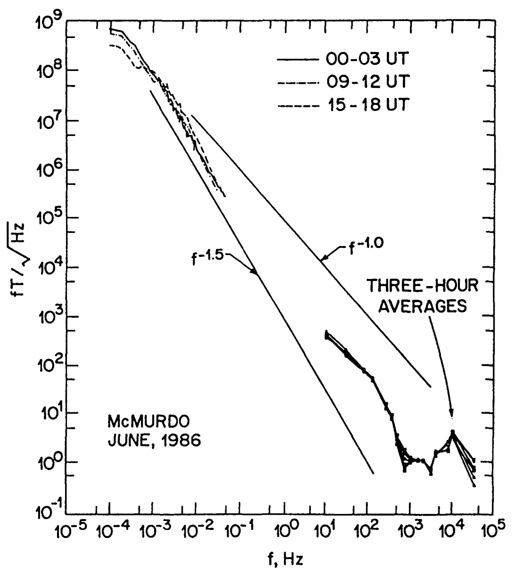

FIG. 7. Daily average amplitude spectra for magnetic field fluctuations for three geomagnetically quiet and three geomagnetically disturbed days in June 1986. From Lanzerotti *et al.* (1990).

or several such events can occur during a 24-h interval depending upon the state of the solar wind. In particular, if the interplanetary magnetic field has a vector component opposite in direction to that of the main dipole field at the magnetopause, the interplanetary and magnetosphere fields can become connected. Such a "reconnection" will drive field-aligned currents into and out of the polar-region ionospheres. These geomagnetic substorms are principally manifest in the ionosphere on the night side of the Earth at latitudes near that of the nominal auroral zone, although some effects can occasionally be seen more globally. For example, at the onset of a geomagnetic substorm, a characteristic magnetic perturbation—a damped wavelike variation with a period of the order of 60 s (termed a Pi2 pulsation)—is observed both on the Earth's surface over a wide range of geomagnetic latitudes and longitudes and in the magnetosphere itself.

Externally produced fluctuations in the geomagnetic field can be investigated and characterized in several ways. These include making time plots of the intensity of the field fluctuations and computing the power spectra (or amplitude spectra) of the fluctuations for a given measurement interval. Plotted in Figs. 6(a) and 6(b) are time–intensity plots of geomagnetic data acquired at ground-based measuring locations in California and in the Pacific Northwest. The data traces show that as the time resolution is increased, higher frequency variations with decreased amplitudes become evident. Further, a comparison of the 1-h traces of the individual components between the two locations on the geomagnetically disturbed day of 11 June shows that the more northern location (Dabob Bay) sees the larger range of variations.

The decreasing amplitudes with increasing frequency of the fluctuations means that the spectra of the geomagnetic variations can be characterized as red. Indeed, power spectra computed for fluctuation periods ranging from as long as a day (24 h) to as short as a fraction of a second have overall frequency dependences that vary as f^{-n}, where n has values in the range ~1 to ~3 to 5, depending upon the geomagnetic location and the level of geomagnetic activity. Superimposed on such mean spectra are often peaks that correspond to hydromagnetic wave resonances in the magnetosphere (typically in the period band ~1 to 600 s). The daily variation of the geomagnetic field due to the 24-h solar illumination cycle, and its harmonics at 12, 8, and 6 h, are also found. Daily average amplitude spectra for geomagnetic field fluctuations measured at McMurdo Station, Antarctica, for quiet and disturbed magnetic conditions in the austral winter are shown in Fig. 7. The daily variation and its harmonics are greatly reduced in magnitude at such a high-latitude station during the winter months.

3. ELECTRIC CURRENTS AT EARTH'S SURFACE

The principal sources of electric currents at the surface of the Earth from sources other than those described in Sec. 2 arise from lightning in Earth's atmosphere and from the atmospheric clear-weather electric field. Some 2000 thunderstorms are, on average, in progress around the world at any given time. These storms produce on the order of 100 cloud-to-ground discharges per second. The lightning occurrence regions are heavily concentrated in the equatorial regions of South America, Africa, and southeast Asia (see ATMOSPHERIC STRUCTURE). Cloud-to-ground lightning discharges typically transfer some 25 C of negative charge from the cloud to Earth's surface. Locally at Earth's surface, the peak current in a lightning discharge flowing upward can be a few hundred amperes for a few tenths of a second. These currents can be deadly to people struck directly or who might find themselves in close proximity to a lightning discharge channel. A hundred or more deaths in the United States can be attributed directly to lightning each year. Lightning also damages or destroys trees and manmade structures.

There is a vertical potential drop at the surface of the Earth of the order of ~200 V/m under clear-weather conditions. The typical clear-weather current density resulting from this is of the order of 3×10^{-12} A/m^2. Essentially, the Earth and the ionosphere can be characterized as forming the two plates of a giant leaky capacitor, with a total voltage drop of perhaps 300 kV. The clear-weather potential has a universal time (UT) variation in amplitude of about 20%, with a broad maximum in the 12–20 UT interval corresponding to the increased daytime thunderstorm activity in South America and Africa. The recharging of the Earth to maintain a net negative charge of ~10^6 C occurs through the transfer of negative charge to the surface by the thunderstorm activity.

4. ELECTROMAGNETIC INDUCTION

4.1 Introduction

Electromagnetic fields are induced in the conducting Earth by the external, ionospheric and magnetospheric, electric current systems. An additional internal source due to dynamo interaction of water currents with Earth's steady magnetic field is important in the oceans and near coastlines, generally at periods of a day or longer. As discussed in Sec. 2, the spectrum of field fluctuations produced by external sources covers a period range from a fraction of a second to more than a year. These fluctuations can interact with the conductive rocks in the Earth to depths of hundred of kilometers through the process of electromagnetic induction. Using measurements of the resulting electric and magnetic fields collected at Earth's surface, it is possible to infer the subsurface electrical conductivity.

The most widely used such electromagnetic method is magnetotellurics (MT) (see GEOPHYSICS), which is based on the principle that the electromagnetic fields induced by a fluctuating external magnetic field will attenuate with depth in the earth through the well known skin effect. From Ampère's law, the time-variable surface magnetic field is a measure of the total electric current flowing inside the Earth. If the surface electric field is also known, then the distribution of current, and hence the subsurface conductivity, can be determined. Since longer-period disturbances penetrate a conductor to greater depths, surface electric and magnetic field data covering a range of frequencies can provide information on the vertical profile of conductivity. Making such measurements with a line or a two-dimensional grid of instruments can in principle give a two- or three-dimensional picture of the subsurface electrical structure. Magnetotelluric investigations are usually applied to specific geophysical targets on a local to regional scale covering a few to several hundred kilometers.

A comparison method is geomagnetic depth sounding (GDS), which is based solely on the analysis of fluctuating magnetic field data collected at Earth's surface. Since GDS requires either measurements of, or assumptions about, the spatial scales of the inducing fields, it is generally applied on a global basis at long periods (hours to days) where a low-order spherical harmonic source is likely to be applicable. The analysis gives valuable information about the deep electrical structure of the Earth, down to as much as 1000 km depth.

A closely related topic occurs in applied or exploration geophysics where the objective is to obtain information about shallow subsurface structures, often for some economic purpose. Electromagnetic exploration equipment typically consists of an artificial source (e.g., electric or magnetic dipole) at the Earth's surface and one or more electric or magnetic receivers in either a fixed or airborne configuration. While the physical principles are identical to those for electromagnetic induction studies using the natural source, exploration practice and interpretation are often distinct, being driven by specific needs.

4.2 Theoretical Considerations

Electromagnetic induction is governed by the pre-Maxwell equations in which the magnetic effects of displacement currents are neglected. In the absence of an explicit source current density, these are

$$\nabla\cdot\mathbf{B}=0, \tag{6}$$

$$\nabla\times\mathbf{E}+\partial_t\mathbf{B}=\mathbf{0}, \tag{7}$$

$$\nabla\times\mathbf{B}-\mu_0\mathbf{J}=\mathbf{0}, \tag{8}$$

$$\mathbf{J}=\sigma\mathbf{E}, \tag{9}$$

where the symbols have their usual meaning and the magnetic permeability is assumed to have its free-space value everywhere (an excellent approximation for most Earth materials). As a consequence of the pre-Maxwell approximation, the electric current density is divergence-free.

Equations (7)–(9) can be combined to yield separate differential equations for the electric field and magnetic induction vectors:

$$\nabla\times\nabla\times\mathbf{E}+\mu_0\sigma\partial_t\mathbf{E}=\mathbf{0}, \tag{10}$$

$$\nabla\times\nabla\times\mathbf{B}-\frac{\nabla\sigma}{\sigma}\times\nabla\times\mathbf{B}+\mu_0\sigma\partial_t\mathbf{B}=\mathbf{0}. \tag{11}$$

These are the equations of electromagnetic induction and are diffusion equations analogous to those for the flow of heat.

In general, analytic solutions of Eqs. (10) and (11) are available only for one-dimensional (1D) conductivity structures, most often by considering a stack of horizontal layers and solving recursively for the fields in each in terms of exponential basis functions. For the simplest instance where the horizontal dimensions of the external, driving magnetic field are infinite (plane-wave approximation), as appears to be reasonable for magnetotelluric sounding at periods shorter than about 10^4 s or so, and when the structure is 1D, induced electric currents will only flow in the horizontal plane. This means that the vertical electric and magnetic fields must be zero everywhere.

Numerical solutions for two-dimensional (2D) structures are widely available using either finite-element, finite-difference, or integral-equation approaches. In this instance, the Cartesian form of Eqs. (6)–(9) may be separated into two independent modes that are described by distinct ordinary differential equations. The transverse electric (TE) mode is described by an electric field component in the invariant conductivity direction and the two orthogonal magnetic induction terms, so that electric currents circulate in horizontal planes. The transverse magnetic (TM) mode is given by the magnetic field component in the invariant conductivity direction and the two orthogonal electric field terms, so that electric currents may flow across the conductivity gradient and hence involve electric charges. Current magnetotelluric practice is centered on studies of 2D structures using the TM mode, which is relatively insensitive to weak three-dimensional (3D) effects. Numerical solutions for fully 3D structures are still in the experimental stage, being limited largely by computing technology (Hohmann, 1987).

Derivation of the electrical conductivity structure given a set of response functions and their associated errors is performed using either trial-and-error forward modeling techniques or a more formal inversion scheme. The latter yields both a model that fits best in some well-defined sense and, in many instances, an estimate of the resolution of the model features. Inversion is now routine for 1D data and is rapidly becoming standard for 2D situations as well.

4.3 Data Analysis

Typical magnetotelluric data consist of time series of the two horizontal electric field and the three magnetic field components collected at a number of sites. The electric field variations are usually measured with a sensitive voltmeter placed across long (~100 m) wires coupled to the Earth with a set of electrodes. The magnetic field variations may be sensed with either induction coils or fluxgate magnetometers.

Magnetotelluric data analysis is accomplished by estimating the elements of the response tensor relating the horizontal electric and magnetic field components in the frequency domain,

$$\begin{bmatrix}E_x\\E_y\end{bmatrix}=\begin{bmatrix}Z_{xx} & Z_{xy}\\Z_{yx} & Z_{yy}\end{bmatrix}\begin{bmatrix}B_x\\B_y\end{bmatrix}. \tag{12}$$

A similar relation between the vertical and two horizontal magnetic field components is also of interest. The response tensor is typically computed using time-series analysis methods covered in standard texts. However, considerable recent progress has been made with robust processing algorithms (Chave and Thomson, 1989) that are relatively insensitive to the dramatically non-Gaussian form of natural electromagnetic variations, yielding much more reliable results than more conventional approaches. In addition, uncorrelated noise on the magnetometer channels in Eq. (12) will inevitably bias the response functions downwards, and can be dealt with using a remote reference method with a second, auxiliary magnetometer.

The response tensor in Eq. (12) possesses symmetry properties that depend on the dimensionality of the underlying conductivity structure. For a 1D earth, the diagonal elements will be zero to within the experimental errors, while the off-diagonal elements will be identical. For a 2D earth, the tensor can be rotated so that the diagonal elements vanish and the off-diagonal terms are unequal; the rotation angle gives the strike direction (the direction of the projection onto Earth's surface) of any subsurface anomaly, with a 90° ambiguity that can be removed using the vertical field measurement. For a 3D earth, the tensor has no special symmetries. In many instances, a good model for the Earth may consist of a regional 1D or 2D structure distorted by near-surface 3D galvanic effects, and special tensor decompositions exist to remove the surface distortion (Groom and Bailey, 1989).

4.4 Conductivity Structures

At low temperatures, the electrical conductivity of rocks is usually controlled by the mobility of ions in pore fluids and hence depends on the amount and connectedness of interstitial fluids. At higher temperatures (> 600 °C), electronic conduction mechanisms become important, and at temperatures above the solidus, partial melting may occur, resulting in a dramatic rise in conductivity. In general, electrical conductivity mechanisms are exponentially thermally activated, so that even if a number of mechanisms are possible, one will typically be dominant for a given set of physicochemical conditions. The range of electrical conductivity in Earth materials covers at least eight decades, more than any other

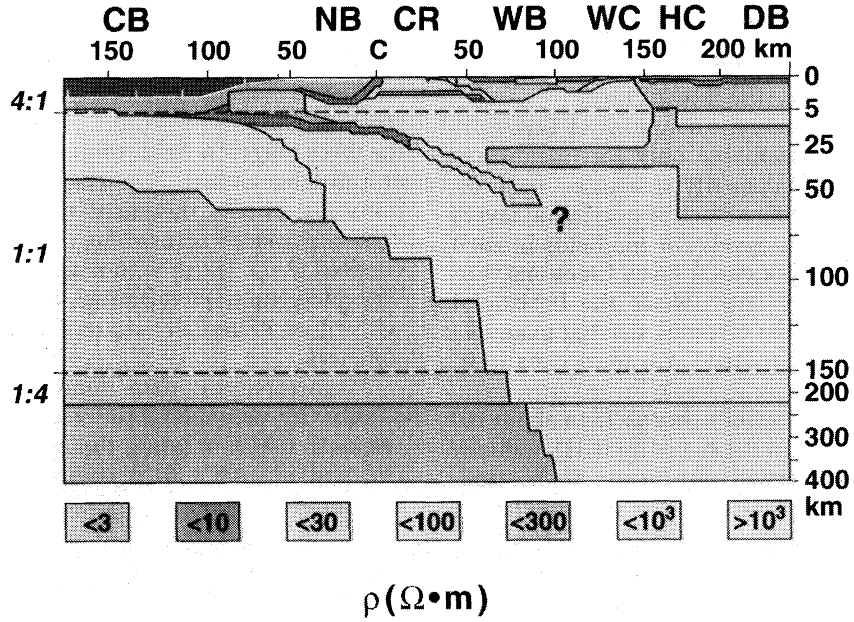

FIG. 8. East–west electrical resistivity cross section derived by forward modeling of magnetotelluric data taken from the Pacific Ocean to east of the Cascade Mountains in central Oregon during the EMSLAB Project. The seafloor portion of the model is shown only to 175 km offshore, beyond which changes are minor (note vertical exaggerations at 5 and 150 km depth). The geologic regions that the transect crossed include the Cascade Basin (CB), Newport Basin (NB), Coast Range (CR), Willamette Basin (WB), Western Cascades (WC), High Cascades (HC), and Deschutes Basin (DB). From Wannamaker *et al.* (1989).

physical parameter used to define such natural materials. Typical values range from 3 S/m, typical of seawater or moderately molten rock, down to 10^{-6} S/m at the top of crystalline pre-Cambrian shields.

The electrical conductivity structure of the Earth is quite heterogeneous in the uppermost 100 km or so on land, reflecting its complex geologic history. The largest coordinated magnetotelluric experiment ever performed is the EMSLAB effort in the Pacific Northwest, where a transect starting 400 km offshore at the Juan de Fuca Ridge was continued across the shoreline and to the eastern side of the Cascade Mountains. A 2D conductivity structure down to 200 km depth constructed from the TM mode data from this investigation is shown in Fig. 8. A key feature is a moderately conductive layer dipping at $\approx 20°$ under the Coast Range, which can be traced to about 100 km inland. This is due to subduction of the Juan de Fuca plate at the coast, and the enhanced conductivity is caused by dewatering of seafloor sediments and crust at the detachment fault. Another high-conductivity zone occurs under the Cascade Mountains, presumably due to enhanced temperature and partial melting associated with orogeny.

Global geomagnetic studies have yielded information about the electrical conductivity down to more than 1000 km depth. While details are elusive, there are suggestions for abrupt increases in conductivity associated with phase-transition–induced seismic velocity changes that have been detected at 350 and 650 km. Recent emphasis has been on detecting lateral heterogeneity of the deep electrical structure of the Earth associated with mantle dynamics.

4.5 Oceanic Studies

Oceanic electromagnetic induction differs from its continental counterpart in two important ways. First, the overlying, conductive seawater layer markedly attenuates the incident ionosphere-produced magnetic field changes at periods shorter than a fraction of an hour; thus the high-frequency magnetotelluric fields that are usable on land cannot be employed for studies at sea. Second, electric fields are induced by the motion of the conductive seawater through Earth's magnetic field at periods longer than a day. While the former means that stand-alone oceanic magnetotelluric studies will have limited resolution, the inclusion of offshore data is essential for land studies near coastlines. The ocean serves as an efficient collector of electromagnetic fields, and the extent to which electric currents in the ocean leak into the continent and down to the conductive deep mantle has a dominant effect on magnetotelluric data to distances of hundreds of kilometers inland.

There is increasing interest in physical oceanographic applications of electromagnetic methods since the electric field at periods longer than a day yields a spatially averaged measure of the water velocity. It can be shown that the horizontal electric field is proportional to the seawater-conductivity–weighted velocity integrated from seafloor to sea surface and averaged over a radius of a few times the water depth. This is effectively the depth-averaged (barotropic) velocity in most of the oceans, a quantity that is difficult to measure with conventional instrumentation. A recent study of the oceanic response to wind forcing (which is barotropic at periods shorter than ~100 days) based on electric field measurements is described in Chave *et al.* (1992). When a seafloor cable is employed, the velocity field is averaged horizontally as well, effectively giving the transport through an ocean section (Larsen, 1992).

GLOSSARY

Aurora: Lights in the upper atmosphere (from about 90 to 300 km altitude) produced by the excitation of atmospheric gases by energetic particles; the localized areas in the two polar regions where aurorae are typically observed are determined by the detailed topology of the magnetosphere.

Core: The center portion of the Earth. Probably composed of an iron–nickel alloy. Divided into two parts: the inner core is a solid (with mushy surface) with radius approximately 1220 km; the outer core is liquid with radius of approximately 3480 km.

Crust: The outermost, solid, layer of the Earth. Its thickness is about 5 km in oceanic areas and between 15 and 70 km in continental areas. The lower boundary of the crust is the Mohorovicic seismic discontinuity (or Moho).

Ferrimagnetic: A substance, generally an iron oxide, that has a strong magnetization because the strength of its antiparallel magnetic lattices is stronger in one direction than in others. The magnetization may be either permanent (remanent) or induced or both.

Ionosphere: Ionized region of the upper atmosphere, generally from about 90 to about 1000 km in altitude; the area beyond this is defined as the magnetosphere.

Magnetic Induction: The diffusionlike process by which electromagnetic fields are produced by a time-varying external magnetic field.

Magnetic Storm: A worldwide variation in the geomagnetic field. Near the Earth a storm typically has the following character in the horizontal field component: (1) sudden commencement or sudden sharp increase in magnitude (not all storms have this), (2) main phase or decrease in magnitude over a period of a few hours, (3) recovery phase or increase of the field to its prestorm or quiet level, typically taking one to four days.

Magnetization: Magnetic moment per unit volume. Rock magnetization may be either permanent (remanent; that is, "frozen" into the rock as it last cooled) or induced (a response of the rock to its ambient magnetic field).

Magnetopause: Boundary between the flowing solar-wind plasma and the magnetosphere.

Magnetosphere: Region of space around the Earth in which the terrestrial magnetic and electric fields usually dominate the transport and motions of charged particles.

Magnetotail: Region of the magnetosphere in the antisunward direction: if visible, the magnetotail would have characteristics like the tail of a comet.

Magnetotellurics: A method for inferring the electrical structure of the Earth using measurements of the time variations of electric and magnetic fields at Earth's surface.

Mantle: The region of the Earth between the core and crust; it has a thickness of about 2300 km.

Motional Induction: The diffusionlike process by which electromagnetic fields are induced by the motion of moving, conducting seawater through Earth's magnetic field. This differs from the core dynamo process in that the water motions are not affected by the induced fields (i.e., the Lorentz force is negligible).

Plasma: Gas (atomic and/or molecular species) that is ionized. Naturally occurring plasmas usually contain magnetic fields.

Solar Wind: Expansion of the solar corona, primarily hydrogen ions, into the interplanetary medium.

Substorm: Interval of one to three hours of auroral, geomagnetic, and magnetospheric activity, usually followed by a several-hour interval of relative quiescence.

Sunspot Cycles: Variation with time of the appearance of the number of sunspot groups on the visible solar photosphere.

INTRODUCTION

The word "geometry" derives from Greek, meaning "earth measurement." Geometry was originally the mathematics describing the shapes of objects and their spatial relationships. Simple geometrical notions and ideas were known to ancient Babylonians and Egyptians 4000 years ago. Starting approximately 2500 years ago, the ancient Greeks developed fundamental geometrical ideas, including some relatively rigorous proofs based on logical reasoning. Dating from this era is Euclid's *Elements*, which introduced the basis for the axiomatic method and summarizes the knowledge at that time.

Prior to the sixteenth century, geometry and algebra were treated as independent subjects. The notion of combining the two was introduced in 1631 by René Descartes (1596–1650). This led to the field of analytic geometry, which permits the investigation of geometric questions using analytical methods. This area was extensively investigated in the eighteenth century, in particular by Leonhard Euler (1707–1783) and Gaspard Monge (1746–1818). Toward the end of the eighteenth century the use of calculus resulted in the beginnings of differential geometry, studied by Christian Gauss (1777–1855) and others. The introduction by Bernhard Riemann (1826–1866) of the theory of algebraic functions initiated the field of algebraic geometry. In parallel with these developments, the synthetic approach to geometry was extended by Victor Poncelet (1788–1867), who formulated postulates for projective geometry. In the past century and a half, the work of David Hilbert (1862–1943) and others has led to an extension of the scope of geometry to include the study of geometrical relationships between abstract quantities.

This article presents material concerning analytical, differential, projective, and algebraic geometry. The choice of topics and their depth of coverage were dictated primarily by consideration of their importance in applied physics and by limitations of space. In particular, the reader is warned that the weighting assigned to the topics discussed is uncorrelated with their present importance as mathematical fields of research. The treatment is not mathematically rigorous, but introduces sufficient mathematical terminology to make basic textbooks in the subject accessible. Some

of these are listed in the references at the end of the article.

1. ANALYTIC GEOMETRY

The underlying concepts of analytic geometry are the simple geometric elements: points, lines and curves, planes and surfaces, and extensions to higher dimensions. The fundamental method is the use of coordinates to convert geometrical questions into algebraic ones. This is called the "method of coordinates."

To illustrate the basic notion, consider a straight line l. Following the method of coordinates, select one point O on l as the origin. This separates l into two halves. Call one half positive, the other negative. Any point P on the line can then be labeled by a real number, given by the distance OP for the positive half and by the negative of the distance OP for the negative half. There is thus a unique real number x assigned to every point P on l, called the Cartesian coordinate of P. Geometrical questions about the line can now be transcribed into analytical ones involving x.

1.1 Plane Analytic Geometry

In two dimensions, basic geometric entities include points, lines, and planes. For a plane π the method of coordinates provides to each point P an assignment of two real numbers, obtained as follows. Take two straight lines in the plane, and attribute Cartesian coordinates to each line as described above. For simplicity, the lines will be assumed perpendicular and intersecting at their origins. These lines are called rectangular coordinate axes, and the Cartesian coordinates of the first are called abscissae while those of the second are called ordinates. The lines themselves are also referred to as the abscissa and the ordinate. The location of a point P on π is then specified uniquely by two real numbers, written (x,y). The number x is defined as the perpendicular distance to the first coordinate axis, while y is the distance to the second. Using these Cartesian coordinates, geometrical questions about points can be expressed in analytical terms. For example, a formula for the distance d between two points P and Q specified by the coordinates (x_1,y_1) and (x_2,y_2) is

$$d=\sqrt{(x_1-x_2)^2+(y_1-y_2)^2}. \tag{1}$$

Given an assignment of Cartesian coordinates on a plane π, a curve segment s in the plane may be analytically specified by providing a set of paired real numbers (x,y) assigned to all points on the curve. In many useful cases, s can be specified by an equation $f(x,y)=0$ between x and y that is satisfied by all points P on s but not by any other points on π. For example, the equation $x=0$ describes the straight line consisting of all points having coordinates of the form $(0,y)$, i.e., the ordinate. The method of coordinates thus permits geometrical questions about s to be transcribed into analytical ones concerning $f(x,y)$. For example, the set of points lying both on a curve $f(x,y)=0$ and on another curve $g(x,y)=0$ is specified by values (x,y) satisfying both equations, which can in principle be found by analytical methods.

A simple example of a curve in the plane is a straight line l. The slope m of l can be defined in terms of the coordinates (x_1,y_1) and (x_2,y_2) of any two distinct points on l. Provided $x_1 \neq x_2$, the slope is given by

$$m=\frac{y_1-y_2}{x_1-x_2}. \tag{2}$$

The slope is zero for lines parallel to the abscissa, and is undefined (infinite) for lines parallel to the ordinate. A line l with given finite slope m is uniquely specified by its intersection point $(x,y)=(0,c)$ with the ordinate. The equation for l is

$$y=mx+c. \tag{3}$$

If l is parallel to the ordinate instead, it is determined by its intersection point $(x,y)=(a,0)$ with the abscissa, and its equation is simply $x=a$.

The equation of a straight line l is also determined entirely by the coordinates (x_1,y_1) and (x_2,y_2) of any two distinct points on l. It can be written

$$\frac{y-y_1}{y_2-y_1}=\frac{x-x_1}{x_2-x_1}. \tag{4}$$

Alternatively, a straight line can be viewed as the curve given by the most general equation linear in the coordinates x and y:

$$Ax+By+C=0, \tag{5}$$

where at least one of A and B is nonzero.

Analytical solutions to geometrical problems involving straight lines and points can be obtained using the above results. For example, the equation of the line l_P that is perpendicular to a given line l with equation $y=mx+c$ and that passes through the point P on l with abscissa x_1 is

$$y=-\frac{1}{m}x+\frac{m^2+1}{m}x_1+c. \tag{6}$$

Another example is the expression for the perpendicular distance d_P between a line l with equation $y=mx+c$ and a point P at (a,b), which is

$$d_P=|b-ma-c|/\sqrt{m^2+1}. \tag{7}$$

1.2 Conic Sections

An important curve is the circle, denoted by S^1, which can be viewed as the set of points in the plane that are equidistant from a specified fixed point. The fixed point C is called the center of the circle, and the distance r between the center and the points on the circle is called the radius. If the Cartesian coordinates of C are (h,k), then the equation of the circle is

$$(x-h)^2+(y-k)^2=r^2. \tag{8}$$

The circle is a special case of a set of curves called conic sections or conics. These curves include ellipses, parabolas, and hyperbolas. Geometrically, the conics can be introduced as the curves obtained by slicing a right circular cone with a plane. Analytically, they can be viewed as the curves given by the most general expression quadratic in the coordinates x and y:

$$Ax^2+Bxy+Cy^2+Dx+Ey+F=0, \tag{9}$$

where at least one of the coefficients A, B, C is nonzero. These are called second-order curves. From this equation it follows that any five points lying on the conic specify it completely. The quantity B^2-4AC is called the discriminant of the conic. If the discriminant is positive, the conic is a hyperbola; if negative, an ellipse; and if zero, a parabola.

A third definition, combining geometrical and analytical notions, is often useful. Consider a straight line l, a fixed point F not on l, and another point P. Denote the distance between P and F by d_F and the perpendicular distance between P and l by d_l. Then the conic sections are given by the set of points P that obey the equation

$$d_F=ed_l, \tag{10}$$

where $e \geqslant 0$ is a constant real number called the eccentricity. The line l is called the directrix and the point F is called the focus. If $e>1$, the conic is a hyperbola. If $e=1$, the conic is a parabola. If $0<e<1$, the conic is an ellipse. The degenerate case $e=0$ gives a circle; in this case, the directrix is at infinity.

The equation determining a conic has a particularly simple form, called the canonical form, if the focus F is chosen to lie on the abscissa and the directrix l is chosen parallel to the ordinate. The canonical form depends on at most two real positive parameters a and b, where $a \geqslant b$ is taken for convenience.

For a hyperbola, the canonical form is

$$(x^2/a^2)-(y^2/b^2)=1. \tag{11}$$

The eccentricity of the hyperbola is $e=\sqrt{a^2+b^2}/a$. One focus is the point $(ae,0)$, and the corresponding directrix is the line $x=a/e$. There is a second focus at $(-ae,0)$ and a second directrix at $x=-a/e$. The hyperbola has two branches, each of which asymptotically approaches the lines $y=\pm bx/a$ as $|x|$ becomes large. The distance between the points where the hyperbola intersects the abscissa is $2a$. This is also the difference between the distances from the two foci to any given point on the hyperbola. If $a=b$, the hyperbola is called rectangular.

For a parabola, the canonical form is

$$y^2=4ax. \tag{12}$$

The eccentricity is $e=1$, the focus is at $(a,0)$, and the directrix is the line $x=-a$.

For an ellipse, the canonical form is

$$(x^2/a^2)+(y^2/b^2)=1. \tag{13}$$

The ellipse has eccentricity $e=\sqrt{a^2-b^2}/a$. There are again two foci, at $(\pm ae,0)$, and two directrices $x=\pm a/e$. The sum of the distances from the two foci to any given point on the ellipse is a constant, $2a$. The line between the points of intersection of the ellipse with the abscissa is called the major axis of the ellipse, and it has length $2a$. Similarly, the minor axis of the ellipse is given by the intersection points with the ordinate and has length $2b$. If

$a=b$ the equation reduces to that of a circle of radius a centered at the origin.

1.3 Plane Trigonometry

Consider a point P with coordinates (x,y) lying on a circle of radius r centered at the origin O. Denote by X the point $(x,0)$. Call θ the angle XOP between the line segments OX and OP. The choice of a unit of measure for angles permits the assignment of a numerical value to θ. One widely used unit is the degree, defined by the statement that there are 360 degrees in a circle. The SI unit is the radian, of which there are 2π in a circle.

Certain functions of the angle θ, called trigonometric or circular functions, are of particular use in plane analytic geometry. The ratio $\sin\theta=y/r$ is called the sine of θ while $\cos\theta=x/r$ is called the cosine of θ. The sine is odd in θ while the cosine is even, and both functions have period π radians. They obey the relations

$$\sin^2\theta+\cos^2\theta=1 \tag{14}$$

following from the Pythagorean theorem, and

$$\sin(\theta\pm\phi)=\sin\theta\,\cos\phi\pm\sin\phi\,\cos\theta, \tag{15}$$

$$\cos(\theta\pm\phi)=\cos\theta\,\cos\phi\mp\sin\theta\,\sin\phi. \tag{16}$$

The latter two equations are called addition formulas. Other, related functions of θ include the tangent $\tan\theta=y/x=\sin\theta/\cos\theta$, the cosecant $\csc\theta=r/y=1/\sin\theta$, the secant $\sec\theta=r/x=1/\cos\theta$, and the cotangent $\cot\theta=x/y=\cos\theta/\sin\theta$. From these definitions and the above equations many identities can be obtained. Inverse trigonometric functions can also be introduced; for example, if $x=\sin\theta$ then $\sin^{-1}x=\theta$.

Consider a triangle with angles A, B, C and sides of length a, b, c, where by convention the side labeled by a is opposite the vertex with angle A and there are similar conventions for the other sides. A basic problem in plane trigonometry is to determine one of a, b, c, A, B, C in terms of the others. This is called solving a triangle. The following relations hold: the law of sines,

$$\frac{\sin A}{a}=\frac{\sin B}{b}=\frac{\sin C}{c}; \tag{17}$$

the first law of cosines,

$$a=b\cos C+c\cos B; \tag{18}$$

and the second law of cosines,

$$a^2=b^2+c^2-2bc\cos A. \tag{19}$$

1.4 Curvilinear Coordinates

For certain geometrical problems, the analytical details of a calculation may be simplified if a non-Cartesian coordinate system is used. Consider two functions $u=u(x,y)$ and $v=v(x,y)$ of the Cartesian coordinates x and y on a plane π. Take the functions to be continuous and invertible, except perhaps at certain special points that require separate treatment. Any curve $u=c$ for some constant c is called a coordinate curve, as is any curve $v=c$. A point P on π is uniquely specified by two real numbers (u_1,v_1) that are the values of the constants determining the two coordinate curves passing through P. This construction generalizes the method of coordinates, and the functions u and v are called curvilinear coordinates. If the coordinate curves meet at right angles, the curvilinear coordinates are called orthogonal. All the analytical geometry described above using Cartesian coordinates can be rephrased using orthogonal curvilinear coordinates.

An important set of orthogonal curvilinear coordinates is generated by the equations

$$x=r\cos\theta,\quad y=r\sin\theta;$$

$$r=\sqrt{x^2+y^2},\quad \theta=\tan^{-1}(y/x), \tag{20}$$

where $r\geqslant 0$ and $0\leqslant\theta<2\pi$. In this system, the coordinate curves consist of circles of varying radii centered at the origin and straight lines through the origin at varying angles with respect to the abscissa. The coordinates (r,θ) of a point P are called plane polar coordinates. As an illustration of their use, consider the conic sections expressed in polar coordinates. In canonical form, with the origin of the polar coordinates placed at the focus at $(ae,0)$, the equation for a conic section is

$$r=l/(1+e\cos\theta), \tag{21}$$

where l is called the latus rectum. It is given by $l=b^2/a$ for hyperbolas and ellipses and by $l=2a$ for parabolas, and it represents the distance from the focus to the curve as measured along a straight line parallel to the ordinate. The quantity l/e is the distance from the focus to the associated directrix.

The conic sections themselves can be used to generate systems of orthogonal curvilinear coordinates. For example, parabolic coordinates can be defined by

$$x=\tfrac{1}{2}(u^2-v^2), \quad y=uv, \tag{22}$$

where $v \geqslant 0$. The coordinate curves are parabolas. Similarly, elliptic coordinates can be defined by

$$x=a \cosh u \cos v, \quad y=a \sinh u \sin v, \tag{23}$$

where $u \geqslant 0$ and $0 \leqslant v < 2\pi$. Here, the so-called hyperbolic functions $\sinh u$ and $\cosh u$ are defined by

$$\sinh u=\tfrac{1}{2}(e^u-e^{-u}), \quad \cosh u=\tfrac{1}{2}(e^u+e^{-u}). \tag{24}$$

The coordinate curves are ellipses and hyperbolas. Another common set is the system of bipolar coordinates, defined by

$$x=\frac{a \sinh v}{\cosh v-\cos u}, \quad y=\frac{a \sin u}{\cosh v-\cos u}, \tag{25}$$

with $0 \leqslant u < 2\pi$. The coordinate curves are sets of intersecting circles.

1.5 Solid Analytic Geometry

Solid analytic geometry involves the study of geometry in three dimensions rather than two. Many of the ideas of plane analytic geometry extend to three dimensions. For instance, the method of coordinates now provides an assignment of three real numbers (x,y,z) to each point P. A three-dimensional rectangular coordinate system can be introduced by taking three mutually perpendicular straight lines, each given Cartesian coordinates, to form the coordinate axes. The axes are called the abscissa, the ordinate, and the applicate. Each of the values (x,y,z) is defined as the perpendicular distance to the corresponding axis.

A two-dimensional surface σ can now be specified by providing an equation $f(x,y,z)=0$ that is satisfied only by points on the surface. The method of coordinates thus converts geometrical questions about σ to analytical questions about $f(x,y,z)$. Similarly, a curve s can be viewed as the intersection set of two surfaces. If the surfaces are specified by the equations $f(x,y,z)=0$ and $g(x,y,z)=0$, s is given analytically by the set of points (x,y,z) obeying both equations simultaneously.

By definition, a surface of the first order is given by the most general equation linear in x, y, z:

$$Ax+By+Cz+D=0. \tag{26}$$

If at least one of A, B, C is nonzero, this equation describes a plane. A straight line can be viewed as the intersection of two nonparallel planes and is therefore given analytically by two equations of this form. Just as in the two-dimensional case, the analytical formulation allows solutions to geometrical questions involving planes, lines, and points to be obtained. For example, the perpendicular distance d_P between a plane given by the above equation and a point P located at (a,b,c) can be shown to be

$$d_P=\frac{|Aa+Bb+Cc+D|}{\sqrt{A^2+B^2+C^2}}. \tag{27}$$

As another example, two planes given by

$$A_1x+B_1y+C_1z+D_1=0,$$

$$A_2x+B_2y+C_2z+D_2=0 \tag{28}$$

are parallel if and only if

$$(A_1,B_1,C_1)=(cA_2,cB_2,cC_2) \tag{29}$$

for some constant c.

In analogy to the two-dimensional introduction of conics as curves obeying a quadratic expression in x and y, a surface of the second order is defined to consist of points satisfying a quadratic expression in x, y, and z:

$$Ax^2+By^2+Cz^2+Dxy+Exz+Fyz+Gx +Hy+Iz+J=0. \tag{30}$$

Such surfaces are also called quadrics. An important example is the sphere, denoted by S^2, which can be viewed as the set of points equidistant from a fixed point called the center. The distance from the center to any point on the sphere is called the radius. If the Cartesian coordinates of the center are (h,k,l), the equation of a sphere of radius r is

$$(x-h)^2+(y-k)^2+(z-l)^2=r^2. \tag{31}$$

The quadrics can be classified. Among the surfaces described are ellipsoids, hyperboloids, paraboloids, cylinders, and cones. Canonical forms of these surfaces are

$$(x^2/a^2)+(y^2/b^2)+(z^2/c^2)=1 \tag{32}$$

for an ellipsoid;

$$(x^2/a^2)+(y^2/b^2)-(z^2/c^2)=1 \tag{33}$$

for a hyperboloid of one sheet;

$$(x^2/a^2)-(y^2/b^2)-(z^2/c^2)=1 \tag{34}$$

for a hyperboloid of two sheets;

$$(x^2/a^2)+(y^2/b^2)=2z \tag{35}$$

for an elliptic paraboloid;

$$(x^2/a^2)-(y^2/b^2)=2z \tag{36}$$

for a hyperbolic paraboloid;

$$(x^2/a^2)+(y^2/b^2)=1 \tag{37}$$

for an elliptic cylinder;

$$(x^2/a^2)-(y^2/b^2)=1 \tag{38}$$

for a hyperbolic cylinder;

$$(x^2/a^2)=2z \tag{39}$$

for a parabolic cylinder; and

$$(x^2/a^2)\pm(y^2/b^2)-(z^2/c^2)=0 \tag{40}$$

for a cone. The parameters a, b, c are called the lengths of the principal axes of the quadric.

The notions of plane trigonometry also extend to three dimensions. A spherical triangle is defined as a portion of a spherical surface that is bounded by three arcs of great circles. Denote by A, B, C the angles generated by straight lines tangent to the great circles intersecting at the vertices, and call the lengths of the opposite sides a, b, c as for the planar case. The angles now add up to more than π radians, by an amount called the spherical excess E:

$$A+B+C=\pi+E. \tag{41}$$

The following relations hold for a spherical triangle: the law of sines,

$$\frac{\sin A}{\sin a}=\frac{\sin B}{\sin b}=\frac{\sin C}{\sin c}; \tag{42}$$

the first law of cosines,

$$\cos a=\cos b\cos c+\sin b\sin c\cos A; \tag{43}$$

and the second law of cosines,

$$\cos A=-\cos B\cos C+\sin B\sin C\cos a. \tag{44}$$

Curvilinear coordinates can be introduced via three locally continuous invertible functions $u(x,y,z)$, $v(x,y,z)$, $w(x,y,z)$, following the two-dimensional case. A coordinate surface is specified by setting any curvilinear coordinate u, v, or w equal to a constant. The coordinate curves are generated by the intersection of the coordinate surfaces, and the system is said to be orthogonal if the surfaces intersect at right angles. Many useful three-dimensional orthogonal curvilinear coordinate systems can be generated from families of quadrics. One particularly useful set is the system of spherical polar coordinates, defined by

$$\begin{gathered} x=r\sin\theta\cos\phi,\\ y=r\sin\theta\sin\phi,\\ z=r\cos\theta, \end{gathered} \tag{45}$$

where $r\geqslant 0$, $0\leqslant\theta\leqslant\pi$, and $0\leqslant\phi<2\pi$. The coordinate surfaces are spheres centered at the origin, right circular cones with axes along the applicate and vertices at the origin, and half-planes with the applicate as one edge. Other common coordinates are the cylindrical coordinates, given by

$$x=r\cos\theta,\quad y=r\sin\theta,\quad z=z, \tag{46}$$

where $r\geqslant 0$ and $0\leqslant\theta<2\pi$. This system is generated from plane polar coordinates by translation along the applicate. The coordinate surfaces are right circular cylinders centered at the origin, half-planes with the applicate as one edge, and planes parallel to the plane of the abscissa and ordinate.

The notions of plane and solid analytic geometry can be extended to higher dimensions, too. A space can be defined in which the method of coordinates specifies a point by n real numbers $(x^1,x^2,\dots,x^n)$. This n-dimensional space, called Euclidean space, is denoted by the symbol R^n. Using coordinates, geometrical questions in n dimensions can be converted to analytical ones involving functions of n variables. Surfaces of the first order are $(n-1)$-dimensional hyperplanes, and surfaces of the second order, or quadric hypersurfaces, can be introduced. An example is the hypersphere of radius r in n dimensions, denoted by S^{n-1}, which when centered at the origin satisfies the equation

$$(x^1)^2+(x^2)^2+\cdots+(x^n)^2=r^2. \tag{47}$$

The notion of curvilinear coordinates also extends to higher dimensions.

A one-dimensional curve s in n dimensions can be specified by $n-1$ equations among the n coordinates $(x^1,...,x^n)$. If s is continuous, its points can be labeled by a parameter t that is a real number. Any particular point can be specified by giving the values of the n coordinates $(x^1,...,x^n)$. As t varies, so do the coordinates. This means that an alternative specification of s can be given in terms of the n expressions

$$x^j=x^j(t), \quad j=1,...,n, \tag{48}$$

determining the n coordinates $(x^1,...,x^n)$ as functions of t. This is called the parametric representation of a curve. Similarly, the points of a continuous two-dimensional surface can be labeled by two real numbers (t^1,t^2). The surface can be specified either in terms of $n-2$ equations among the n coordinates $(x^1,...,x^n)$ or in parametric form by the n equations

$$x^j=x^j(t^1,t^2), \quad j=1,...,n. \tag{49}$$

A parametric representation can also be given for continuous surfaces of more than two dimensions.

1.6 Example: The Kepler Problem

An example of the appearance of analytic geometry in a physical problem occurs in the study of the classical motion of two bodies under a mutual inverse-square attractive force. Consider for definiteness two bodies of masses m_1 and m_2, each acted on by the gravitational field of the other and free to move in three dimensions. This is called the Kepler problem.

The first step is to introduce a convenient coordinate system. For simplicity, the origin can be placed on one mass. The problem can then be reduced to determining the relative position of the second mass and the uniform motion of the center of mass. The latter is neglected here for simplicity. It is natural to select a system of spherical polar coordinates with the applicate along the direction of the angular momentum. Since angular momentum is conserved, the motion of the second mass about the origin must lie in a plane. This means that plane polar coordinates (r,θ) suffice to describe the position of the second mass relative to the first.

It can be shown that the resulting equations governing the motion of the second mass are precisely those obtained for the behavior of a reduced mass $m=m_1m_2/(m_1+m_2)$ orbiting a fixed center of force. In polar coordinates, the kinetic energy T of the reduced mass is

$$T=\tfrac{1}{2}m(\dot{r}^2+r^2\dot{\theta}^2), \tag{50}$$

where a dot over a letter signifies a derivative with respect to time. The potential energy is

$$V=-k/r \tag{51}$$

with $k=Gm_1m_2$, where G is Newton's gravitational constant.

The equations of motion are

$$\frac{d}{dt}(mr^2\dot{\theta})=0 \tag{52}$$

and

$$m\ddot{r}-mr\dot{\theta}^2+(k/r^2)=0. \tag{53}$$

The first of these integrates immediately in terms of the constant magnitude L of the angular momentum:

$$mr^2\dot{\theta}=L. \tag{54}$$

This equation can be used to eliminate $\dot{\theta}$ from Eq. (53) by direct substitution. Also, since

$$\frac{d}{dt}=\dot{\theta}\frac{d}{d\theta}, \tag{55}$$

the independent variable in Eq. (53) can be converted from time t to angle θ. An additional change of dependent variable from r to

$$s=(1/r)-(mk/L^2) \tag{56}$$

converts Eq. (53) into the simple form

$$\frac{d^2s}{d\theta^2}=-s. \tag{57}$$

The solution is readily found. Reconverting s to the variable r yields the equation for the orbit as

$$r=l/(1+e\cos\theta), \tag{58}$$

where a particular choice for the location of the abscissa relative to the orbit has been made for simplicity. In this equation,

$$e=\sqrt{1+2EL^2/mk^2},\quad l=L^2/mk, \tag{59}$$

and E can be identified with the energy of the two bodies in the orbit. This demonstrates that the motion of two masses under gravity is described by a conic section; cf. Eq. (21). The energy E determines the shape of the orbit. If $E>0$, $e>1$ and the orbit is a hyperbola. If $E=0$, $e=1$ and the orbit is a parabola. If $E<0$, $e<1$ and the orbit is an ellipse. Finally, if $E=-mk^2/2L^2$, $e=0$ and the orbit is a circle.

2. DIFFERENTIAL GEOMETRY

The requirement of differentiability provides a restriction on geometrical objects that is sufficiently tight for new and useful results to be obtained and sufficiently loose to include plenty of interesting cases. Differential geometry is of vital importance in physics because many physical problems involve variables that are both continuous and differentiable throughout their range.

2.1 Manifolds

A manifold is an extension of the usual notions of curves and surfaces to arbitrary dimensions. The basic idea is to introduce an n-dimensional manifold as a space that is like Euclidean space R^n locally, i.e., near each point. Globally, i.e., taken as a whole, a manifold may be very different from R^n. An example of a one-dimensional manifold is a straight line. This is both locally and globally like R^1. Another one-dimensional example is a circle S^1. The neighborhood of each point on a circle looks like the neighborhood of a point in R^1, but globally the two are different. The circle can be constructed by taking two pieces of R^1, bending them, and attaching them smoothly at each end. Generalized to n dimensions, this notion of taking pieces of R^n and attaching them smoothly forms the basis for the definition of a manifold.

To define a manifold more rigorously, first introduce the concept of a topological space T. This is a set S and a collection t of (open) subsets of S satisfying the following criteria:

1. Both the null set and S itself are in t.
2. The intersection of any two subsets of t is in t.
3. The union of any collection of subsets of t is in t.

Suppose in addition there is a criterion of separability: For any two elements of S there exist two disjoint subsets of S, each containing one of the elements. Then T is called a Hausdorff space. The elements of S for a manifold are its points.

Next, define a chart C of the set S as a subset U of S, called a neighborhood, together with a continuous invertible map $f:U\to R^n$ called the coordinate function. For a manifold, the subset U plays the role of a region locally like R^n, and the function f represents the introduction of local coordinates in that region. Two charts C_1, C_2 with overlapping neighborhoods and coordinate functions f_1, f_2 are called compatible if the composition map $f_1\circ f_2^{-1}$ is differentiable. The requirement of compatibility basically ensures that the transition from one coordinate patch to another is smooth. A set of compatible charts covering S is called an atlas.

A differentiable manifold M can now be defined as a Hausdorff topological space with an atlas. Given that the range of the coordinate functions is R^n, the dimension of M is defined as n and M is sometimes denoted by M^n. An example of an n-dimensional manifold is the hypersphere S^n. An example of an object that is *not* a manifold is a figure-eight curve, since the neighborhood of the intersection point is not locally like R^n for any n.

2.2 Vectors and One-Forms

The usual definition of a vector in a Euclidean space as a directed straight-line segment does not immediately extend to a general manifold. For instance, the circle S^1 does not contain any straight-line segments. Instead, vectors at a point of a manifold can be introduced using the notion of the tangents to curves passing through the point.

Consider a curve s through a point P. In a neighborhood of P, local coordinates $(x^1,\dots,x^n)$ can be used to specify s in the parametric representation $x^j=x^j(t)$, $j=1,\dots,n$. A vector tangent to s at P can be specified by the n quantities dx^j/dt forming its components. A familiar example in mechanics is the velocity vector of a moving particle, obtained by differentiation with respect to time of the particle's position vector. If the tangent vectors to all possible curves in the manifold through P are considered, an n-dimensional vector space (see ALGEBRAIC METHODS, Sec. 3) is generated. This is called the tangent space T_PM to M at P.

In differential geometry, it is desirable to introduce basic concepts in a manner that is independent of any coordinate choice. For this reason, the differential-geometric definition of a tangent vector is different from the more intuitive one above. Given a curve s, introduce an arbitrary differentiable function f assigning a real number to every point t on s. The derivative df/dt of f along s is called the directional derivative. In a local coordinate patch,

$$\frac{df}{dt}=\sum_{j=1}^{n}\frac{dx^j}{dt}\partial_j f, \tag{60}$$

where $\partial_j f=\partial f/\partial x^j$. This shows that the operator d/dt acting on the space of real functions on M contains all components of the tangent vector, each associated with the corresponding partial derivative ∂_j. A tangent vector at P can therefore be defined as the directional-derivative operator d/dt, with a natural coordinate basis of vectors for the vector space being the set of partial-derivative operators $\{\partial_j\}$. However, this definition has the disadvantage that it still explicitly includes the parameter t.

The formal definition of a tangent vector is therefore slightly more abstract. Given the space $F(M)$ of all differentiable real functions on a manifold M, a tangent vector at P is defined as an object v acting on elements of $F(M)$ to produce real numbers,

$$v:F(M)\rightarrow R, \tag{61}$$

that satisfies two criteria:

$$v(af+bg)=av(f)+bf(g),$$

$$v(f\circ g)=g(P)v(f)+f(P)v(g), \tag{62}$$

where $f,g\in F(M)$ and $a,b\in R$. This definition extracts the important properties of the tangent vector without explicit reference to a coordinate system or parametrization. Note that the coordinate realization of a tangent vector at P along x_j as ∂_j acting at P satisfies this definition. The set of all linearly independent tangent vectors at P spans the tangent space T_PM to M at P, and the set $\{\partial_j\}$ forms a basis for T_PM called the coordinate basis. An arbitrary vector v can be expanded in this basis as $v=\Sigma_j v^j\partial_j$. Physicists sometimes say that the components v^j are the contravariant components of a vector. Although in a coordinate basis the intuitive physics notion of a vector and the differential-geometric one contain the same information about components, the latter also contains information about the coordinate basis itself. In the remainder of this article except where noted, the word vector refers to the differential-geometric object.

Since T_PM is a vector space, there exists a dual vector space $\mathrm{Hom}(T_PM,R)$ consisting of linear maps

$$\omega:T_PM\rightarrow R \tag{63}$$

(see ALGEBRAIC METHODS, Sec. 3.7). This space is called the cotangent space at P and is denoted by T^*_PM. Notice that duality also implies $T_PM=\mathrm{Hom}(T^*_PM,R)$. Elements of T^*_PM are called one-forms. An important example of a one-form is the total differential df of a function $f\in F(M)$, defined as the element of T^*_PM satisfying

$$df(v)=v(f) \tag{64}$$

for any $v\in T_PM$.

In a chart around P, the set $\{dx^j\}$ of total differentials of the coordinates forms a natural coordinate basis for the cotangent space T^*_PM. It is a dual basis to $\{\partial_j\}$, since

$$dx^j(\partial_k)=\partial_k x^j=\delta^j_k. \tag{65}$$

An arbitrary one-form ω can be expanded in the dual basis as $\omega=\Sigma_j\ \omega_j dx^j$. Note that for an arbitrary vector $v=\Sigma_j v^j\partial_j$ the action of ω on v is then

$$\omega(v)=\omega_j v^k dx^j(\partial_k)=\omega_j v^j. \tag{66}$$

In this equation and subsequent ones, the Einstein summation convention is introduced to simplify notation: Repeated indices in the same term are understood to be summed. The vector v is said to be contracted with the one-form ω. Physicists sometimes say the components ω^j form the covariant components of a vector. As an example, the definitions above can be used to show that

$$df=\partial_j f dx^j, \tag{67}$$

a standard result.

2.3 Tensors

The generalization of vectors and one-forms to tensors is straightforward. A tensor T of type (a,b) can be defined at a point P of a manifold M as a multilinear mapping of a one-forms and b vectors giving a real number:

$$T\colon T^*_P M \otimes \cdots \otimes T^*_P M \otimes T_P M \otimes \cdots \otimes T_P M \to R, \quad (68)$$

where there are a factors of $T^*_P M$ and b factors of $T_P M$. The space of tensors of type (a,b) at P is denoted $T^a_b(P)$. Examples introduced above include $T^1_0(P) = T_P M$ and $T^0_1(P) = T^*_P M$.

A tensor T of type (a,b) can be expanded using a coordinate basis. In the natural basis introduced above,

$$T = T^{j_1 j_2 \cdots j_a}_{k_1 k_2 \cdots k_b} \partial_{j_1} \cdots \partial_{j_a} dx^{k_1} \cdots dx^{k_b}. \quad (69)$$

Almost all physicists and the older mathematics literature call the quantities $T^{j_1 j_2 \cdots j_a}_{k_1 k_2 \cdots k_b}$ the components of an ath-rank contravariant and bth-rank covariant tensor. Most modern mathematicians by convention interchange the usage of contravariant and covariant. This article uses the physicists' convention.

A tensor is called symmetric with respect to two contravariant or two covariant indices if its components are unaltered when the indices are interchanged. A tensor with indices of only one type is said to be totally symmetric if it is symmetric with respect to all pairs of indices. Similarly, a tensor is antisymmetric with respect to two contravariant or two covariant indices if its components change sign when the indices are interchanged, and a totally antisymmetric tensor is one with pairwise-antisymmetric indices of only one type. The sum and difference of two tensors of the same type is another tensor of the same type. The tensor product $T_1 \otimes T_2$ of two tensors T_1 and T_2 of types (a_1,b_1) and (a_2,b_2), respectively, is a tensor of type (a_1+a_2,b_1+b_1) with components given by the product of components of T_1 and T_2 (see ALGEBRAIC METHODS, Sec. 3.8). Various contractions of two tensors can be introduced that generalize the contraction of a vector with a one-form.

A useful concept in physical applications is that of a tensor field of type (a,b), defined as a particular choice of tensor of type (a,b) at each point of M. The field is called smooth if the components $T^{j_1 j_2 \cdots j_a}_{k_1 k_2 \cdots k_b}$ of a tensor field are differentiable. Special cases are vector fields and one-form fields. By convention, if $a=b=0$ the field is called a scalar field and is just an element of $F(M)$, the real-valued functions on M.

An example of a tensor that plays a crucial role in physics is the metric tensor g. On the manifold M, it is a symmetric tensor field of type $(0,2)$ such that if $g(v_1,v_2)=0$ for any $v_1 \in T_P M$, then $v_2=0$. In component form in a coordinate basis near a point P

$$g = g_{jk} dx^j dx^k, \quad (70)$$

where g_{jk} form the components of a symmetric, invertible matrix. The metric tensor g associates any two vectors with a real number. For instance, in the usual geometry in a Euclidean space R^n the matrix $g_{jk} = \delta_{jk}$ and the real number is the scalar or dot product of the two vectors. In other applications different metrics may be required. For example, in special relativity space-time is taken as a four-dimensional manifold with a Minkowskian metric. If the number $g(v_1,v_2)$ has the same sign for all v_1, v_2 at all P on M, i.e., if the eigenvalues of the matrix g_{jk} are all of the same sign, the metric is called Riemannian. Manifolds admitting such metrics are called Riemannian manifolds. Other metrics are called pseudo-Riemannian. The special case of a metric with one eigenvalue of different sign is called Lorentzian. By diagonalization and normalization, it is always possible to choose a basis at any given P such that $g_{jk}(P)$ is a diagonal matrix with entries that are ± 1. If the entries are all of the same sign, the metric in this form is called Euclidean. If one entry has a different sign, it is called Minkowskian.

Since g is a map $T_P M \otimes T_P M \to R$, any given vector v defines a linear map $g(v, \ )$ from $T_P M$ to R. This map is evidently a one-form, by definition. The components v_j of this one-form are given by

$$v_j = g_{jk} v^k. \quad (71)$$

The map is said to lower the index of the vector, and the result is called the associated one-form. An inverse map can be defined that uses the matrix inverse g^{jk} of g_{jk} to raise the index of a form, yielding a vector.

A significant part of the classical literature on differential geometry is concerned with the relationships between different manifolds, in particular in manifolds endowed with metrics. Consider two manifolds M_1 and M_2 of dimensions n_1 and n_2. If there exists a smooth and regular map $f:M_1 \rightarrow M_2$, then M_1 is said to be a submanifold of M_2. The map f is called an embedding. The notion of a regular map is readily understood in coordinate patches $\{x^j\}$ on a chart U in M_1 and $\{y^k\}$ on a chart V in M_2: the matrix with components $\partial y^k/\partial x^j$ must have maximal rank n_1 at each point. Intuitively, the requirements for an embedding can be viewed as ensuring for the submanifold its differentiability, the absence of self-intersections, and that curves through a point in M_1 look locally like their images in M_2. The references at the end of this article provide details of the methods and results of this subject. A simple example of a question involving the notion of embedding is the determination of equations, called the Frenet-Serret formulas, for a curve in R^n. A more complicated example is the description of the embedding of a hypersurface M into R^n, which, according to Bonnet's theorem, is determined by the metric tensor g on M (which in this context is called the first fundamental form), by another symmetric tensor of type (0,2) called the second fundamental form, and by a set of partial differential equations called the Gauss-Codazzi equations. General results on the possibility of embedding an m-dimensional manifold into R^n are also available. An example is Whitney's theorem, which may be viewed as the statement that for compact manifolds such an embedding is possible for $n=2m+1$.

2.4 Differential Forms

A particularly important class of tensors is the set of totally antisymmetric tensors of type $(0,p)$ at a point of M^n. These span a vector space denoted by $\wedge^p T^*_P M$ or just $\wedge^p T^*$, and they are called p-forms. The number $p \leqslant n$ is called the degree of the form. For the case $p=0$, $\wedge^0 T^*_P M$ is chosen as $F(M)$, the space of real smooth functions on M. The dimension of $\wedge^p T^*$ as a vector space is given by the binomial coefficient ${}^nC_p$. Note that this implies that $\wedge^p T^*$ and $\wedge^{(n-p)} T^*$ have the same dimension.

Introduce the wedge product $\omega_1 \wedge \omega_2$ of two one-forms by the definition

$$\omega_1 \wedge \omega_2 = \omega_1 \otimes \omega_2 - \omega_2 \otimes \omega_1. \tag{72}$$

By construction, this is an antisymmetric tensor of type (0,2), i.e., a two-form. It can be shown that a coordinate basis for the two-forms is the set $\{dx^j \wedge dx^k\}$. In general, antisymmetric tensor products of one-forms can be used to generate p-forms, and an element $\omega \in \wedge^p T^*$ can be expanded in a coordinate basis as

$$\omega_p = \frac{1}{p!} \omega_{j_1 \cdots j_p} dx^{j_1} \wedge \cdots \wedge dx^{j_p}. \tag{73}$$

A natural induced wedge product exists that combines a p-form ω_1 with a q-form ω_2 to give a $(p+q)$-form. This product obeys

$$\omega_1 \wedge \omega_2 = (-1)^{pq} \omega_2 \wedge \omega_1. \tag{74}$$

A larger vector space $\wedge T^*$ consisting of the direct sum of all the spaces $\wedge^p T^*$ can also be considered. Its dimension is 2^n, and it is called the Cartan exterior algebra of $T^*_P M$.

Analogous constructions can be introduced for the case of antisymmetric tensors of type $(p,0)$, called p-vectors. The totality of these spans a space denoted $\wedge^p T$. The p-forms, $(n-p)$-forms, p-vectors, and $(n-p)$-vectors thus all form vector spaces of dimension ${}^nC_p$ at a point P of M^n. Various relations can be constructed between these spaces. An important example is the Hodge star map $*$, defined for manifolds M that have a metric g. This is a linear map $*: \wedge^p T^*_P M \rightarrow \wedge^{(n-p)} T^*_P M$ that is most easily understood by its action on coordinate components. Define the totally antisymmetric symbol by

$$e_{j_1 \cdots j_n} = \begin{cases} +1 & \text{if } (j_1 \ldots j_n) \text{ is an even permutation of } (1,\ldots,n) \\ -1 & \text{if } (j_1 \ldots j_n) \text{ is an odd permutation of } (1,\ldots,n) \\ 0 & \text{otherwise.} \end{cases} \tag{75}$$

If a p-form ω is given in a coordinate basis by Eq. (73), then

$$*\omega=\frac{\sqrt{|g|}}{p!(n-p)!}\, g^{j_1k_1}\cdots g^{j_pk_p}\omega_{k_1\ldots k_p}e_{j_1\ldots j_n}dx^{j_{p+1}} \wedge\cdots\wedge dx^{j_n}, \tag{76}$$

where g^{jk} is the inverse metric matrix introduced in Sec. 2.3 and g is the determinant of the matrix g_{jk}.

From the definition (64), the total differential of a zero-form is a one-form. An extension of the notion of differential can be introduced to obtain a $(p+1)$-form via a p-form. Formally, a map $d: \wedge^p T^* \rightarrow \wedge^{(p+1)} T^*$ called the exterior derivative can be defined by the following requirements:

1. $d(\omega_1+\omega_2)=d\omega_1+d\omega_2$ for $\omega_1,\omega_2 \in \wedge^p T$;
2. $d(\omega_1 \wedge \omega_2)=(d\omega_1 \wedge \omega_2)+(-1)^p(\omega_1 \wedge d\omega_2)$ for $\omega_1 \in \wedge^p T$ and $\omega_2 \in \wedge^q T$; and
3. $d(d\omega)=0$ for $\omega \in \wedge^p T$.

It can be shown that the exterior derivative is unique. In a coordinate basis, the exterior derivative of a p-form given by Eq. (73) is

$$d\omega_p=(1/p!)\partial_k\omega_{j_1\ldots j_p}dx^k \wedge dx^{j_1} \wedge\cdots\wedge dx^{j_p}. \tag{77}$$

A p-form field with vanishing exterior derivative is said to be closed, while one that is obtained as the exterior derivative of a $(p-1)$-form is called exact. The definition of d implies that an exact form is necessarily closed.

The exterior derivative combines in a single notation valid for manifolds M^n extensions of the gradient, divergence, and curl operations of usual three-dimensional vector calculus. For instance, the gradient of a function f is a covariant vector with components $\partial_j f$. These are precisely the components of the one-form in Eq. (67). The components of the curl make their appearance in the exterior derivative of a one-form $\omega=\omega_x dx+\omega_y dy+\omega_z dz$:

$$d\omega=(\partial_x\omega_y-\partial_y\omega_x)dx \wedge dy+(\partial_y\omega_z-\partial_z\omega_y)dy \wedge dz + (\partial_z\omega_x-\partial_x\omega_z)dz \wedge dx. \tag{78}$$

The divergence enters the expression for the exterior derivative of a two-form $\omega=\omega_{xy}dx \wedge dy + \omega_{yz}dy \wedge dz+\omega_{zx}dz \wedge dx$:

$$d\omega=(\partial_x\omega_{yz}+\partial_y\omega_{zx}+\partial_z\omega_{xy})dx \wedge dy \wedge dz. \tag{79}$$

The statement $dd=0$ contains the usual identities div(curl v) = curl(grad f) = 0 for a vector v and a function f.

The existence of the Hodge star map $*$ makes it possible to define a map from p-forms to $(p-1)$-forms by applying first $*$ [producing an $(n-p)$-form], then d [giving an $(n-p+1)$-form], and finally $*$ again. This map is called the adjoint exterior derivative and denoted δ. For Riemannian metrics it is defined as

$$\delta=(-1)^{np+n+1}*d*, \tag{80}$$

while for Lorentzian metrics there is an additional factor of -1. The adjoint exterior derivative satisfies $\delta\delta\omega=0$. A p-form field with vanishing adjoint exterior derivative is said to be coclosed, while one that is obtained as the adjoint exterior derivative of a $(p+1)$-form is called coexact.

It is possible to express the Laplacian Δ on a manifold M^n in terms of the maps d and δ:

$$\Delta=(d+\delta)^2=d\delta+\delta d. \tag{81}$$

For example, acting on a function f in three dimensions, this definition reproduces the standard expression of vector calculus,

$$\Delta f=(1/\sqrt{|g|})\partial_j(\sqrt{|g|}g^{jk}\partial_k f). \tag{82}$$

A p-form ω is said to be harmonic if $\Delta\omega=0$. This generalizes the usual notion of harmonic functions.

2.5 Fiber Bundles

In addition to involving a manifold of variables, many physical situations also exhibit symmetry of some kind. The natural geometrical framework in which to formulate such problems is the language of fiber bundles. Here, attention is restricted to a special type of bundle, appearing widely in physics, that involves continuous symmetries. The latter are described mathematically via the theory of Lie groups.

This paragraph presents a few essential definitions involving Lie groups. More details may be found in the articles GROUP THEORY and ALGEBRAIC METHODS. For the present purposes, a Lie group G may be viewed as a group that is also an r-dimensional manifold such that for two group elements $g,h \in G$ the map $gh^{-1}: G \times G \rightarrow G$ exists and is continuous. Denote coordinates in a chart near some point P of G by $\{a^A\}$, $A=1,\ldots,r$. Then the group composition function $f{:}G\times G\to G$ defined for $g(a),h(b),k(c)\in G$ by $f(h,g)=k=hg$ can be written in terms of r functions ϕ^A acting on the coordinates as

$$c^A=\phi^A(b,a). \tag{83}$$

The generators D_A of infinitesimal group transformations on G span the tangent space T_0G at the group identity and are given by

$$D_A=U_A^B\partial_B,\quad U_A^B=\frac{\partial\phi^B}{\partial b^A}\bigg|_{b=0}. \tag{84}$$

This space is called the Lie algebra associated with the group. The dual basis is spanned by the one-forms

$$\Omega^A=da^B(U^{-1})_B^A. \tag{85}$$

As a simple example, consider the group $U(1)$. The group manifold is a circle S^1; if the coordinate is denoted by θ, the group composition function is $\theta_3=\theta_2+\theta_1$. The generator D_θ is just ∂_θ and the dual basis is $d\theta$.

A fiber bundle is basically a manifold acted on by a symmetry. One important type of bundle, called a principal bundle, looks locally (but not necessarily globally) like a product of a continuous symmetry group with a manifold. The action of the symmetry provides a natural means of moving around in each local piece of bundle. The idea is to patch together these local pieces in a smooth way to get the whole principal bundle. Globally, the patching can introduce various twists into the overall structure, in which case the bundle is called nontrivial. A trivial bundle is one where no twists arise: the global and local structure are similar.

Here is a more formal definition. Given a manifold B and a Lie group G, a principal fiber bundle $E(B,G)$ is a manifold such that

1. G acts differentiably and without fixed points on E;
2. B is the quotient space of E by equivalence under G, and there exists a differentiable map $\pi{:}E\to B$; and
3. for each chart U_j in an atlas for B, there exists a differential and invertible mapping $\phi_j{:}\ \pi^{-1}(U_j)\to U_j\times G$ given by $E\to(\pi(P),f(P))$ for any point $P\in E$, where $f{:}\pi^{-1}(U_j)\to G$ satisfies $f(gP)=gf(P)$ for any $g\in G$.

The group G is called the structure group and the manifold B is called the base manifold. The map π is called the projection. The inverse image of π is the fiber; in effect, each fiber is like a copy of G. A (global) cross section or section s of a bundle is defined as a smooth map s: $B\to E$ such that $\pi\circ s$ is the identity on B. Local sections, i.e., sections defined only on $\pi^{-1}(U_j)$, always exist. If the bundle admits a global section, it is called trivial.

2.6 Connection and Curvature

Since $\{\partial_j\}$ is a basis for the tangent space of the base manifold and $\{D_A\}$ is one for the tangent space of the group, a basis for the tangent space to a point in the bundle is the set $\{\partial_j,D_A\}$. It has dual basis $\{dx^j,\Omega^A\}$. However, linear combinations could also be taken. The existence of this freedom permits the definition of a natural one-form called the connection that contains essential information about the structure of the bundle. The connection is basically a separation of the tangent space of E into two pieces, one along the group.

Formally, a connection is a choice of a subspace T_PH of T_PE at each point P of E such that

1. $T_PE=T_PG\otimes T_PH$, where T_PG is the space of vectors tangent to the fiber at P;
2. T_PH is invariant under action by G; and
3. the components in T_PG and T_PH of a smooth vector field in T_PE are also smooth. The spaces T_PG and T_PH are called the vertical and horizontal subspaces, respectively.

Some of the implications of this definition are most easily seen in a coordinate basis on the bundle. Let a basis for T_PH be defined as the linear combination

$$D_j=\partial_j-h_j^AD_A, \tag{86}$$

and require that D_j commute with D_A (among other consequences, this implies that h_j^A transforms under a particular representation of the Lie algebra of G, called the adjoint representation). Then the coefficients h_j^A are called connection coefficients and the basis elements $\{D_j\}$ are called the horizontal lifts or the covariant derivatives of the basis elements $\{\partial_j\}$. The dual to the basis $\{D_j,D_A\}$ for T_PE is the set $\{dx^j,\omega^A\}$, where the ω^A are given by

$$\omega^A=\Omega^A+h_j^Adx^j. \tag{87}$$

They form the components of a composite one-form $\omega=\omega^AD_A$ called the connection form.

The connection form ω encodes many of the interesting properties of the bundle in a concise notation. Its exterior derivative is also an important quantity in physical applications. Introduce a two-form R called the curvature form of the bundle by the definition

$$R=d\omega+\omega\wedge\omega. \tag{88}$$

The curvature is said to be a horizontal form because its action on any vertical vector vanishes. Its nonzero components are given by the expressions

$$R=R^A D_A, \quad R^A_{jk}=R^A(D_j,D_k), \tag{89}$$

and it follows that

$$[D_j,D_k]=R^A_{jk}D_A. \tag{90}$$

Applying another exterior derivative gives an identity

$$dR\equiv R\wedge\omega-\omega\wedge R=0 \tag{91}$$

called the Bianchi identity, with components

$$\sum_{jkl} D_j R^A_{kl}=0, \tag{92}$$

where the sum is over cyclic permutations of the indices j, k, l.

2.7 Example: Electromagnetism

An illustration of the role of some of these ideas in physics is provided by the formulation of the theory of electromagnetism in differential-geometric language. First, here is a summary of a few of the key equations of electromagnetism. In this section, a boldfaced symbol denotes a vector viewed as a collection of components. The symbol ∇ is the usual vector gradient operator, while $\cdot$ indicates the vector dot product and $\times$ represents the vector cross product. The Maxwell equations in SI units include Gauss's law,

$$\nabla\cdot\mathbf{E}=\rho/\epsilon_0; \tag{93}$$

Faraday's law,

$$\nabla\times\mathbf{E}+\partial_t\mathbf{B}=0; \tag{94}$$

the equation expressing the absence of magnetic monopoles,

$$\nabla\cdot\mathbf{B}=0; \tag{95}$$

and the Ampère-Maxwell law,

$$\nabla\times\mathbf{B}=\mu_0\mathbf{J}+c^{-2}\partial_t\mathbf{E}, \tag{96}$$

where ϵ_0 is the absolute permittivity, μ_0 is the absolute permeability, and $c=1/\sqrt{\epsilon_0\mu_0}$ is the speed of light *in vacuo*. Although these equations can be solved directly in simple cases, it is often useful to introduce new variables, called potentials, in terms of which the four first-order Maxwell equations are replaced with two second-order equations. The scalar and vector potentials ϕ and $\mathbf{A}$ are defined by

$$\mathbf{E}=-\nabla\phi-\partial_t\mathbf{A}, \quad \mathbf{B}=\nabla\times\mathbf{A}. \tag{97}$$

With these definitions, the homogeneous equations (94) and (95) are automatically satisfied. The two inhomogeneous Maxwell equations become coupled second-order equations for the potentials:

$$\nabla^2\phi+\partial_t\nabla\cdot\mathbf{A}=-\rho/\epsilon_0 \tag{98}$$

and

$$\nabla^2\mathbf{A}-c^{-2}\partial_t^2\mathbf{A}-\nabla(\nabla\cdot\mathbf{A}+c^{-1}\partial_t\phi)=-\mu_0\mathbf{J}. \tag{99}$$

There exists a freedom in the definition of ϕ and $\mathbf{A}$. The electric field $\mathbf{E}$ and the magnetic induction $\mathbf{B}$ are unchanged by the replacements

$$\phi\rightarrow\phi'=\phi-\partial_t\Lambda \tag{100}$$

and

$$\mathbf{A}\rightarrow\mathbf{A}'=\mathbf{A}-\nabla\Lambda, \tag{101}$$

where Λ is a function of $\mathbf{x}$ and t. These replacements are called gauge transformations. Their existence provides sufficient freedom to decouple Eqs. (98) and (99). For more details on the subjects of this paragraph, see ELECTRODYNAMICS, CLASSICAL.

It is easiest to approach the differential-geometric formulation of electromagnetism in stages, each incorporating more aspects of the theory. Here, the Maxwell equations for $\mathbf{E}$ and $\mathbf{B}$ are first expressed using the language of differential forms. The structure of the theory as a fiber bundle is then described, thereby incorporating the potentials ϕ and $\mathbf{A}$ and the notion of gauge transformations. To obtain consistent physical dimensionalities within expressions, it is convenient to work with a coordinate $x^0=ct$ with dimensions of length rather than with the time coordinate t. In what follows, the spatial coordinates (x,y,z) are denoted (x^1,x^2,x^3).

Begin with the identification of the space and time dimensions as a four-dimensional smooth manifold M. The manifold is often taken to be R^4 but this is not essential. The tangent space to M at a point P is also four-dimensional, and a basis for this space is the set $\{\partial_\mu\}$, $\mu=0,1,2,3$, of derivatives with respect to the four coordinates (x^0,x^1,x^2,x^3). An arbitrary vector can be expanded with respect to this basis. One vector, denoted by j and called the four-vector current, has components j^μ formed from the charge and current densities ρ, $\mathbf{J}$:

$$j=j^\mu\partial_\mu=(\mu_0\rho/c)\partial_0+\mu_0\mathbf{J}\cdot\boldsymbol{\nabla}. \tag{102}$$

An important tensor field on M is the Minkowskian metric g, defined to have components $g_{\mu\nu}$ in a coordinate basis forming a matrix given by

$$g_{\mu\nu}=\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}. \tag{103}$$

This incorporates the essential elements of special relativity.

The Maxwell equations can be expressed in terms of a two-form field F defined on M. This antisymmetric tensor of type (0,2) is called the field strength. The components $F_{\mu\nu}$ of F are related to the components of the electric field and magnetic induction, and are given by

$$F_{\mu\nu}=\begin{pmatrix} 0 & +E^1/c & +E^2/c & +E^3/c \\ -E^1/c & 0 & -B^3 & +B^2 \\ -E^2/c & +B^3 & 0 & -B^1 \\ -E^3/c & -B^2 & +B^1 & 0 \end{pmatrix}. \tag{104}$$

This assignment of **E** and **B** is not *a priori* mathematically unique but establishes agreement of the resulting theory with experiment. In terms of the two-form F, the inhomogeneous Maxwell equations can be rewritten as

$$dF=j, \tag{105}$$

and the homogeneous ones become

$$d{*}F=0. \tag{106}$$

The two-form $*F$ is called the dual field strength. In component form in a coordinate basis, these equations read

$$\partial_\mu F^{\mu\nu}=j^\nu \tag{107}$$

and

$$e_{\mu\nu\rho\sigma}\partial^\rho F^{\mu\nu}=0. \tag{108}$$

Each of these represents four equations, and an inspection shows they reduce to the usual form of the Maxwell equations upon substitution in F and j of **E**, **B**, ρ, and **J**.

The discussion so far has excluded the potentials ϕ and **A**. These can be combined to form the components A^μ of a vector, called the gauge potential:

$$A^\mu\partial_\mu=(\phi/c)\partial_0+\mathbf{A}\cdot\boldsymbol{\nabla}. \tag{109}$$

The factor of c is introduced to maintain dimensional consistency. The metric g provides the associated one-form

$$A=A_\mu dx^\mu=g_{\mu\nu}A^\nu dx^\mu, \tag{110}$$

with components obtained by lowering the index. A complete description of the differential-geometric role of the gauge potential in electromagnetism requires a framework in which to place its nonuniqueness under gauge transformations. This freedom can be interpreted as a symmetry of Eqs. (98) and (99) expressing electromagnetism in terms of the potentials. It can be shown that this symmetry is a Lie group, called $U(1)$. A natural geometrical framework to express this is a fiber bundle, as is discussed next. For simplicity in what follows, the charge and current densities are taken to vanish. Nonzero distributions can be incorporated consistently with the addition of some extra structure.

The bundle of interest is a principal fiber bundle with the four-dimensional space-time manifold taken as the base manifold B and the symmetry group $U(1)$ of gauge transformations taken for the structure group G. Since the manifold of the group $U(1)$ is a circle S^1, the principal bundle is five-dimensional. Denote the coordinate on S^1 by θ. The introduction of a connection separates the tangent space to a point P in the bundle into a four-dimensional horizontal subspace spanned by the basis $\{D_\mu=\partial_\mu\}$ and a one-dimensional vertical subspace spanned by the generator $D_\theta=\partial_\theta$ of the Lie algebra of $U(1)$. The dual basis is the set $\{dx^\mu,\Omega^\theta=d\theta\}$. The composite connection form ω is $\omega=\Omega^\theta D_\theta=d\theta\partial_\theta$.

The gauge potential A can be identified with the value of the one-form Ω^θ on a section s of the bundle. Suppose that the surface s through the bundle E is specified in a chart U by choosing the group coordinate θ as a function of the coordinates $\{x^\mu\}$ provided by U. Then the dual form becomes

$$\Omega^\theta \equiv d\theta = \partial_\mu \theta(x) dx^\mu \equiv A_\mu(x) dx^\mu, \tag{111}$$

where the identification of the components of the one-form Ω^θ with the components of the gauge-potential one-form has been made. Under a change of cross section, which is equivalent to the action of a group element with a parameter Λ, say, the potentials A_μ change by an amount $\partial_\mu \Lambda$. This provides the geometrical interpretation for the gauge transformations (100) and (101).

The curvature two-form $d\omega + \omega \wedge \omega$ derived from the connection form ω is denoted by F. Evaluated on a local section, it has components

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu. \tag{112}$$

In terms of the scalar and vector potentials, this equation reproduces the definitions of Eq. (97). The Bianchi identity in component form in this case can be written

$$d{*}F = 0, \tag{113}$$

thereby reproducing the homogeneous Maxwell equations. To complete the specification of the bundle, additional equations are needed that explicitly determine in each section the connection and the curvature. These are called equations of motion. Requiring these to transform as usual under Lorentz transformations and to be second-order differential equations for the connection or first-order equations for the curvature significantly restricts the options. An inspection of the Lorentz representation content of the general first-order term $\partial_\lambda F_{\mu\nu}$ shows that the simplest choice is $\partial_\mu F_{\mu\nu} = 0$ or its form equivalent

$$dF = 0. \tag{114}$$

This reveals the geometrical role of the remaining two equations in Maxwell's theory.

In the presence of monopoles, the homogeneous Maxwell equations are modified by the introduction of sources. A geometrical setting for the equations describing the fields of a monopole is provided by a nontrivial principal bundle. It can be shown that the essential physics is contained in a bundle with base space S^2 and structure group $U(1)$. The bundle space E looks like S^3 and the projection map π is called the Hopf map.

2.8 Complex Manifolds

Just as the requirement of differentiability for manifolds introduces many useful structures, a further restriction imposing complex analyticity is of considerable interest. The resulting manifolds, called complex manifolds, look locally like the complex plane. Some of their main features are outlined in this section. Basic methods of complex analysis are assumed here. See ANALYTICAL METHODS, Sec. 1, for more details.

The formal definition of a complex manifold M parallels that for a real differentiable manifold presented in Sec. 2.1. The key difference is that the local charts now contain maps f taking neighborhoods U into C^n, the product of n complex planes C, and that the composition map $f_1 \circ f_2^{-1}$ is required to be holomorphic rather than differentiable. This ensures that the methods of complex analysis can be used on M independently of any choice of chart. The number n is called the complex dimension of M; the real dimension is $2n$. An important feature is that a complex manifold may have two or more incompatible atlases, i.e., the union of two atlases may not satisfy the requirements for an atlas. In this case the atlases are said to define different complex structures. An example is the torus T^2 with two real dimensions; it can be shown that the complex structures on the torus are distinguished by a complex number called the modular parameter.

Denote the n complex coordinates on M in a chart U by $z^j = x^j + iy^j$, $j = 1,\ldots,n$, with $\bar{z}^j = x^j - iy^j$. The tangent space T_PM at a point P of M^n is spanned by a $2n$-dimensional coordinate basis $\{\partial/\partial x^j, \partial/\partial y^j\}$. It is useful to define

$$\partial_j \equiv \frac{\partial}{\partial z^j} = \frac{1}{2}\left(\frac{\partial}{\partial x^j} - i\frac{\partial}{\partial y^j}\right),$$

$$\partial_{\bar{j}} \equiv \frac{\partial}{\partial \bar{z}^j} = \frac{1}{2}\left(\frac{\partial}{\partial x^j} + i\frac{\partial}{\partial y^j}\right). \tag{115}$$

The cotangent space is spanned by the dual basis $\{dx^j, dy^j\}$, or equivalently by

$$\{dz^j = dx^j + i dy^j,\quad d\bar{z}^j = dx^j - i dy^j\}. \tag{116}$$

Define the linear map $J: T_PM \to T_PM$ by

$$J\partial_j = i\partial_j,\quad J\partial_{\bar{j}} = -i\partial_{\bar{j}}. \tag{117}$$

Note that $J \circ J = -I$. This map is smooth and globally defined on any complex manifold M.

It is called the almost complex structure of M. The action of J separates T_PM into two separate vector spaces, one spanned by vectors v such that $Jv=iv$ and the other by vectors such that $Jv=-iv$. It follows that a vector in T_PM can be uniquely decomposed into two pieces, called the holomorphic and antiholomorphic parts. The cotangent space T_P^*M can be separated into two corresponding pieces.

Complex differential forms of degree (p,q) can also be introduced. These are elements of a vector space denoted by $\wedge^{(p,q)}T$. In local coordinates, $\wedge^{(p,q)}T$ is spanned by a coordinate basis containing p factors of dz^j and q factors of $d\bar{z}^j$. The exterior derivative d naturally separates into the sum of two pieces,

$$d=\partial+\bar{\partial}, \tag{118}$$

called the Dolbeault operators. They satisfy

$$\partial\partial=\bar{\partial}\bar{\partial}=\partial\bar{\partial}+\bar{\partial}\partial=0. \tag{119}$$

All complex manifolds admit a Hermitian metric. A Riemannian metric g on M is said to be Hermitian if

$$g(Jv_1,Jv_2)=g(v_1,v_2) \tag{120}$$

for all vectors $v_1,v_2 \in T_PM$ at all points P. In a coordinate basis, g can be shown to have the form

$$g=g_{j\bar{k}}dz^j\wedge d\bar{z}^k+g_{\bar{j}k}d\bar{z}^j\wedge dz^k. \tag{121}$$

One can also define a two-form Ω called the Kähler form by

$$\Omega(v_1,v_2)=g(Jv_1,v_2). \tag{122}$$

If the Kähler form is closed, $d\Omega=0$, the manifold is called a Kähler manifold and the metric g is said to be a Kähler metric. In a chart, the components of a Kähler metric can be written as

$$g_{j\bar{k}}=\partial_j\partial_{\bar{k}}K, \tag{123}$$

where K is a scalar function called the Kähler potential. Compact Kähler manifolds in one complex dimension are called Riemann surfaces and are of great importance in certain branches of physics, notably string theory. Examples of Riemann surfaces are the two-sphere S^2 and the two-torus T^2.

2.9 Global Considerations

Essentially all the differential geometry considered above has involved local concepts. It is also of interest to address the issue of the extent to which the local properties of a manifold determine its global ones. The study of global properties of a manifold forms part of the branch of mathematics called topology (*q.v.*) and as such is tangential to the scope of this article. This section provides a sketch of some connections between the two subjects. Details may be found in the references provided at the end of the article.

One link between the geometry and topology of a differentiable manifold M can be introduced by considering the space of all closed p-forms on M. This space can be separated into classes, each containing closed forms differing from one another only by exact ones. The set of all classes is a vector space called the pth de Rham cohomology group of M and denoted $H^p(M)$. This vector space contains topological information about M. For example, the dimension of H^p, called the pth Betti number, is a topological invariant of M that contains information about the holes in M. The Betti numbers also determine the number of harmonic forms on M.

There are relationships between the number of critical points of functions on a manifold M and the topology of M. This is the subject of the calculus of variations in the large, or Morse theory. Among the results obtained are the Morse inequalities, which relate the number of certain types of critical points of a function to combinations of the Betti numbers on M.

The presence of a metric on M permits other types of global information to be obtained. An example is the Hodge decomposition theorem. This can be viewed as the statement that on a compact orientable Riemannian manifold M without boundary, any p-form can be uniquely decomposed into the sum of an exact form, a coexact form, and a harmonic form.

The issue of describing the global structure of a bundle (not necessarily principal) provides another link between geometry and topology. It is possible to develop measures of the ways in which a given bundle differs from the trivial bundle. The relevant mathematical objects are called characteristic classes. They are elements of the cohomology classes of the base manifold, and are given different names depending on the type of bundle being considered. Among these are Pontrjagin, Euler, and Chern classes, corresponding to orthogonal, special orthogonal, and unitary structure groups. Elements in these classes can be expressed in terms of the curvature two-form of the bundle. Another set of characteristic classes, the Steifel-Whitney classes, determines the orientability of a manifold and whether a spinor field can be consistently defined on it.

There are also relations between certain aspects of differential operators on bundles and the topology of the bundles. These are given by index theorems. An important example is the Gauss-Bonnet theorem, which connects the number of harmonic forms on a manifold (this is a property of the exterior derivative operator) to an integral over the Euler class (this is a topological quantity). Another important example is the Riemann-Roch theorem for complex manifolds. These are special cases of the Atiyah-Singer index theorem.

2.10 Further Examples

Many sets of smooth physical variables can be viewed as differentiable manifolds, and so differential-geometric concepts such as vectors, tensors, forms, and bundles play key roles in much of theoretical physics. Examples can be found in every major branch of physics. For instance, the modern formulation of the Hamiltonian dynamics of a system proceeds via the investigation of a manifold M called the phase space, with local coordinates corresponding to the generalized coordinates and momenta of the system. A closed nondegenerate two-form called the symplectic form is defined on M, making the phase space a symplectic manifold. The study of the properties of the phase space using the methods of differential geometry provides information about the behavior of the system. An extension of this example occurs in quantum mechanics (see QUANTUM MECHANICS). Quantization of a system involves the introduction of complex structure on the symplectic manifold. The study of this procedure is called geometric quantization.

Differential geometry is particularly crucial in the development of theories of fundamental interactions and particles. The geometrical constructions presented above for electromagnetism can readily be extended to other theories of fundamental forces. For example, the equations believed to describe the underlying physics of the strong interactions (see the article STRONG INTERACTIONS) form a theory called chromodynamics. This theory can be expressed geometrically using a principal bundle over space-time but where the structure group is the eight-dimensional Lie group called SU(3) rather than U(1). The presence of a multidimensional group manifold with a nontrivial group composition law means that, unlike the electrodynamic case, the horizontal lifts are inequivalent to the basis for the tangent space to the base manifold. As a result, the structure of the Bianchi identities and the equations of motion are somewhat more complicated in detail. The essential construction, however, remains the same.

Another important physical theory is general relativity, which provides a good description of the gravitational interactions at the classical level (see the article GRAVITATION AND GENERAL RELATIVITY). This theory can also be given a geometrical interpretation as a fiber bundle, but it is of a somewhat different kind, called a bundle of frames. Each point on a fiber of this bundle consists of a choice of basis vectors for the tangent space to the space-time manifold, and the symmetry group that plays the role of the structure group of a principal bundle now acts to rotate these bases into one another. A connection form and an associated curvature still exist, and they are closely related to the Christoffel symbols and the Riemann space-time curvature tensor of general relativity. In addition, there exists new freedom arising from the choice of basis vector on the base manifold, which leads to the existence of a second natural one-form on the bundle called the solder form or vierbein. This also has an associated two-form, called the torsion. In Einstein's general relativity the torsion form is specified to be zero, although other possibilities can be envisaged.

Attempts to unify the known fundamental forces and particles (see UNIFIED FIELD THEORIES) make wide use of geometrical constructions. Examples of such theories in four dimensions are the grand unified theories, describing the strong, weak, and electromagnetic forces in a single framework. The geometrical structures discussed above can be extended to more complicated symmetry groups large enough so that the connection forms include all the force fields needed for these theories. Certain elementary particles (see PARTICLES, ELEMENTARY) play the role of sources for these fields and can also be incorporated in bundles called associated bundles. Many unified theories involve higher-dimensional manifolds, in which physical space-time is a submanifold. These include the so-called Kaluza-Klein theories. Often, the symmetries of the extra dimensions permit them to play the role of the structure group in a principal bundle.

Generalizations of the geometrical framework of gravitation are also possible. For example, if the base manifold for a bundle of frames is generalized in a certain way, it is possible to specify bundles describing extensions of general relativity that include fundamental particles and forces other than gravity and that incorporate enlarged symmetries called supersymmetries. The resulting theories are called supergravities.

String theories are candidate unified theories including gravity that are believed to be consistent with quantum mechanics. In these theories, the fundamental forces and particles are interpreted as objects that are extended in one dimension (hence the name string). As a string propagates in space-time, it sweeps out a two-dimensional surface called the world sheet. A description of the world sheet involves the study of complex manifolds, in particular Riemann surfaces, as well as the notions of global differential geometry.

3. PROJECTIVE GEOMETRY

In its basic form, projective geometry is essentially the theory of perspective, i.e., the study of those features of geometrical objects that remain the same when the objects are projected from a point onto a line or plane. The elements of projective geometry are implicitly used by artistic painters, designers, and other people who represent three-dimensional objects on a two-dimensional medium. In its generalized form, the subject is fundamental in axiomatic geometry. It can be viewed as subsuming the classical Euclidean and non-Euclidean geometries.

There are two approaches to projective geometry. Synthetic projective geometry seeks to develop the subject as a series of deductions starting from certain axioms, in the Euclidean tradition. Analytical projective geometry introduces homogeneous coordinates and uses analytical techniques to obtain results. The two approaches are complementary, although projective geometries exist for which coordinates cannot be introduced.

A key feature of projective geometry is that parallel lines are assumed to meet in a single point, called the point at infinity, and that parallel planes meet in a single line, called the line at infinity. One advantage of these assumptions is that geometrical statements do not require exceptions for parallelism. For example, it is now true that any two lines in the plane determine a point, and any two planes in three dimensions determine a line.

In a plane, the statement that two lines determine a point is strikingly similar to the statement that two points determine a line. In general, projective-geometric statements involving points and lines in the plane remain valid when the roles of the points and lines are interchanged. In the plane, points are said to be dual to lines. In three dimensions the notion of duality applies between points and planes, or between lines and lines. A similar concept exists in higher dimensions.

With these ideas, a set of axioms for synthetic projective geometry can be formulated in terms of three basic notions: point, line, and incidence. The latter is meant in the sense of intersection: for example, a point is incident to a line if it lies on the line. The axioms can be expressed in dual pairs, so that propositions deduced necessarily have valid duals.

3.1 Some Theorems

There are several theorems that play a central role both in the development of the basic theory and in its extension to more abstract situations. A key result is Desargues's theorem: Given six distinct points in two sets, $\{A_1,A_2,A_3\}$ and $\{B_1,B_2,B_3\}$ (i.e., the vertices of two triangles), if the lines A_1B_1, A_2B_2, A_3B_3 meet at a point, then the three points C_1, C_2, C_3 given respectively by the pairwise line intersections A_1B_2 and A_2B_1, A_2B_3 and A_3B_2, A_3B_1 and A_1B_3 are collinear. This theorem holds in all projective geometries in three dimensions or more and in certain two-dimensional cases, including the usual plane projective geometry. However, in two dimensions non-Desarguesian geometries also exist.

Another important result that holds for a large class of projective geometries including the usual plane and solid ones is Pappus's theorem: Given two lines a and b lying in a plane and two sets of three distinct points $\{A_1, A_2, A_3\}$ incident to a and $\{B_1, B_2, B_3\}$ incident to b, then the three points C_1, C_2, C_3 given respectively by the pairwise line intersections A_1B_2 and A_2B_1, A_2B_3 and A_3B_2, A_3B_1 and A_1B_3 are collinear. Non-Pappian geometries also exist.

A pencil of lines about a point P is defined as the set of all lines lying in a plane and incident with P. A line s in the plane not incident with P is called a section of the pencil, and the pencil is said to project the section from P. Two pencils can be projectively related through a common section. Two distinct sections are said to be related by a projective transformation from the point P. The fundamental theorem of projective geometry states that a projective transformation is specified when three collinear points and their images are given. The theorem generalizes to projective transformations of higher-dimensional figures.

Conic sections (see Sec. 1.2) have a natural construction in projective geometry, and their theory can be developed entirely within this subject. Since all conics can be generated by projection of a circle from a point onto a plane, the projective approach gives them a unified treatment and consequently several results of analytical geometry can follow from a single projective theorem. Plane-projective definitions also play an important role. For example, the locus of intersections of corresponding lines in two projectively related pencils is a conic. A well-known result in this branch of the subject is Pascal's theorem: Given six points $\{A_1,A_2,A_3,A_4,A_5,A_6\}$ incident to a conic, then the three points B_1, B_2, B_3 given respectively by the pairwise line intersections A_1A_2 and A_4A_5, A_2A_3 and A_5A_6, A_3A_4 and A_6A_1 are collinear. The dual to Pascal's theorem is sometimes called Brianchon's theorem. These methods of projective geometry can also be extended to the study of quadrics and higher-dimensional hypersurfaces.

3.2 Homogeneous Coordinates

In analytical projective geometry, a set of coordinates called homogeneous coordinates is introduced. Consider first homogeneous coordinates on the line. A Cartesian coordinate system assigns a single real number x to each point P. In contrast, a homogeneous coordinate system assigns *two* real numbers (x_0,x_1) to each point, where $x=x_1/x_0$ and at least one of (x_0,x_1) is nonzero. Evidently, the homogeneous coordinates (x_0,x_1) and (cx_0,cx_1), where c is a constant, both represent P. The advantage of homogeneous coordinates is that the point $(0,1)$ at infinity is treated on the same footing as, say, the origin $(1,0)$. It also makes any polynomial equation $f(x)=0$ homogeneous in (x_0,x_1) without affecting the degree of the equation.

In the plane, the homogeneous coordinates of a point P specified in Cartesian coordinates by (x,y) are three real numbers (x_0,x_1,x_2), not all zero, for which $x=x_1/x_0$, $y=x_2/x_0$. A line in Cartesian coordinates is given by the linear equation $Ax+By+C=0$. In homogeneous coordinates this becomes the homogeneous linear equation

$$Ax_1+Bx_2+Cx_0=0. \tag{124}$$

The line at infinity has equation $x_0=0$ and is thereby treated on a similar footing to other lines; for example, the x and y coordinate axes have equations $x_2=0$ and $x_1=0$, respectively. All these ideas generalize to higher dimensions.

In addition to providing a framework in which analytical calculations can be developed, the homogeneous coordinate system offers a simple setting for duality. For example, given Eq. (124), the three numbers (A,B,C) can be viewed as homogeneous coordinates for a line in the plane. Then, coordinate statements about a point are expressed in terms of three numbers (x_0,x_1,x_2), while statements about a line are expressed in terms of a dual set of three numbers (A,B,C). A single equation thus represents a line or a point depending on which three numbers are considered variables.

Any set of three coordinates $(\hat{x}_0,\hat{x}_1,\hat{x}_2)$, obtained from the homogeneous coordinate system (x_0,x_1,x_2) in the plane by an invertible linear transformation

$$\hat{x}_j=A_{jk}x_k \tag{125}$$

(see ALGEBRAIC METHODS, Sec. 3.3), also leaves unchanged the degree of any polynomial function of the coordinates. The set $(\hat{x}_0,\hat{x}_1,\hat{x}_2)$ can be taken as alternative homogeneous coordinates.

3.3 Group of Projective Transformations

Instead of being taken as a change of coordinates for a fixed point P, the linear transformation (125) can be interpreted as a mapping from a point P at (x_0,x_1,x_2) to another point $\hat{P}$ at $(\hat{x}_0,\hat{x}_1,\hat{x}_2)$. This provides a mapping of the projective plane onto itself. Such mappings form a group G called the group of projective transformations for the plane. Similarly, groups of projective transformations can be introduced for higher-dimensional cases.

According to the so-called erlangen program, projective geometry can be viewed as the study of properties of figures that are invariant under the action of G. Various other geometries can be obtained by requiring invariance under a subgroup of G. They include the regular Euclidean geometry, as well as affine geometry and the non-Euclidean elliptic and hyperbolic geometries.

Extensions of projective geometry to fields other than the real numbers exist. For example, complex projective geometry is defined over the complex numbers. The field may be finite or even noncommutative (see ALGEBRAIC METHODS, Sec. 2). For example, a finite geometry in the plane called $PG(2,5)$ can be constructed using 31 points and 31 lines, with six points on each line and six lines through each point. Details of these generalized projective geometries may be found in the references at the end of this article.

4. ALGEBRAIC GEOMETRY

Algebraic geometry involves the study of mathematical objects called varieties, which are generalized curves, surfaces, and hypersurfaces. The subject has several levels of abstraction, in each of which the precise meaning of the word variety is different. For the purposes of this article a relatively simple level of sophistication suffices, in which a variety can roughly be viewed as the solution to a set of polynomial equations for variables in a space. Note, however, that the modern definition of variety is considerably more abstract. It uses a branch of mathematics called the theory of schemes, about which more can be found in the references at the end of this article.

This section presents a few simple notions of algebraic geometry in the framework of polynomial equations. The discussion refers to several concepts (e.g., field, polynomial ring, rational functions) that are defined and described in the article ALGEBRAIC METHODS.

4.1 Affine Varieties

Here is a more precise definition of one important type of variety. Consider an algebraically closed field F. An n-dimensional affine space A^n over F is defined as the set of points specified by the coordinates $(f_1,...,f_n)$ with $f_j \in F$. Denote by $F\,[f_1,...,f_n]$ the polynomial ring in n variables over F. An affine variety V is a subset of A^n given by the common zeros of a set S of polynomials in $F\,[f_1,...,f_n]$. If S contains only one polynomial, V is called an affine curve for $n=2$, an affine surface for $n=3$, and an affine hypersurface for $n>3$.

A subset of V satisfying the definition of a variety is called a subvariety. If V is the union of two subvarieties, it is called reducible; otherwise, it is irreducible. For example, an irreducible affine curve is one for which the defining polynomial is irreducible (i.e., cannot be factored). An irreducible component of V is defined as a maximal irreducible subvariety of V. One result in this subject is that any variety V can be written uniquely as the union of finitely many distinct irreducible components.

Starting with a variety V, a sequence of irreducible varieties can be constructed such that each member of the sequence is a subvariety of the preceding one. This sequence is of finite length, and the number of subvarieties in it is called the dimension of V.

The unions and finite intersections of subvarieties of V are also subvarieties. This means that the complements of the subvarieties of V can be used as the collection t of subsets for a topological space (see Sec. 2.1) Therefore, A^n and hence also V can be endowed with a topology, called the Zariski topology. This topology is not Hausdorff but, unlike the usual Hausdorff topology on C^n, it is defined for all affine varieties over F.

4.2 Projective Varieties

Several extensions of the notion of affine variety to more general varieties exist. One generalization uses an approach similar to that taken in the construction of differentiable manifolds: The meaning of variety is extended to include objects constructed by patching together affine varieties. This generalization then looks locally like an affine variety but globally is different. An important result in algebraic geometry is that certain subsets of projective spaces form varieties of this sort, called projective varieties.

An n-dimensional projective space P^n over F can be introduced as the set of points specified by the homogeneous coordinates $(f_0,f_1,...,f_n)$ with $f_j \in F$ not all zero, subject to the restriction that two such sets of homogeneous coordinates related via a single nonzero constant $c \in F$ as

$$(f_0,f_1,...,f_n)=(cf_0,cf_1,...,cf_n) \tag{126}$$

specify the same point (cf. Sec. 3.2). Denote by $H[f_1,...,f_n]$ the ring of homogeneous polynomials in n variables over F. A projective variety V is a subset of P^n given by the common zeros of a set S of polynomials in $H[f_1,...,f_n]$. If S contains only one polynomial, V is called a projective curve for $n=2$, a projective surface for $n=3$, and a projective hypersurface for $n>3$.

4.3 Classification

The ultimate aims of algebraic geometry are the classification and characterization of varieties. These are difficult and unsolved problems in the generic case. To attack the classification problem, a means of relating varieties to one another is needed. This is provided by the notion of a rational map.

A rational map $f:V \to A^n$ from an affine variety to n-dimensional affine space is basically a set of n rational functions f_j. The domain of f is by definition taken as the union of the domains of the n functions f_j. A rational map $f:V_1 \to V_2$ between two affine varieties $V_1 \subset A^{n_1}$ and $V_2 \subset A^{n_2}$ is defined to be a rational map $f:V_1 \to A^{n_1}$ such that the range of f lies in V_2. If the map f also has a rational inverse, it is called a birational equivalence.

The classification problem is approached by seeking a classification up to birational equivalence. Ideally, this means providing discrete and/or continuous numerical quantities that are invariant under birational equivalence and that characterize inequivalent varieties. Then, given a birationally equivalent set of varieties, a standard subset with desirable features (e.g., no singularities) can be sought and a classification attempted. Finally, one can seek some means of measuring the deviation from this standard subset of the remaining members of the birational-equivalence class.

An example is provided by the special case of the algebraic curves over F. For these varieties, a discrete quantity called the genus g can be introduced, which is a nonnegative real number that is invariant under birational equivalence. Curves with $g=1$ are sometimes called elliptic curves. For each nonzero g the birational-equivalence classes can be labeled by a one-dimensional continuous variable if $g=1$ and by a $(3g-3)$-dimensional set of continuous variables otherwise. The continuous variables are called moduli. They also form an irreducible variety, called moduli space, that can in turn be studied with the methods of algebraic geometry.

If the field F is the field C of complex numbers, the resulting algebraic curves are the Riemann surfaces. A curve with $g=0$ is topologically a sphere, while one with $g=1$ is topologically a torus. The set of Riemann surfaces plays an important role in string theories (see Sec. 2.10). For example, at a particular order in perturbation theory for a scattering process the string world sheet is topologically a Riemann surface with punctures for the incoming and outgoing strings. The methods of differential and algebraic geometry play a significant role in the evaluation of such contributions to the scattering amplitudes.

GLOSSARY

Considerations of space prevent an extensive glossary being provided for this article. Instead, the following is a list incorporating important concepts together with the number of the section in which the concept appears.

Abscissa: See Sec. 1.1.
Adjoint Exterior Derivative: See Sec. 2.4.
Affine Space: See Sec. 4.1.

Affine Variety: See Sec. 4.1.
Almost Complex Structure: See Sec. 2.8.
Antisymmetric Symbol: See Sec. 2.4.
Antisymmetric Tensor: See Sec. 2.3.
Applicate: See Sec. 1.5.

INTRODUCTION: THE WORLD OF GEOPHYSICS

Geophysics is an interdisciplinary science that integrates the observations, hypotheses, and laws of geology with the techniques and principles of physics to understand the composition, nature, structure, and processes of the Earth. The world of geophysics extends from the magnetosphere—the outermost limits of the universe surrounding the Earth that are affected by the magnetic field of the Earth—to the center of the Earth some 6372 km from the Earth's surface. The term *solid-Earth geophysics* is applied to the branch of the science of geophysics that relates to the solid Earth including the liquid outer core of the Earth.

Geophysics is the "remote sensing" science that permits us to investigate the Earth's interior indirectly. Just as a physician uses our pulse, heart rate, temperature, x rays, and other physical evidence to investigate the composition, structure, and nature of the interior of our bodies, the solid-earth geophysicist uses a range of measurements on a variety of force fields that traverse the Earth to obtain information on the "internal condition" of the Earth. This approach is necessary because we have neither the resources nor technology to

sample adequately the Earth's third dimension in a more direct fashion.

The geophysical methods are based on measuring force fields, which in turn respond to the physical properties of Earth materials that they encounter. For example, seismic methods utilize elastic properties and the density of the Earth and thus the velocity of propagation of elastic waves, while electric methods are based on a variety of electrical properties of the Earth that affect its carrying of electrical current. In a similar manner, gravity and magnetic methods are dependent on the mass (density) and magnetization, respectively, of the Earth. Thus the measurements of force fields such as seismic (mechanical), gravitational, magnetic, and electric fields provide significant information about the properties of the Earth. This is especially true when the observations are taken over the surface of the Earth. Spatial variations in the measurements are ample proof that the Earth is not homogeneous, although to a first degree it is spherically symmetric in structure and composition.

A major effort of solid-Earth geophysicists is the mapping of spatial variations or the anomalies in the various force fields. Once an anomaly is adequately detailed, the geophysicist translates the effect into its source within the Earth by a procedure termed *inversion*. Unfortunately, this process does not provide unique answers, but by integration of the inversion of the results from several geophysical force fields and use of available surface geologic information, an appropriate geologic interpretation is made of the location, structure, and composition of the anomalous Earth materials.

The variety of force fields that are available to geophysicists for studying the Earth is advantageous in decreasing the ambiguity of geologic interpretation. In addition, the methods contrast significantly in depth of investigation, resolution of discrete anomalous Earth materials, efficiency, and ease of observation. The common characteristics of each of the methods is the strong base on physical principles, the need for geologic information in all phases of conducting the methods, and the intensity of computational aspects necessary to make force-field observations geologically significant.

In the following discussion, we will limit our presentation to the principal geophysical methods that are used to investigate the Earth's lithosphere. The lithosphere is the semirigid outermost shell of the Earth that varies in thickness over the surface of the Earth. It normally has a thickness of the order of 150 km, but in limited regions, such as the mid-oceanic ridge, it is almost absent, with the underlying plastic mantle (i.e., asthenosphere) nearly reaching the surface. The lithosphere is composed of two shells of variable thickness: a lower unit composed of dense, high–seismic-velocity mantle and the crustal surface shell. The crust, which has an average thickness of less than 10 km in the ocean basins and is generally 35 km thick in the continents, is highly complex, reflecting the erosion, sedimentation, metamorphism, igneous activity, and plastic movement of the mobile asthenosphere underlying the lithosphere that have occurred over the Earth's 4600-Ma history. These processes have led to the differentiation of chemical elements, vertical and horizontal movements, zones of crustal weakness, and the focusing of geological processes, such as volcanism, in limited areas of the Earth's surface. In this manner, the variations in the structure, composition, and nature of the lithosphere and specifically the crust that are mapped and investigated by solid-Earth geophysics control man's Earth resources and such prominent societal concerns as volcanic activity and earthquakes.

The following discussion considers the principles of the major methods (i.e., seismic, gravity, magnetic, and electrical) that are used to explore the Earth's interior. Applications of these methods range from global or regional scale surveys designed to image the crustal properties of an ocean or continent to essentially microscale surveys conducted down a borehole to establish the physical properties of the adjacent rocks. The discussion is concluded with a few examples of how geophysics affects our understanding of the Earth and related societal problems.

1. SEISMIC EXPLORATION

Seismology involves the temporal and spatial analysis of ground motion to deduce information concerning the structural and compositional properties of the subsurface. Measured phenomena include signal wavelengths, travel times, amplitudes, and phases. Seismic survey results present a relatively explicit and highly resolved picture of the subsurface that appears very analogous to a cross section of the subsurface. As a result the seismic method has found extensive and preferred use for many subsurface investigations. The tradeoff, however, is in the extreme cost of the method. Next to drilling, the seismic method is the most expensive exploration tool to use because it involves sophisticated field procedures and data-processing capabilities.

1.1 Principles

In seismic exploration, a displacement of the ground surface is introduced at the source point. Common mechanisms for producing the disturbance include explosions, hammer blows, ground vibrators, or strain release due to earthquake activity. The passage of the disturbance at a distant point of observation is measured by an instrument called a seismometer or geophone. The ground motion as observed by the geophone is recorded by a seismograph as a seismogram. Seismograms commonly exhibit a number of simple harmonic wave forms that describe the disturbance in time at the geophone position. Because the Earth is elastic to a first order, these wave forms can be interpreted in terms of vertical and lateral elastic property variations to help identify the compositional and structural characteristics of the media through which the disturbance has traveled.

Most of the materials of the Earth are elastic and therefore resist an applied stress by a force that is approximately proportional to the displacement. These materials follow Hooke's law that relates the elastic moduli to the ratio of stress to strain. Stress and strain in elastic materials are both tensors described by nine components, of which six are independent. Therefore, in the most general case, six equations, having a total of 36 unknown coefficients, are required to relate stress to strain. These coefficients may be simplified to the two Lamé constants λ and μ (or the shear modulus) for isotropic and homogeneous materials.

A material is said to be isotropic if its elastic properties are the same in all directions, and it is called homogeneous if strain is the same from point to point throughout the body. Applying Hooke's law to evaluate time-dependent stresses on a unit cube of isotropic, homogeneous material yields an equation of motion for the ground particles in each of the three orthogonal (j) directions, given by

$$\sigma\frac{\partial^2 u_j}{\partial t^2}=(\lambda+\mu)\frac{\partial\theta}{\partial x_j}+\mu\nabla^2 u_j, \tag{1}$$

where u_j is the displacement in the jth direction, σ is the density, θ is the cubical dilation (i.e., volume strain), x_j is the unit spatial coordinate in the jth direction, and ∇ is the gradient operator.

The equation of motion (1) predicts the existence of body waves called *P* and *S* waves that travel through the interior of elastic media. The *P* wave is also called the pressure, primary, compressional, longitudinal, or dilatational wave. In this wave, the direction for particle motion is back and forth along the direction in which the wave is traveling. The wave front advances by alternating compressions and rarefactions and travels through solid materials at a rate that is about 1.7 times the velocity V_S of the *S* wave.

The *S* wave is also called the shear, secondary, transverse, or rotational wave. In this wave, the direction of particle motion is transverse or perpendicular to the direction in which the wave is traveling. *S* waves are said to be vertically polarized in the sense that particles move in parallel lines in the vertical direction, or horizontally polarized in the sense that the motion moves in parallel lines in the horizontal plane.

Other types of waves that may be derived from the equation of motion (1) are the surface waves. The most important of these in seismic exploration are the Rayleigh waves, which exist only along a free surface such as the air–ground boundary. They represent the principal component of ground roll, which often severely distorts the occurrence of other wave forms on the seismogram. When generated by strong earthquakes or explosions, this ground roll can be very damaging to buildings, bridges, dams, and other structures. Rayleigh-wave particle motion is vertical, elliptical, and retrograde with respect to the direction of propagation. Amplitudes decrease exponentially with depth. Rayleigh-wave velocity is less than the velocities of any of the body waves, being approximately $0.9V_S$ in a homogeneous isotropic medium.

Rayleigh-wave velocity also varies with frequency, and hence it is said to be *dispersive*. Seismic velocity basically increases with depth in the Earth, so that the longer-period components tend to appear on the seismogram ahead of the shorter-period components that have propagated through shallower zones of lower velocity. Accordingly, the observed patterns of Rayleigh-wave dispersion are useful for analyzing the broad-scale velocity structure of the outer part of the Earth.

The propagation of seismic waves is governed by Huygens's principle, Fermat's principle, and Snell's laws. By Huygens's principle, each point on a wave front acts as the source of new wavelets, whose envelope constitutes the wave front at later time. For a homogeneous isotropic material, wave propagation can be described in terms of rays that are normal to the wave fronts because constructive interference of wavelets occurs only at the envelope. Seismic disturbances propagating through a first-order Earth of homogeneous isotropic strata follow straight ray paths in regions of constant velocity. However, in regions where velocities increase or decrease in the direction of propagation, curved ray paths are followed that bend respectively away from or toward the directions normal to the strata interfaces.

Basic to propagation theory is Fermat's principle, which states that the ray reaching a given point from a given source has reached the point by a minimum-time path between the two points. If the intervening medium contains parts having different velocities, the ray path will not be straight, but it will be minimum in time. In seismic prospecting, we are particularly interested in minimum-time paths.

Three things occur when an advancing wave front in one medium characterized by a velocity V_1 encounters a boundary with another medium with a different velocity V_2. First, waves are reflected according to Snell's law of reflection as given by

$$\text{angle of incidence } (i) = \text{angle of reflection.} \tag{2}$$

Second, waves enter the second medium as refracted waves at angles i_r according to Snell's law of refraction, which states that

$$\sin i / \sin i_r = V_1/V_2. \tag{3}$$

When $V_2 > V_1$, Eq. (3) predicts a "critical angle" i_c of incidence where reflected and refracted wave paths are equal and the wave travels along the interface between the two media so that

$$\sin i_c = V_1/V_2. \tag{4}$$

Finally, each incident wave type produces refracted and reflected waves of the opposite wave type across the boundary, having incidence and transmission angles that are governed by the velocity properties of the media in a fashion comparable to the relationships described in Eqs. (2) and (3).

In seismic prospecting the strength of signals returned to the detector or geophone is commonly quite weak, and hence we seek to minimize the conversion of incident energy into other wave types at media boundaries in the subsurface. The energy partitioning of the incident wave at the boundary between media is governed by a set of relations known as the Zoepperitz equations. These equations indicate that if we set up our experiment such that incident angles of 20° or less are maintained, the conversion of incident wave energy into other wave types is minimized. Under this circumstance, the fraction of incident energy reflected at an interface is given by

$$R = (\sigma_2 V_2 - \sigma_1 V_1)/(\sigma_2 V_2 + \sigma_1 V_1), \tag{5}$$

where $\sigma_1 V_1$ and $\sigma_2 V_2$ are the acoustic impedances of media 1 and 2, respectively. The sign of the reflection coefficient R for any boundary between media gives the polarity of the reflections from that boundary that are received at the geophone. Accordingly, reflections identified on a seismogram provide a straightforward indication of how acoustic impedances vary with depth.

Other factors affect the propagation of seismic waves through the subsurface including diffraction effects, spherical divergence or geometric spreading effects, and nonelastic wave-energy absorption effects. Factors such as these can severely distort seismic signals and hence greatly complicate the identification and interpretation of events recorded on the seismogram. Analytical techniques that migrate diffraction events back onto the diffracting point in the seismic section are commonly implemented to minimize the effects of diffractions, whereas amplitude corrections based on a simplistic exponential attenuation curve of amplitude with time or distance may be applied to minimize the effects of spherical divergence, absorption, and other transmission losses.

1.2 Velocity

Seismic data are interpreted in terms of the elastic-wave velocity variations of the subsurface formations. These velocities are dependent on a number of factors including depth of burial of the rocks, lithology, geologic age, fluid saturation, and the anisotropic properties of the subsurface rocks. In general, elastic velocities increase with depth, but this trend can be modified by the effects of temperature, pressure, compaction, cementation, and density of the subsurface materials. Velocities generally increase as these parameters increase, except for temperature, where velocity decreases with increasing temperature at the rate of about 2% per 100 °C.

Elastic-wave velocity variations due to lithology involve the effects of porosity, lithification, chemical composition, and texture of the rocks. Porosity is a major factor particularly in sedimentary rocks and unconsolidated materials. In general, velocity decreases with increasing porosity. Velocities increase for igneous and metamorphic rocks with decreasing silica content and metamorphic grade. In general, igneous and metamorphic rocks are higher-velocity materials than sedimentary rocks and unconsolidated materials. Unconsolidated materials generally exhibit lower velocities than consolidated materials. Velocity variations related to geologic age involve the effects of depth of burial and lithology variations within the subsurface rocks. In general, velocity values are greater for older rocks than younger rocks, although this generalization has many exceptions.

Regions of sedimentary rocks or unconsolidated materials that are water saturated tend to be characterized by increased *P*-wave velocities over those in the same formations that are unsaturated. However, because the shear strength of water is zero, *S*-wave velocities for fluid-saturated regions are markedly less than the propagation velocities of the *P* wave, which is the wave type used most commonly in exploration.

Many rocks tend to show stratification in the organization of their constituent materials, which leads to velocity anisotropy. As a result, velocities for sediments are generally greater parallel to bedding by 10%–15% than across the beds. In some igneous and metamorphic rocks, velocities parallel to banding may be 100% greater than velocities across the banding. Other sources of velocity anisotropy include crystal layering and fracturing at microscopic to macroscopic scales.

1.3 Instrumentation

The instrumentation of seismic surveying has become extremely portable with the recent advances in solid-state microcircuitry and processing. Seismic instrumentation basically involves geophones connected to a clock that provides timing to ground motion for estimating the time of travel of a disturbance between the source point and the geophone position. A processing unit is used to make a number of adjustments to the output from the geophones. These adjustments include gain control to compensate for variations in input geophone signal strength. Filters and other signal enhancement processing are also commonly applied. Ultimately the processed output from the geophones is electronically digitized for video display and archiving on magnetic tape or optical disk.

Seismic sources for exploration applications must transfer energy efficiently into the ground, producing a wave form with a sharp rise time to facilitate interpretation. Chemical explosives are traditionally used in the search for hydrocarbons and mineral resources. For engineering applications, the sledgehammer, weight drop, shotgun, studgun, and other mechanical impactors find widespread application. In regions where the use of explosives is prohibited, such as urban areas, mechanical vibrators (e.g., VIBROSEIS, Mini-Sosie) are commonly implemented. In this application, a sinusoidal vibration of continuously varying frequency is applied to the ground during a sweep period, typically lasting 7 s or longer. The field record, which consists of a superposition of many such long wave trains reflected from multiple interfaces, is correlated with the sweep frequency. The correlated record resembles the conventional seismic record that results from an impulsive source. For marine applications, sparkers, pingers, boomers, gas exploders, and air guns are commonly used to input mechanical energy to the water and ultimately the solid Earth.

Modern geophones are constructed as small as golf balls and operate along electromagnetic principles. An effective geophone design uses a wire coil rigidly attached to the geophone housing, which in turn is coupled to the ground. Surrounding the wire coil is an inertial mass that is magnetic and suspended by springs from the geophone housing. When the seismic event or ground disturbance passes the geophone position, the housing moves with the ground and an electromagnetic current is induced in the wire coil, thereby providing a temporal history of ground motion. Generally, the fundamental frequency of the geophone is tuned to the ground vibrations and thus senses the time derivative of the ground displacement.

1.4 Interpretation

Inversions of seismic data are predominantly implemented in the context of stratified Earth models. The Earth is basically a stratified system as a consequence of the action of its gravity field since it was formed. Indeed, seismic data provide the principal line of evidence for our view of the Earth as a stratified planet consisting of a layered core, overlain by a layered mantle, which in turn is overlain by a predominantly layered crust.

A seismogram records ground motion at the geophone position as a function of time. It may show several distinct seismic arrivals produced not only by the different wave types, but also by the different wave paths that exist through the stratified Earth. As an example, consider the simple horizontal two-layered system shown in Fig. 1. Seismograms collected at various source-to-receiver spacings or offsets would show a systematic pattern of arriving seismic events that may be identified to produce the travel-time curve given in Fig. 1. For example, out to the distance *A*, the earliest arrivals at the shorter distances are *P* waves following a direct path from the source to the geophone. For the direct wave paths, travel times increase linearly with impact distance so that the slope of this line is inversely proportional to the velocity V_1 of the first layer.

Later-arriving events will include the slower shear waves, surface waves, and reflected *P* waves. The arrival times for *P*-wave reflections increase hyperbolically with increasing offset. At offsets greater than or equal to the critical reflection point (see Fig. 1), *P* waves

FIG. 1. Idealized response of geophones to *P* waves and Rayleigh surface waves propagating through a horizontal two-layer subsurface. *S* waves (etc.) have not been included to simplify the travel-time graph. However, *S* waves propagate at a rate of about $0.6V_P$ so that they follow the *P*-wave arrival times by a delayed time which is proportional to offset.

refracted from the base of the V_1 layer will begin to appear on the seismogram. The critical reflection is defined at the offset where the reflected and refracted wave paths are equal. Refracted waves lag behind the direct waves out to the crossover distance A. At larger offsets, the refracted P waves arrive ahead of the direct waves. Arrival times for the refracted P waves vary linearly with distance, where the slope of the travel-time branch is inversely proportional to the P-wave velocity of the second layer, V_2. The projection of the refracted-wave branch to zero offset (i.e., $x=0$) is defined as the intercept time for this refraction. The extension of this analysis for obtaining travel-time graphs for systems consisting of three or more horizontal layers follows directly from the preceding discussion.

Analyses of travel-time graphs focus basically on the use of refracted or reflected waves for computing the depth to the underlying layers. Accordingly, two independent seismic surveying methods exist for locating and mapping subsurface interfaces. The method of seismic refraction surveying uses seismic energy that returns to the surface after traveling through the ground along refracted ray paths. This method is normally used to locate refracting interfaces (refractors) that separate layers of increasing seismic velocity with depth, but the method is also applicable where velocities vary laterally. In seismic reflection surveying, the travel times are measured for arrivals reflected to the surface from subsurface interfaces (reflectors) between zones of varying reflectivity which is a function of acoustic impedance differentials.

1.4.1 Seismic Refraction Surveying.

Analyses of refraction travel-time graphs involve ambiguities that must be considered in any interpretation. For example, a refractor branch of decreasing slope or gradient with respect to the previous branch can signal the existence of a zone of velocity increasing either laterally or vertically away from the shot point. Zones of decreasing velocity at depth will not be detected. A complexity in analyzing refraction travel-time graphs is that refractors in the most general case involve significant components of dip. For the more general case, the reciprocal of the gradient of the refractor branch is an apparent velocity dependent not only on the velocity of the layer, but the dip as well. Apparent velocity is higher than the refractor velocity when recording along a survey line up dip from the shot point, and lower when recording down dip. To deal with the possible presence of refractor dip, we reverse the refraction experiment by recording signals from energy sources positioned at each end of the survey line. The forward and reverse travel-time curves for refracted rays will differ in their gradients and intercept times in the presence of components of refractor dip. In general, the travel-time graph provides all parameters necessary for estimating the attributes of subsurface refractors such as velocity, depth, thickness, and dip.

A further complexity in the interpretation of refraction travel-time graphs is that the refracting interfaces more commonly involve irregular, nonplanar variations, which in turn, cause travel-time variations to occur along the refractor branches. However, analyzing the differences in travel time (i.e., the delay times) that occur at common offsets between the up-dip and down-dip refractor branches permits us to map the refracting interface irregularities.

In the reduction of seismic refraction data, two corrections are commonly applied. A topographic or elevation correction may be needed to remove travel-time variations due to differences in elevation of individual shots and geophones. Thickness variations in the low-velocity zone of weathering at the Earth's surface will also distort the arrival times on a refraction travel-time branch. Hence, elevation and weathering corrections may be applied to reduce travel times to a common elevation datum plane. In shallow marine refraction surveying, the water layer is commonly treated as a weathered zone and the correction is applied to replace the water layer by material of velocity equal to the velocity of the seabed.

The refraction method is applied at regional to global scales using earthquake or high-energy explosion-generated seismic data to provide basic information on the distribution and nature of the Earth's layering from the core to the surface. The refraction method using smaller energy sources is also a principal tool for investigating more local attributes of the near-surface Earth, such as the distribution of refractor interfaces, thicknesses, dips, and velocities to distinguish layer composition, and for finding vertical discontinuities (e.g., faults, areas of steep dip, salt domes). In application, however, the refraction method may suffer from several limitations. For example, to obtain complete travel-time graphs, profile lengths of up to 3 to 5 times the depth of investigation are required. This causes rapidly increasing demands on the energy source for carrying out the refraction survey. The refraction method also suffers from the velocity-inversion problem, where it cannot detect low-velocity zones beneath higher-velocity layers. In addition, refraction surveys can suffer from the blind-zone problem, where a layer is encountered that is so thin that it produces a critical refraction at only a single geophone position. To pick a refractor branch reliably, the layer must be thick enough to produce refractions on several seismograms. The occurrence of blind zones and velocity inversions within the subsurface can significantly affect the accuracy of the interpretation of refraction data. Finally, the complexities of picking refraction travel times and constructing the travel-time graph essentially limit the interpretation to a relatively small number of layers (up to about 5 or 6 layers) in most applications.

1.4.2 Seismic Reflection Surveying.

Reflection surveying offers several significant advantages over the refraction method for subsurface exploration. For example, reflection surveying can provide much greater subsurface detail in terms of the number of layers that can be mapped, as well as greater detail on the relief of the beds. Velocity inversions and blind zones also are not a concern to reflection surveys. In addition, geophone array lengths or spread lengths are generally much smaller than those required for refraction surveying, so that the source energy requirements for conducting reflection surveys can be much less.

A major problem with the application of reflection surveying is to distinguish reflections from all the other seismic events on the seismogram. Reflected pulses are commonly weak and do not appear in isolation on a seismogram, but rather they are distorted by interfering effects of numerous other seismic events arriving along different wave paths and from different wave types. As a result, sophisticated and expensive equipment, field techniques, and processing technologies are required to facilitate the recognition of reflections in the survey data. A further complication in the interpretation of the reflection data is that independent determinations of the subsurface velocities are required for effective and accurate depth analysis of the reflectors.

The interpretation of reflections on the seismogram involves the highly idealized assumption of normal-incidence reflection through a stratified subsurface, which invokes a problematic representation of reality. For example, seismograms in practice are commonly collected at significant offsets with respect to the position of the source, so that the condition of true normal incidence is rarely obtained. In practice, we find that the arrival times for reflections on adjacent seismograms increase hyperbolically with increasing offset, and hence these reflections as they were obtained do not conform to the condition of normal incidence. Furthermore, interpretations based on this condition ignore refractions, which must occur across any layer interface separating different velocities. As a result, in addition to maximizing the signal-to-noise ratio of reflections in any application, a primary objective in reflection survey design, data reduction, and processing is to adjust the observed data to the normal-incidence condition for accurate interpretation.

Seismic reflection survey data are commonly presented as a suite of seismograms called a record section. Figure 2 presents a seismic section obtained from a split-spread, multichannel reflection survey. In this case, the shot point is roughly centered within an array of 48 channels recording the output from geophones. The portions of the seismograms, or seismic traces, corresponding to upward motion of the ground surface have been shaded to facilitate the recognition of reflections. Shortly after shot detonation the first arrival of seismic energy produced by direct and refracted waves reaches the innermost geophones, and this energy passes out symmetrically through the two arms of the split spread. The first arrivals are followed by a series of reflection events revealed by their hyperbolic moveout or increasing arrival times.

In conventional reflection surveying, each detector in a profile consists of an array of geophones where the geophone outputs are simply summed or integrated to produce a single channel of output for the seismic sec-

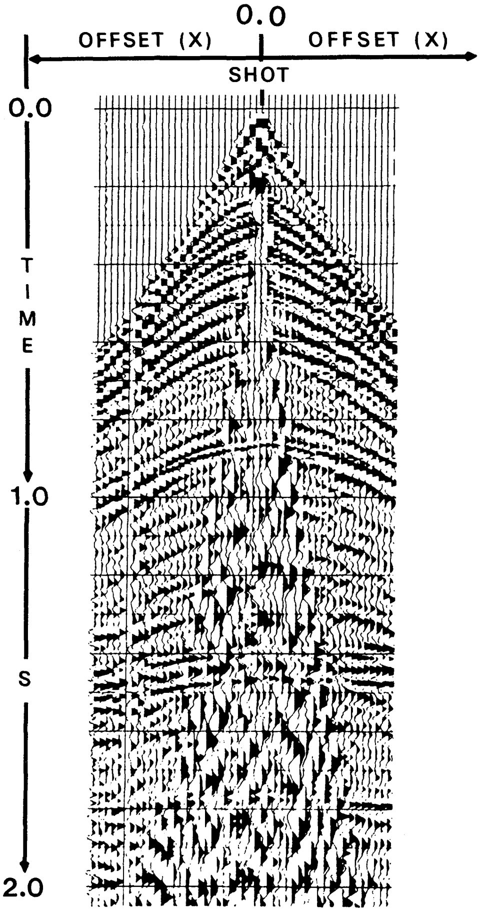

FIG. 2. A draped seismic section from a split spread array (from Prakla-Seismos GMBH by Keary and Brooks, 1984). Sets of reflected arrivals from individual interfaces are recognizable by their characteristic hyperbolic form. Reflected arrivals are masked within a triangular-shaped central zone by the arrivals of slow, large-amplitude and low-frequency surface waves (ground roll).

tion. The effective offset of a detector array is given by the distance from the shot to the center of the array. Geophone arrays provide a directional response to enhance the detection of near-vertically traveling reflected pulses, while breaking up or suppressing nonvertically traveling seismic events such as horizontally traveling Rayleigh surface waves.

In conventional reflection surveying, two reductions known as the static and dynamic corrections are commonly applied to facilitate geologic interpretation. The static correction is a combined weathering and elevation correction that removes the effects of the low-velocity surface layer and reduces all reflection times to a common elevation datum. This correction is static in the sense that it represents a constant time adjustment for the entire seismogram. Calculation of the static correction requires knowledge of the velocity and thickness of the weathered layer as well as the velocity of the material beneath the weathered layer. Shallow refraction surveys may be used to obtain this information. The velocity of the weathered layer may also be obtained directly by lowering a geophone into the layer through a borehole and measuring the arrival times for small shots fired from the surface or vice versa.

The dynamic correction is applied to adjust reflections from an interface for their hyperbolic increase in arrival times with offset. This hyperbolic effect is commonly called the *normal moveout,* defined as the difference between the arrival times of reflections from an interface observed at different offset distances. This correction is dynamic in the sense that the adjustment is not constant, but rather it must be uniquely determined for each reflection on the seismogram.

Reflections from horizontal interfaces that are below the first layer do not have purely hyperbolic moveouts because the travel paths involve refractions and other path complexities. The moveout for deeper reflections tends to decrease to zero with increasing reflector depth. The dynamic correction for these deeper reflection events may be effectively estimated by calculating the root mean square velocity of the layers overlying the reflector.

The signal-to-noise ratio of reflections may be greatly improved where the survey is performed according to the common-depth-point (CDP) method. This method is designed to enhance reflected signals and to attenuate nearly all other seismic arrivals. As illustrated in Fig. 3, this is achieved by the summation or stacking of successive seismograms taken at various offsets that are all centered about a common point on the reflector. For such symmetric wave paths, the reflected arrival-times are all nearly equal when corrected for moveout, so that the reflection will be enhanced when the CDP seismograms are stacked. Nearly all other seismic arrivals, by contrast, have wave paths that depend strongly on the offsets, so that their effects are minimized and less coherent in the stack.

The seismograms generated around a common depth point are known as a CDP gather.

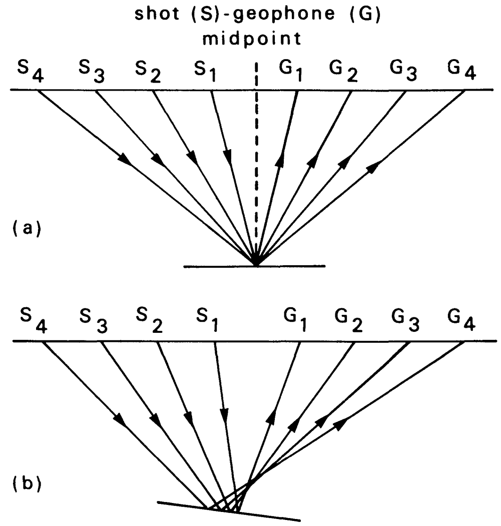

FIG. 3. Common depth point (CDP) reflection profiling (after Keary and Brooks, 1984) showing how (a) a set of rays from different shots to geophones are all reflected off a common point on a horizontal reflector, and (b) the common depth point is not achieved for a dipping reflector.

The four seismograms obtained from the wave paths illustrated in Fig. 3 provide a fourfold stack or alternatively represent 400% coverage. In theory, the CDP method is only applicable to horizontal reflectors. However, a statistical procedure has been developed that, when applied to a CDP gather, yields a stacking velocity for calculating the dynamic correction for almost any dip geometry of the reflector. The stacking velocities for a gather are computed over narrow time increments along the stack to produce a velocity spectrum. At each time increment, a range of velocity values is used to determine the dynamic corrections and the corrected traces are stacked. The stacking velocity is defined as the velocity that produces the maximum reflection amplitude in the stack.

In general, the CDP method can be applied to almost any geometry of field operation, and the performance of stacking improves with increasing multiplicity of coverage, allowing almost any desired improvement in the signal-to-noise ratio of reflections at the cost of recording more and more redundant data. Furthermore, better subsurface velocity information can be derived as a by-product of CDP stacking. Accordingly, this approach has become the standard method of multichannel reflection surveying.

Additional processing procedures are commonly implemented to facilitate the interpretation of reflection data. For example, rays that reverberate between the reflector interfaces may return to the surface to distort or masquerade as primary reflections. The correct identification of these multiple reflections is essential to avoid serious interpretation errors. In general, properties of multiple reflections such as their arrival times, amplitudes, and polarities are predictable from the attributes of the primary reflections so that procedures for identifying and removing multiple reflections are readily implemented. In addition, the differences in moveout between multiple and primary reflections increase with increasing depth so that CDP stacking will attenuate the occurrence of deeper multiple reflections in the reflection section.

A further adjustment of the reflection data is commonly warranted in the presence of diffracting sources in the subsurface and reflector undulations that are more convex than the incident wave front. For example, in the presence of a concave or synclinal undulation of the reflector surface, reflections are produced on the seismogram at vertical incidence only where the interface is horizontal. Where components of reflector dip exist, such as in the syncline, reflections will arrive on the seismogram along paths normal to reflector dip and not at normal incidence. Accordingly, such reflector undulations produce characteristic "bow-tie" signatures in the reflection section that cannot be interpreted in terms of vertically incident refections. Point diffractors such as the edges of thin faults also produce a cusp signature similar to the cusp illustrated in Fig. 4, but at maximum convexity, which distorts and may be confused with the signatures of primary reflections. Migration procedures are implemented to adjust the diffracted pulses and reflections from dipping interfaces into equivalent normal-incidence reflections. The migrated sections may be interpreted according to the idealized procedure for normal-incidence reflection using appropriate estimates of the layer velocities.

In addition to static and dynamic corrections, reflection seismograms also may undergo an amplitude correction to increase the continuity of reflection events across a section for enhanced interpretation, and to study the relative amplitude properties of the reflections. Hydrocarbon accumulations, for exam-

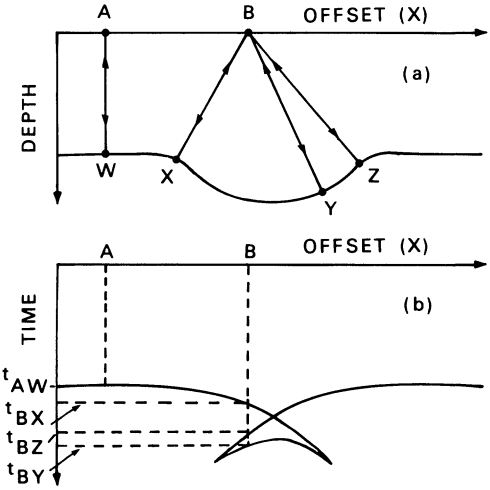

FIG. 4. (a) Reflections from a sharp synclinical feature in a reflecting interface, and (b) the resultant "bow-tie" shape of the reflection event on the non-migrated seismic section (after Keary and Brooks, 1984).

ple, may be directly revealed on amplitude-corrected sections by localized zones of anomalously strong reflections known as *bright spots*. These relatively prominent events are related to large-amplitude reflections from the top and bottom of gas zones such as gas-filled sands in the subsurface. In addition, fluid accumulations along a reflector interface may be directly signaled by *flat spots*, which are local horizontal or nearly horizontal reflection events splaying off the dipping reflector.

2. GRAVITY EXPLORATION

Gravity exploration focuses on measuring perturbations (anomalies) of the Earth's gravitational field caused by horizontal variations or contrasts in the mass and hence density properties of the subsurface. The process of obtaining models of mass distributions that fit the gravity anomalies can help to solve subsurface problems related to engineering and archaeological applications, hazard assessment, resource evaluation, studies of the Earth's tectonic features and processes, and other subsurface problems of considerable societal and scientific concern.

The multiple-stage process for applying the gravity method to the solution of subsurface problems involves data acquisition, data reduction, identification and isolation of significant anomalies, inversion of the selected anomalies for attributes of the subsurface, and finally the translation of these attributes into the context of a geological solution. Each stage of this process must be handled with appropriate care to ensure useful and accurate interpretations.

2.1 Principles

Gravity anomaly fields are potential fields, and thus they obey Laplace's equation. Their magnitudes are functions of the change in potential energy (work) so that they depend upon the relative position of the anomalous source and the point of measurement. In gravity exploration, we predominantly map the vertical component of the gravity field, because the gravity anomalies of geological mass variations are so small that perturbations of the Earth's gravity field in any direction other than the normal (i.e., vertical or radial) are negligible. For a unit point mass, the radial component of its gravity anomaly is given by

$$g(x_1,x_2,x_3) = -G \frac{\partial}{\partial R}\left(\frac{1}{R}\right)\frac{\partial R}{\partial x_1} m, \qquad (6)$$

where G is the universal gravitational constant, which has a measured value of 6.672×10^{-8} cm^3/g s^2; R is the distance from the observation point with generalized coordinates (x_1,x_2,x_3) to source point with generalized coordinates (x'_1,x'_2,x'_3); x_1 and x'_1 are the radial distances from the Earth's center to the observation point and source point, respectively; and m is the mass of the point source; with distances in cm and mass in g, the anomaly g is in milligals (1 mGal $= 10^{-5}$ m/s^2), which is the unit of measure most commonly used in gravity exploration.

Gravity anomaly fields are the summation of the effects of all anomalous sources regardless of quantity and distance. The gravity anomaly for an arbitrarily shaped body of uniform density σ, or mass per unit volume $m/dx'_1dx'_2dx'_3$, is obtained at the observation point by integrating Eq. (6) over the volume of the body according to

$$\int_{x'_{3a}}^{x'_{3b}} \int_{x'_{2a}}^{x'_{2b}} \int_{x'_{1a}}^{x'_{1b}} g(x_1,x_2,x_3)\,dx'_1dx'_2dx'_3\,, \qquad (7)$$

where the subscripts a and b refer, respectively, to the geometric lower and upper limits of the body in the orthogonal system of generalized coordinates (x'_1, x'_2, x'_3).

Conventional implementation of the above gravity equations expresses the effect of a subsurface body directly in terms of its density σ. However, in gravity exploration the density contrast, $\Delta\sigma$, is more commonly used in these equations. This is defined as the density of the subsurface source minus the density of the surrounding "country" material. Similarly, the observed gravity values are compared with the response of a homogeneous Earth; that is, the anomaly value is the observed value minus the theoretical or the normal value where there are no horizontal variations in density.

2.2 Density

Densities of crustal Earth materials vary roughly from 1.0 to 3.0 g/cm^3 (1 g/cm^3=10^3 kg/m^3). Individual mineral densities may exceed the upper limit of this range, because in addition to mineral composition, void space and void filling also control the density of Earth materials. The density of igneous rocks is primarily controlled by the relative mineral proportions. Felsic rocks contain a higher percentage of quartz and potassium- and sodium-rich feldspars than do mafic rocks such as gabbros, and thus they have a lower density. In contrast, the densities of clastic sediments and sedimentary rocks are controlled by the void space and void filling. Chemical sediments and sedimentary rocks vary considerably in density, but are primarily determined by mineral composition. In sediments and sedimentary rocks, voids will primarily be intergranular and will decrease with depth in the Earth due to compaction and, to a lesser degree, cementation. However, voids may occur in all rock types. For example, vuggy porosity can exist in chemical sedimentary rocks and in volcanic rocks, while fracture porosity is present wherever there are joints, faults, bedding planes, etc.

In geologic exploration with the gravity method, we are only concerned with horizontal variations in density or density contrasts. Vertical variations in density will not be recognized as a local crustal anomaly until they are horizontally truncated. Horizontal density contrasts in the subsurface may arise from inherent or imposed density variations. Inherent density variations may be caused, for example, by facies changes in sedimentary rocks and differentiation in plutonic bodies. Imposed effects can also lead to horizontal density contrasts. For example, deformed sedimentary strata of different densities will cause horizontal density variations, and fracturing or variable solutioning of rocks will also lead to horizontal mass disturbances.

The void space in rocks, which ranges from less than 2% in most igneous and metamorphic rocks to greater than 50% in some unconsolidated sediments at the Earth's surface, necessitates distinguishing between grain density σ_g and bulk density. Dry bulk density σ_d assumes moisture-free voids, and wet bulk density σ_w assumes complete saturation. The relationship between void space and density is

$$\sigma_w = \sigma_g - V_c\sigma_g/100 + F_c\sigma_f/100, \tag{8}$$

where V_c and F_c are the void content and fluid content, respectively, in percent, and σ_f is the fluid density.

2.3 Instrumentation

The utility of the gravity method in subsurface studies is dependent upon the efficient acquisition of precise data. Instrumentation for the measurement of gravitational acceleration has continued to improve, especially with the development of microprocessors and other electronic advances. Over the years numerous schemes have been developed and tested for measuring either the absolute or relative changes in gravity acceleration. However, today essentially all gravity measurements for geophysical exploration are relative measuring devices, gravimeters, which are based on the zero-length spring principle (LaCoste, 1934). Changes in the acceleration of gravity cause a variation in the gravitational force on a constant mass attached to a lever arm suspended from a zero-length spring. The relative position of the lever arm changes with gravity acceleration variations. Observations are made by determining the force that must be applied to the lever arm to bring it to a null position. This force is calibrated into gravity acceleration.

Standard gravimeters used in geologic exploration have a sensitivity of 0.01 mGal, and range without reset from a hundred mGal to several thousand mGal, depending on the specific instrument. However, gravimeters having a sensitivity of 0.001 mGal or 1 μGal are readily available for microgravity studies used in engineering and environmental investigations.

2.4 Surveying Procedures

Gravity surveying is usually conducted on a grid or along convenient transportation routes, with the station interval determined by the depth of geologic sources under investigation. The interval should be no greater than one-half the depth anticipated for target sources for the purpose of accurately mapping the gradients of the anomalies that are very important in interpretation. However, commonly the station interval needs to be decreased to map high-amplitude noise so that it can be identified and eliminated from the observed data. Elevations of the stations and their horizontal positions must be determined to an accuracy of approximately 4 cm (0.13 ft) and 12 m (40 ft), respectively, where we want gravimeter observations precise to 0.01 mGal, and 0.1 of those distances for μGal surveying. For this level of survey precision, accurate topographic surveying, which may have a significant impact on surveying costs and number and distribution of stations, is demanded.

2.5 Gravity-Data Reductions

Raw or field gravity data are affected by a wide variety of sources, which generally mask out the effect of the geologic sources that are the objective of the survey. As a result, field observations are subject to corrections to eliminate the extraneous effects. These corrections or reductions are derived theoretically, geologically, and empirically. Some reductions are applied universally to gravity data, while others are applied only for specific objectives and for certain geologic, topographic, and spatial size conditions.

Gravimeter observations are only relative. Therefore, to adjust measurements made at different times and with different meters relative to each other, all daily observations are referred to a single base station. Wherever possible, this base should be tied through observations to a national gravity base station. Information on base stations is available from appropriate federal agencies and many state geologic surveys.

Time variations in gravity or "drift" of the gravity measurements must be eliminated for essentially all exploration surveys. The two principal sources of drift are tidal effects and inherent fluctuations in gravimeter observations that reflect the ambient environment of the meter. Tidal effects are calculated by taking into account variations in the mass effect due to the changing relative positions of the Sun and the Moon with respect to positions on the Earth's surface. The maximum tidal variations of the Moon and Sun are respectively ±0.11 and ±0.05 mGal, and the maximum rate of change is 0.05 mGal/h. Inherent drift of gravimeters is caused by temperature and air-pressure changes, as well as fatigue of the sensing element and the mechanical shocks to which the instrument may be exposed. Under normal operating conditions the effect of inherent drift is less than the tidal variations, except for temperature-compensated meters that are subject to extreme temperature variations. Drift rates may exceed 0.1 mGal/h under these extreme conditions. Observed gravity values are generally corrected for temporal variations by monitoring the change in gravity by reoccupation of gravity stations assuming a linear change with time.

The gravity acceleration on the surface of the Earth increases as a function of latitude by approximately 5 Gal from the equator to the poles because of decrease in the Earth's radius and centrifugal force. The most recent internationally accepted equation for computing this latitude variation at sea level is the Geodetic Reference System of 1967 (GRS-1967) given by

$$g_\phi = 978.0318(1 + 0.005\,302\,4\sin^2\phi - 0.000\,005\,9\sin^2\phi), \qquad (9)$$

where g_ϕ is the predicted gravity in Gal at sea level at a north or south latitude of ϕ.

The elevation (or free-air) correction takes into account the decrease in gravity with distance from the center of the Earth. The gradient is given by

$$dg/dh = 0.308\,55 + 0.000\,219\cos 2\phi - 7.2\times10^{-8}h, \qquad (10)$$

where dg/dh is the vertical gradient of gravity in air in units of mGal/m at a station located an elevation h in meters above sea level and at latitude ϕ. The gradient changes only by 0.2% from the equator to the pole and by 0.3% from sea level to 10 km. Therefore the gradient is usually calculated assuming

$$dg/dh = 0.3086 \text{ mGal/m} = 0.094\,06 \text{ mGal/ft.} \tag{11}$$

The mass or Bouguer correction takes into account the gravitational attraction of the Earth material between the station elevation and the elevation datum. The correction is assumed to be equal to the gravity effect of a horizontal slab of infinite radius and thickness equal to the elevation difference, which can be shown to be

$$\begin{aligned} g_m &= 2\pi G\sigma h \\ &= 0.041\,85\sigma h \text{ mGal/m} \\ &= 0.012\,76\sigma h \text{ mGal/ft} \end{aligned} \tag{12}$$

for σ in g/cm^3 and h in meters or feet, respectively. The assumption of a horizontal slab made in the mass correction is commonly violated in practice where sufficient topographic relief exists between gravity stations. Therefore, a terrain correction is used to account for topographic deviation from a slab that has a thickness equal to the height of the gravity station. The effect of topography, whether above or below the station, is always to decrease the mass correction, because the attractive force of the topography above the observation site is away from the Earth, and the effect of topography below the station is also negative because it involves lack of Earth material. The precision with which terrain corrections can be made for surveys conducted in areas of rugged topography is often the controlling factor in the success of a gravity survey.

Additional specialized reductions are used for marine and airborne gravimetry. Gravity observations made in moving platforms such as ships or aircraft are corrupted by extraneous accelerations including horizontal and vertical accelerations produced by three-dimensional platform motions, the Eötvös effect of modified centrifugal acceleration that every moving gravimeter experiences, and other effects. Accelerations from local motions such as pitch, roll, and heave of the measurement platform are readily minimized by using an effectively damped gravimeter on a gyroscopically stabilized platform that can maintain the horizontal position to within a few seconds of arc. Removal of extraneous Eötvös effects from gravity observations requires relatively accurate knowledge of the vessel's navigation parameters such as its speed, heading, and latitude coordinates.

A number of other corrections are applied to gravity data for specialized purposes, particularly in regional surveys, which are becoming increasingly available as a result of technological advances in adapting shipborne, airborne, and spacecraft platforms for gravity mapping. They include

1. geologic correction, which takes into account the gravitational effect of geology known from direct geologic information or supplemental geophysical studies;
2. isostatic correction, which is the gravity effect of the Earth's topography and related isostatic compensating masses according to an isostatic theory;
3. curvature correction, which considers the gravity attraction of the actual curvature of the Earth's surface in contrast to the flat slab of the mass correction; and
4. indirect reduction, which accounts for the difference in elevation between the Earth's geoid, the reference surface for elevations, and the spheroid, the reference surface for gravity measurements.

2.6 Gravity Anomalies

When corrected for a wide variety of known variations as described above, the observed or raw gravity data yield a gravity anomaly that isolates variations due to mass (geologic) variations in the Earth. Several types of gravity anomalies have been devised on the basis of the corrections actually considered in calculating the predicted gravity. They all have their specific uses, but the most useful for exploration surveys is the complete Bouguer gravity anomaly, which takes into account the latitude, elevation, mass, and terrain corrections. By contrast, the simple Bouguer gravity anomaly omits the terrain effect.

Conventional Bouguer gravity-anomaly maps of regional areas (states, nations, etc.) are based on a density of 2.67 g/cm^3 (2670 kg/m^3) in the mass correction. This density has been assumed to be the average density of upper continental rocks. Use of the standard value facilitates compositing and comparison of gravity-anomaly maps. However, where the surface material is made up of rock units of a different density, errors will result that are proportional to the station elevation.

A gravity anomaly used commonly in marine, satellite, and other regional studies is the free-air gravity anomaly, which omits both the mass and terrain effects. The free-air anomaly is useful in mapping mass imbalances of the Earth that are of interest in long-term stability studies and in investigating stress variations in the Earth that may trigger or even cause local earthquakes (Hinze and Hildenbrand, 1988). The free-air anomaly is especially useful in regions of limited local terrain. Another anomaly that is also occasionally used for a similar purpose to that of the free-air anomaly is the isostatic anomaly. This anomaly eliminates the effect of topographic compensating masses by assuming that the Earth is in isostatic equilibrium according to a specified hypothesis. Thus mass imbalances from the assumed ideal condition are reflected in the anomalies.

2.7 Anomaly Isolation and Enhancement

Gravity anomaly fields combine the effects of all horizontal variations in density within the Earth, and thus the anomalies of interest in a particular geologic application are commonly distorted by overlapping anomalies. The gravity anomaly fields include the effects of deeper, broader sources called regional anomalies, local sources, which are considered noise, as well as the anomalies of interest which are commonly called residual anomalies. The definition of the residual anomaly is not very precise, but perhaps can best be defined as the anomaly of geologic interest in a particular study. Broader anomalies than the residual are often called regional anomalies and the smaller anomalies are generally referred to as noise. Thus the specification of an anomaly as a residual is problem dependent. The separation of the residual anomaly from the gravity field is a critical problem that controls the accuracy of the interpretational process. The subjectivity of the residual determination process makes it potentially one of the major limitations of applying the gravity method to many geological problems.

Over the years numerous graphical and numerical techniques, which are in reality filters, have been devised to focus on particular anomaly types, of specified characteristics, within a field of superimposed anomalies of varying properties. These techniques can be divided into two broad categories as *isolation* and *enhancement* methods. Isolation techniques are used to eliminate from the anomaly field all anomalies that do not have a certain set of qualitatively or quantitatively specified characteristics. Thus, the remaining anomaly, the residual anomaly, is the isolated gravity expression of the geologically significant source. Enhancement techniques, in contrast, accentuate a particular characteristic or group of characteristics of anomalies that are qualitatively or quantitatively definitive of anomalies that have special geologic significance. In the process of enhancing these characteristics, the anomalies are accentuated to increase their perceptibility. The "enhanced" potential fields are primarily used in qualitative visual inspection analysis and interpretation.

The most widely used method currently of isolating and enhancing anomaly data is digital filtering in the frequency (wavelength) domain of the data. In this procedure, the input data are Fourier transformed into the frequency domain (i.e., their spectrum) by the direct transform, multiplied by an appropriate filtering function, and the modified spectrum is transformed back into the space domain by the inverse Fourier transform. This is an efficient process on digital computers, and filters can be simply and accurately designed to carry out a wide variety of anomaly isolation and enhancement processes.

Fourier transforms depend only on the amplitudes and positions of the observations and require no information on the subsurface sources of the observations for their implementation. The transforms, however, may be directly processed or filtered for breaking up the data set into wavelength components (wavelength filtering) to remove, for example,

1. the higher-frequency noise due to small, near-surface sources with a low-pass filter,
2. the longer-wavelength component of the regional anomalies with a high-pass filter, or
3. both long- and short-wavelength components with a band-pass filter.

This approach also is used for separating anomaly components on the basis of their directional attributes (directional filtering), and for extracting the horizontal gradients. The vertical gradients of gravity anomalies are related to the horizontal gradients by Laplace's equation, so that the vertical gradients too may be extracted from the wavelength transform. Horizontal and vertical derivatives depict the gradient variations in the anomaly field and emphasize higher gradients, which are related to anomalies of near-surface sources and are associated with the positions of the boundaries of gravity anomaly sources. Consequently, derivative filter data will provide approximate shape outlines for modeling anomaly sources.

In addition, because the vertical gradients of gravity anomalies can be estimated, it is a straightforward matter to design upward and downward continuation filters that process the Fourier transform for accurate models of the observations over parallel surfaces respectively above and below the observation surface. Upward continuation minimizes the effect of higher-frequency components associated with more local, shallower source anomalies. In contrast, downward continuation emphasizes these components and increases the resolution of the anomaly field to individual sources. Downward continuation and anomaly gradient filters are particularly powerful tools in the study of near-surface sources. However, they are especially susceptible to distortion from noise, measurement errors, and other data inaccuracies, so that care must be taken in the interpretation of their results.

2.8 Interpretation

The level of interpretation achieved in gravity exploration is highly variable depending on the survey objectives, the quality of the data, and the available time and resources. Interpretation can range from simple identification and location of anomalous density contrasts in the subsurface to three-dimensional modeling, leading to complete characterization of anomaly sources. A key element in gravity interpretation is the availability and quality of ancillary data regarding the subsurface. Interpretation is ambiguous because the observed anomaly can be reproduced by an infinite number of source distributions shallower than the actual source of the anomaly and because of imprecision in the data. As a result, ancillary data, especially direct geologic data, provide important constraints to interpretation. These data can be used to develop conceptual subsurface models (hypotheses) to be tested by the data interpretation. Interpretation is commonly performed in an iterative manner utilizing previous interpretations as well as other geologic and geophysical data to develop improved models for testing until an interpretation is achieved that is compatible with all data sets.

The amplitude and character of the anomaly signatures of gravity sources in the subsurface are dependent on several key factors or variables. Anomalies vary with source geometry, including volume and shape, and with source depth. The amplitude and sign (or polarity) of the gravity anomaly are direct functions of the magnitude and sign, respectively, of the density contrast. Some examples of typical gravity anomaly profiles over idealized geological mass variations are presented in Fig. 5.

The general problem of estimating quantitative parameters of the source from the anomaly data is known as anomaly inversion. The inversion of residual anomalies is used to determine shape attributes, volume, depth, depth extent, densities, and other features of the geologic sources. For example, the maximum depth to sources of gravity anomalies can be easily derived from simple horizontal distance measurements on observed anomalies as indicated in Table 1. Solving the inverse problem requires postulating a mathematical model of the source with parameters that can be related to variations in the anomaly data.

Table 1. Maximum depth to the center (Z_c) or top (Z_t) of ideal gravity sources. Here $X_{1/2}$ is one-half the width of the anomaly at one-half the amplitude; $X^*_{1/2}$ is the horizontal distance from one-half the amplitude to either one-fourth or three-fourths of the amplitude; and DE is the depth extent of the source.

Geometric form	Depth
Sphere	$Z_c \leqslant 1.3X_{1/2}$
Horizontal cylinder	$Z_c \leqslant 1.0X_{1/2}$
Vertical cylinder	$Z_t \leqslant 0.58X_{1/2}$
Vertical fault	$Z_c \leqslant X^*_{1/2}$
Vertical thin dike	$Z_t \approx 0.7X_{1/2}$, $Z_t = \mathrm{DE}$ $Z_t \approx 1.0X_{1/2}$, $Z_t \gg \mathrm{DE}$

Schematic gravity (dashed) anomalies, and total-intensity magnetic (solid) anomalies (after Breiner, 1973), over idealized geologic sources with positive physical property contrasts (symbolized by k_1 for the fault between two rock units). Legend gives geomagnetic field (*F*) and anomaly profile orientations.

Evaluating anomaly values from the mathematical model of the source is called *forward modeling*. The solution of the inverse problem is based on how well anomaly predictions derived from forward modeling compare with the residual anomaly. However, a close match between predicted and residual anomalies does not guarantee a unique solution, but rather the solution is only one of a family of possible interpretations. This is because of the source ambiguity of potential fields, solution uncertainties related to errors in the residual anomaly values, and errors in postulating the mathematical model, which in every instance represents a simplified approximation of the source.

Numerous equations and algorithms exist in the literature for computing gravity anomalies of geologic sources that are used in the forward-modeling component of anomaly inversion. Relatively complex computations of gravity anomalies derived from arbitrarily shaped two- and three-dimensional sources are routinely performed by established procedures (e.g., Hinze, 1990). Simpler computations that idealize the anomaly source in terms of symmetric shapes are presented in Table 2.

Upon completion of the modeling procedures and the consequent definition of the anomaly source characteristics, there remains the problem of putting the physical model and the density contrast into a geologic context. This calls for integration of geologic principles and laws and rock properties with the gravity model.

Table 2. Equations for computing gravity anomalies of ideal sources. Here g is the gravity anomaly in Gals (m/s^2) due to a density contrast σ in g/cm^3 (kg/m^3); G is the gravitational constant, 6.672×10^{-8} cm^3/g s^2; V is volume; R is the distance between observation point and center (sphere) or axis (cylinder) or center line; x is the horizontal distance from observation point to center (sphere) or axis (cylinder) or center line (sheet) or edge (fault); d is depth to center (sphere) or axis (cylinder) or top (d_1) or bottom (d_2) of sheet or center line (fault); t is thickness; r is radius; θ is angle from horizontal. All distances are measured in centimeters.

Source	Gravity anomaly
Basic	$g=\frac{G\sigma Vd}{R^3}$
Sphere	$g=\frac{4\pi G\sigma r^3}{3d^2}\frac{1}{[1+(x^2/d^2)]^{3/2}}$
Vertical cylinder (infinite)	$g=\frac{\pi G\sigma r^2}{(x^2+d^2)^{1/2}}$
Horizontal cylinder (infinite)	$g=\frac{2\pi G\sigma dr^2}{(x^2+d^2)}$
Narow vertical sheet	$g=\frac{2G\sigma t\ \ln(x^2+d_2^2)^{1/2}}{\ln(x^2+d_1^2)^{1/2}}$
Vertical fault	$g=2G\sigma t\theta$
Finite slab	$g=2G\sigma t(\theta_1-\theta_2)$

3. MAGNETIC EXPLORATION

Magnetic exploration is based on mapping perturbations or anomalies of the geomagnetic field related to lateral magnetic property variations of the subsurface. Magnetic anomalies detected by conventional magnetometers range from small-scale features derived from magnetic property differences within the uppermost meter of soil to very-long-wavelength anomalies related to broad-scale variations of the magnetic properties near the base of the lithosphere. Hence the magnetic method is used in the solution of geologic problems over a considerable number of applications ranging from archaeological and engineering site investigations, to exploration for economic resources, to studies of crustal tectonic features and processes.

The geomagnetic field is a potential field so that any set of magnetic observations can be related to an infinite number of magnetic source distributions. This inherent ambiguity of the magnetic method plus additional uncertainties resulting from the observation, reduction, and processing of these data limit the accuracy of geologic interpretation. This ambiguity can be significantly diminished, however, with the use of constraining geologic and geophysical data.

The application of the magnetic method to the solution of geologic problems requires a multiple-step process that is analogous to that previously described for the implementation of the gravity method.

3.1 Principles

Magnetic surveys involve measuring perturbations of the geomagnetic field caused by anomalous subsurface sources at or near the Earth's surface, extracting the geological component from these measurements, and translating the anomaly data into the anomalous geology. Perturbations of the geomagnetic field are caused by horizontal variations in the magnetic polarization of the Earth, and hence by horizontal variations of the magnetic properties of the subsurface. Magnetic anomaly fields are potential fields and thus obey Laplace's equation.

In magnetic exploration, measurements are predominantly restricted to the scalar intensity (magnitude) of the total component of the Earth's magnetic field because of instrumental limitations. This total-field component represents the vector sum of the normal geomagnetic field, which originates largely in the outer core of the Earth, and the anomalous effects of magnetic sources in the subsurface. As long as the normal geomagnetic field is large compared to the anomalous field, we can assume to good approximation that the total field anomaly represents a perturbation of the geomagnetic field along its principal direction. This assumption seems to hold almost always, except in the near fields of large steel objects, or in the vicinity of iron ore deposits, or various mafic rocks and other features which produce anomalies with absolute magnitudes equal to or greater than about 10,000 nT. In the older literature, another unit was commonly employed for magnetic field strength, known as the gamma (γ), which is equivalent to the nanotesla.

For a unit point dipole, the total-field magnetic anomaly at an observation point with generalized coordinates (x_1,x_2,x_3) is

$$T(x_1,x_2,x_3) = -\mathbf{c}\cdot\nabla[\mathbf{c}'\cdot\nabla'(1/R)]M, \qquad (13)$$

where R is the distance between the observation point and source point with generalized coordinates (x'_1,x'_2,x'_3) ∇ and ∇' are the vector gradient operators in observation-point and source-point coordinates, respectively; M is the magnitude of the dipole's magnetic moment; $\mathbf{c}$ is the unit geomagnetic field vector at the observation point; and $\mathbf{c}'$ is the unit vector in the direction of the source magnetic moment. To obtain the total field magnetic anomaly of an arbitrarily shaped body of uniform magnetization intensity J, or magnetic moment intensity per unit volume $M/dx'_1dx'_2dx'_3$, at the observation point, we integrate Eq. (13) over the volume of the body:

$$\int_{x'_{3a}}^{x'_{3b}}\int_{x'_{2a}}^{x'_{2b}}\int_{x'_{1a}}^{x'_{1b}} T(x_1,x_2,x_3)\,dx'_1dx'_2dx'_3, \qquad (14)$$

where the primed variables refer to the generalized coordinates of the anomalous body as described for Eq. (7) above.

In the application of Eqs. (13) and (14), the unit vectors $\mathbf{c}$ and $\mathbf{c}'$ are expressed in terms of geomagnetic field inclination (I,I') and declination (D,D') at the observation and source points, respectively. Also, the magnetization is a function of the geomagnetic field strength at the source point. These parameters vary markedly about the Earth to complicate the analysis and interpretation of total-field anomalies. For example, the inclination and intensity of the normal field increase, respectively from 0° and about 22 000 nT at the geomagnetic equator to 90° and nearly 70 000 nT at the geomagnetic pole. The normal geomagnetic field is shifted approximately 11° from the axis of rotation of the Earth as illustrated in Fig. 6. The components of the Earth's normal magnetic field in mid-latitudes in the northern hemisphere are illustrated in Fig. 7.

To see how variations of the normal geomagnetic field can affect interpretation of total-field anomalies, consider Fig. 8, which shows

1. the vectorial representation of the Earth's field,
2. the source, which is magnetized by induction in the Earth's field, and
3. the resultant of the two fields

at a series of positions along the magnetic meridian. It is the scalar of the resultant field that is measured by most magnetometers and that, when the Earth's normal field (scalar) is subtracted, results in the anomalous field. The anomalous field is plotted above the cross section of the Earth and shows that a source of positive magnetization (higher magnetization than the country rock), which produces a

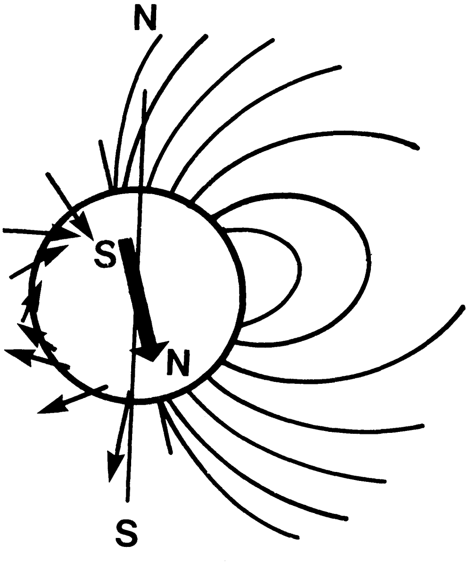

FIG. 6. Schematic diagram showing the lines of magnetic force and vectorial representation of the geomagnetic field.

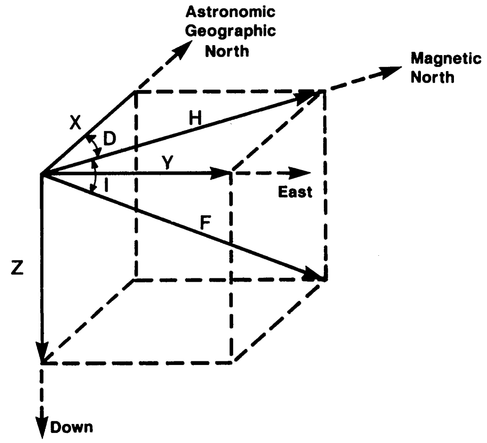

FIG. 7. Schematic diagram of components of the geomagnetic field at mid-latitudes in the northern hemisphere. In geomagnetism, declination (*D*) and inclination (*I*) are also called magnetic strike and dip, respectively.

dipolar charge with a negative pole near the upper surface in the northern geomagnetic hemisphere, will actually result in a negative anomaly on the north side of the positive anomaly. Also, the peak of the positive value is shifted to the south from the magnetic source. This shift and the intensity of the negative anomaly will increase with decreasing magnetic inclination to 45° where the positive and negative portions of the anomaly are antisymmetrical and the crossover from positive to negative values occurs directly over the anomalous source. The variation in the anomaly becomes even greater at lower inclinations, resulting in a symmetrical magnetic minimum over a positive magnetic source at the magnetic equator. In the southern magnetic hemisphere, the anomalies are reversed, with the minimum to the south of a positively magnetized source and the peak of the positive anomaly shifted to the north. The anomalies will be inverted where the anomalous source is less magnetic than the country rock. Over the United States, the magnetic anomaly from the same source magnetized by the Earth's field will increase in symmetry from the southern to the northern limits and will increase in intensity because of the increasing inclination and geomagnetic field strength.

For a point mass that is also magnetized, the anomaly-field calculations involve the same observation-to-source point geometries, so that the magnetic and gravitational potentials of the common source can be related. We can use this result, which is a manifestation of Poisson's theorem, to combine, for example, Eqs. (6) and (13) at the geomagnetic pole to obtain

$$T = (J/\sigma G)(\partial g/\partial x_1). \qquad (15)$$

This equation has many uses in comparing gravity and magnetic fields, but it shows in very simple terms that the magnetic field

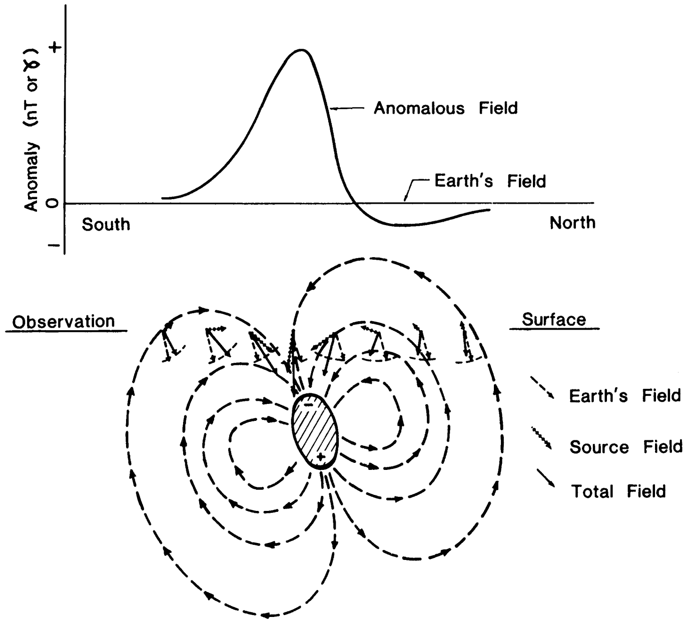

FIG. 8. Schematic illustration of the summing of the Earth's magnetic field and the anomalous source field to produce the observed total magnetic intensity plotted at the top of the figure.

varies one power faster with respect to distance than does gravity. Thus the magnetic anomaly of a source will be more sensitive to depth and will better define the location of the source than the gravity anomaly from the same source.

Conventional implementation of the above magnetic-anomaly equations expresses the effect of the subsurface body directly in terms of its magnetization intensity, J. However, in magnetic exploration, the magnetization intensity contrast ΔJ is more commonly used, defined as the magnetization intensity of the subsurface source minus the magnetization intensity of the surrounding country material. Similarly, the observed magnetic values are compared with the response of a homogeneous Earth; that is, the anomaly value is the observed value minus the theoretical or the normal value where there are no horizontal variations in magnetic polarization.

3.2 Magnetic Properties

The intensity of magnetization or the magnetic polarization J of a magnetized body is defined as the magnetic moment per unit volume, and thus it is a function of the number and orientation of elementary dipoles. The magnetization is the vectorial summation of the induced and remanent (permanent) magnetization. Induced magnetization is the magnetic polarization caused by Earth's normal (main) field and is the product of the intensity of the Earth's field and the magnetic susceptibility of the substance.

The magnetic susceptibility of rocks is primarily dependent on the volume percent content of magnetite. This ferrimagnetic mineral is a common accessory mineral in igneous and metamorphic rocks and occurs in trace amounts in sediments and sedimentary rocks. In general, the magnetic susceptibility of rocks increases with the mafic content, but the notable exceptions suggest caution in the use of this "rule" as anything other than a broad generality.

Remanent magnetization is another component of the magnetic polarization of rocks that may originate in different ways and at different times in the history of the rock. The net remanent magnetization of a rock in place is the natural remanent magnetism. This is the magnetization measured by the field magnetometer. In paleomagnetism studies, the less stable components are stripped from the rock so that particular remanent components, such as thermal remanent magnetism imposed upon an igneous rock as it cooled through the Curie point, can be investigated. Sedimentary rocks typically have low values while unmetamorphosed basalts have high natural remanent magnetizations.

In engineering, environmental, and archaeological studies with the magnetic method, we are interested not only in the magnetic properties of the common rock types, but also in those of soils and iron objects. The magnetic susceptibilities of soils reflect their parentage. Soils derived from igneous and metamorphic rocks, particularly the more mafic components of these lithologies, commonly will be relatively rich in magnetite. This is emphasized by the resistance of magnetite to alteration. Furthermore, magnetite tends to concentrate in sediments where the streams carrying magnetite and other heavy minerals lose velocity and thus deposit these mineral grains. As a result, magnetite tends to concentrate in the distributary streams in alluvial fans at the base of mountains, and in terranes covered by glacial deposits, magnetite will be concentrated in eskers, outwash deposits, and beaches of ancient glacial lakes. In addition, maghemite, a relatively magnetic form of hematite, is produced in high-organic soils. Surface soils often acquire a remanent magnetization with twice the intensity of induced magnetization by thermal effects due to fires or simply by isothermal "viscous" remanent magnetization acquired over a long period of time. Disruption of the soils by man will result in local anomalies as will natural or man-made fires. Relative to most rocks and soils, typical iron or steel objects such as pipes, drums, etc. have very large magnetizations, which often include remanent magnetizations that reach values of 10 or more times the induced components.

3.3 Instrumentation

Essentially all magnetic measurements made, whether in a stationary mode or from a moving platform, use a fluxgate, proton-precession, or alkali-vapor magnetometer. These have individual attributes that need to be considered in selecting an instrument for a particular magnetic survey.

The fluxgate magnetometer measures only the relative change in the Earth's magnetic field and is directionally dependent. The latter quality is a disadvantage because it must be oriented for measurements, and an advantage because not only can the total field be measured as is the case for the other magnetometer types, but by proper orientation the instrument can be used to measure the vertical and horizontal components of the field, which may provide an interpretational advantage under specific circumstances. The fluxgate magnetometer normally has a sensitivity of 1 nT, although with special care a sensitivity of 0.1 nT has been achieved in airborne sensors. Problems encountered in orientation of the fluxgate magnetometer on a moving platform require that the sensor be oriented in the direction of the geomagnetic field; thus the total field is measured.

The most commonly employed magnetometer in both stationary and mobile modes is that of the proton-precession magnetometer, which measures the absolute total intensity of the geomagnetic field, without the need for orienting devices, to a precision of the order of 0.1 nT. The proton-precession magnetometer measures the precession frequency of protons in a hydrogen-rich fluid that have been oriented at a large angle to the Earth's field by the strong magnetic field from a current passed through a coil of wire wound around the fluid container. On termination of the current through the coil and relaxation of the imposed magnetic field, the protons return to their original alignment about the Earth's normal field direction with a precessional frequency related to the absolute Earth's field through a well-known constant, the gyromagnetic ratio. The proton-precession magnetometer has many advantages, but it has two principal disadvantages. The observations of the magnetic field are not continuous; rather they require a finite period of time for orienting the protons with the current passing through the coil and for measuring the precessional frequency. Decreasing the reading interval will decrease the sensitivity of the instrument. This may cause a problem in making observations from a mobile platform where a choice must be made between data interval and data sensitivity. However, sampling rates can be increased with an Overhauser-effect proton magnetometer. Furthermore, the proton-precession magnetometer is subject to erroneous observations resulting from ac power interference and large magnetic gradients. Gradients of the order of 300 to 1000 nT/m, which may occur close to iron or steel objects and magnetic iron formations, may cause the instrument to malfunction.

The alkali-vapor magnetometer, which is capable of an order of magnitude or greater sensitivity over the proton-precession magnetometer, is primarily used for airborne observation of the total magnetic field. This magnetometer is based on the principle of optical pumping used in radio-frequency spectroscopy. The sampling rate of the alkali-vapor magnetometer is much higher than that of the proton-precession magnetometer and it will operate in much higher magnetic gradients. Unfortunately, the optical pumping principle will not operate when the axis of the instrument is parallel or perpendicular to the magnetic field. This problem has been eliminated in some units by including multicelled sensors.

Measurement of the gradients of magnetic fields, both vertical and horizontal, offers several attractive advantages over simple fields. Gradients minimize regional anomalies, increase resolution, and eliminate temporal magnetic variations. As a result, magnetic gradiometers, normally employed in the vertical mode and occasionally in a horizontal configuration, are regularly used, especially in the study of near-surface anomalies. Magnetic gradiometers are simply two magnetic sensors that are separated by a fixed distance, with measurements made simultaneously in both and compared for recording. Hood *et al.* (1979) present a comprehensive discussion of magnetic gradiometers as well as other magnetic instrumentation.

3.4 Surveying Procedures

Magnetic surveying for geoexploration purposes can be land, airborne, or shipborne. In land measurements, observations can be made at extremely close intervals, which permits high resolution of near-surface sources. However, they are time consuming and expensive if the survey is measured in kilometers. Furthermore, surface observations are susceptible to local magnetic anomalies originating from cultural features and magnetic polarization variations in soils and near-surface bedrock. The effects of near-surface magnetic sources are minimized by placing the magnetic sensor on a staff of several meters height and by making several observations within a limited area (a few to several meters) to detect any local source that would invalidate the observation site. However, for purposes of mapping magnetic variations in the soil, the sensor may be placed at only about 0.5 m above the ground surface. In any event, several measurements are generally made at each site to improve the precision of the observation by using an average value and to detect instrument malfunction and temporal variations in the magnetic field. Stations are laid out either on a grid or, in mapping linear anomalies, on profiles perpendicular to the magnetic strike, that may be spaced at a distance of several times the station interval.

Temporal variations in the geomagnetic field must be monitored and removed from most land surveys. These variations can be monitored by reoccupying a base station at intervals not to exceed one hour in magnetic "quiet" periods or by directly monitoring the temporal variations with a recording magnetometer established at a base within the survey area. For surveys covering limited regions, the base magnetometer can be electronically tied to the moving magnetometer and only the difference in the measurements made at the same time needs to be recorded.

Airborne magnetic surveying is preferred for most applications except for high-resolution studies of limited areas. Great care is required in planning airborne surveys to achieve the study objective in a timely and economical manner. Reid (1980) showed that to avoid aliasing errors in the data, the survey flight lines should have a maximum spacing of twice the combined altitude and depth to the expected source of anomalies, and that this should be decreased to the combined altitude and depth in cases where the data will be processed for computation of gradients, etc. The sampling interval along the flight line should be much less than this spacing. An interval of 50 m is commonly used. Flight lines should be flown perpendicular to the prevailing strike of the anomalies, with additional control lines at right angles to the principal flight lines at a spacing of roughly five times the basic flight-line interval. Control lines are used to tie the data of the principal flight lines together, minimizing temporal variations. Temporal variations are monitored by a ground-based continuous recording magnetometer, and commonly these variations are directly removed from the data before tying together the control and flight lines.

Flight elevation is a critical specification, which is generally minimized commensurate with safe operation of the aircraft and navigational requirements to maximize anomaly resolution. Surveys are flown either at a constant barometric altitude or at a constant terrain clearance, depending on the survey objectives and local geology and topography. For example, in magnetic surveying for geological mapping purposes, the principal concern is for anomaly resolution, thus these surveys are normally flown at a constant terrain clearance of 150 m or less. Survey altitude is monitored by radar and barometric altimeters, and positions are fixed by a combination of photography or videotape, radar altimeter, and electronic navigational aids. Active navigational systems deployed to increase the precision of positioning can significantly increase the cost of magnetic surveying.

3.5 Magnetic-Data Reductions

Magnetic observations can be affected by a number of extraneous sources in addition to the signature of subsurface magnetic polarization effects that we are interested in mapping. For example, the total magnetic intensity is subject to vertical changes of the geomagnetic field at the surface of the Earth of approximately 0.025 nT/m over the conterminous U.S.A. Most magnetic observations, unlike gravity measurements, are made with absolute-reading instrumentation, eliminating the need for reference stations.

Only two corrections are generally applied to observed magnetic measurements to determine the anomaly value. These account for temporal and spatial variations of the magnetic field. Temporal variations are primarily caused by particle and electromagnetic radiation from the Sun acting upon the external magnetic field, of the Earth. Lesser effects are caused by tidal effects of the Moon perturbing the ionosphere of the Earth and thus the geomagnetic field, and magnetic fields from electrical currents induced in the Earth. These temporal variations have a wide range of period and amplitude such that significant effects are observed in magnetic surveying and thus must be eliminated in most applications. Temporal variations in the geomagnetic field are monitored by reoccupation of a base at prescribed time intervals or by a recording base magnetometer, or, in the case of aeromagnetic surveying, by leveling survey observations to minimize differences in cross-line data.

Spatial variations in the geomagnetic field are caused not only by subsurface sources of magnetic polarization, but also by the geomagnetic field derived from the outer core of the Earth. To a first order, this field can be represented by a small, intensely magnetized dipole near the Earth's center and oriented approximately along the axis of rotation of the Earth (Fig. 6). An internationally accepted equation defines the field. This field, the International Geomagnetic Reference Field (IGRF), is derived from global magnetic observations and is updated every half decade. It includes time-variable terms that attempt to predict the secular (longterm) changes in the main field of the Earth from previous fluctuations, and it takes into account the latitude and longitude of the position on the Earth's surface as well as its height relative to sea level. In most local surveys, the station locations are relative only and are not defined in latitude and longitude. In these surveys the north–south and east–west gradients of the IGRF are determined and assumed to be linear over the survey area. Typically, east–west gradients range from zero near the center of the United States to 2.5 nT/km on the coasts, and in the north–south direction gradients change from 6 nT/km in the south to 2.5 nT/km along the Canadian border.

3.6 Anomaly Isolation and Enhancement

Magnetic anomaly fields combine the effects of all horizontal variations in magnetic polarization within the Earth, and thus the anomalies of interest in a particular geologic application are commonly distorted by overlapping anomalies as is the case for gravity anomalies. The requirements and procedures for isolating and enhancing residual magnetic anomalies are completely analogous to those implemented in the gravity residual anomaly separation problem described in Sec. 2.7.

Magnetic anomalies, like gravity anomalies, are readily represented by Fourier transforms to facilitate isolating and enhancing residual anomalies. Accordingly, anomaly attributes such as their wavelength and directional components, gradients, and continuations may be efficiently and accurately estimated by filtering the transform. Additional processing specific to the analysis of magnetic anomalies includes the reduction-to-pole (RTP) filter that is used to remove the distorting effect of magnetic polarization at non-normal inclination from the inductive components of the magnetic anomaly.

In conventional exploration applications, the geomagnetic-field attributes (i.e., intensity, declination, and inclination) can be assumed to be constant and equal over the subsurface sources and at the observation positions. Accordingly, total-field magnetic anomalies observed where the geomagnetic-field inclination is less than normal (vertical) are related by their directional derivatives to their equivalent anomalies at normal polarization. These directional derivatives, in turn, are nothing more than the horizontal and vertical gradients of the total magnetic anomalies weighted by the known values of geomagnetic field inclination and declination. Because the horizontal and vertical gradients are readily available from the Fourier transform of the anomalies, the design and implementation of the RTP filter are straightforward.

The RTP filter adjusts the total-field magnetic anomalies to the idealized condition of vertical polarization, which is achieved in practice only at the geomagnetic poles. As a result of this operation, the source is centered within its inductive anomaly components in the same manner that a gravity source is centered within its anomaly field. Hence, where remanent magnetic anomaly components are negligible, the RTP filter facilitates the correlation of magnetic sources with their anomalies and anomaly gradients to enhance subsurface modeling efforts. In addition, comparing total-field magnetic anomalies with their equivalent RTP anomalies facilitates identifying anomalies related to sources with significant remanent magnetization. RTP magnetic anomalies also are required to undertake quantitative analyses of the correlations between magnetic and gravity anomaly fields described in Eq. (15).

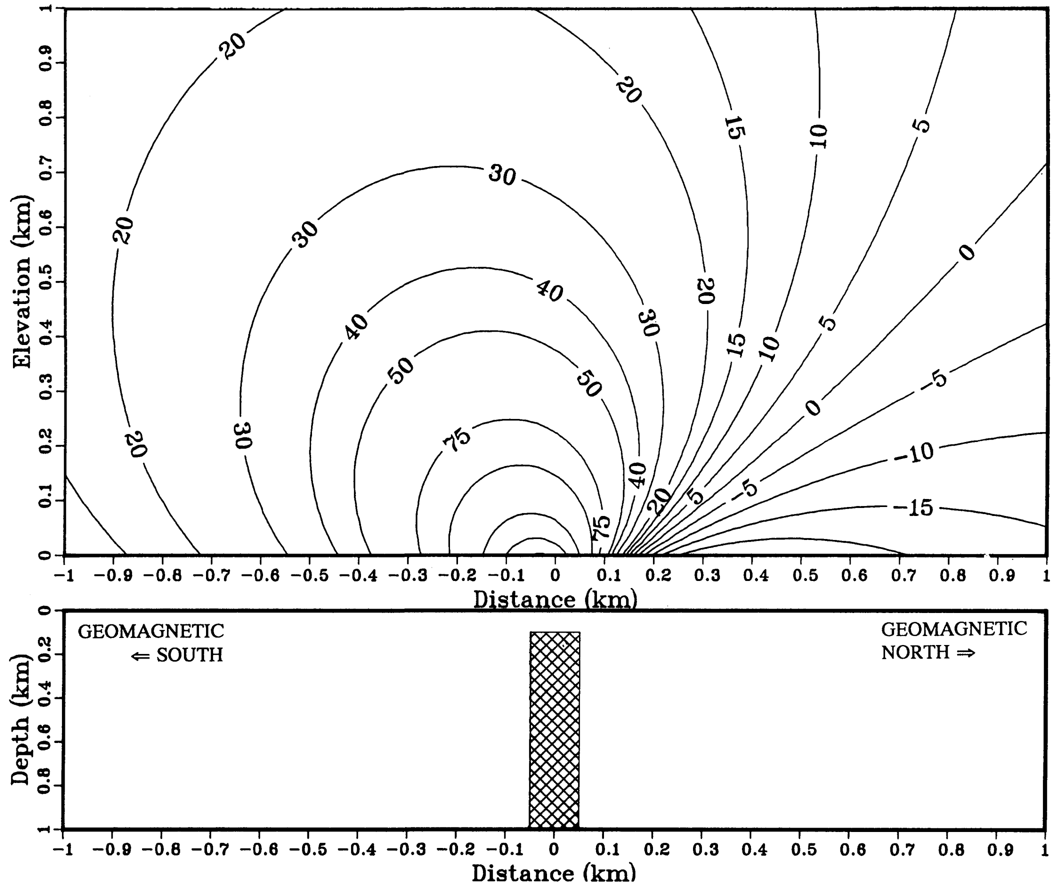

FIG. 9. Vertical contour map of total intensity magnetic anomaly in gammas (nT) for the vertical dike source with cross-section as shown extending infinitely perpendicular to the south-to-north (S-N) section in the northern geomagnetic hemisphere. The magnetization is induced due to a magnetic susceptibility contrast of 0.0025 emu/cm^3 in a field (*F*) of 60,000 nT oriented with 75° inclination (*I*) from the horizontal and 0° declination (*D*) from geographic north. Note variable contour interval.

3.7 Interpretation

The generalized approach to magnetic-anomaly interpretation is analogous to the approach for gravity-anomaly interpretation, and the reader is referred to Sec. 2.8 for more detailed discussion.

The amplitude and character of the anomaly signatures of magnetic sources in the subsurface are dependent on several key variables. Anomalies vary with source geometry, including volume and shape, and with source depth. The amplitude of the magnetic anomaly is a function of the magnetic property contrast of the source, which varies in a complex manner because of the combination of magnetization induced by the geomagnetic field and the intensity and direction of the remanent magnetization. Thus, in considering typical magnetic anomaly signatures, we must consider the relative orientation of the source in the geomagnetic field, the directional and intensity attributes of the geomagnetic field, and the total (induced plus remanent) magnetization of the source.

Typical total magnetic intensity anomaly profiles are presented in Fig. 5 in a schematic fashion for a variety of geometric shapes under five different geomagnetic field directions. The rate of decay in amplitude with distance R between sensor and source is an important variable, which changes with source shape and magnetization direction. Anomaly amplitude is proportional to $1/R^n$, where n is a real number decreasing from 3 to 0 as the

Table 3. Maximum depth to the center (Z_c) or top (Z_t) of ideal magnetic sources based on one-half the width of the anomaly ($X_{1/2}$) at one-half its maximum amplitude.

Geometric form	Depth
Sphere (single dipole)	$Z_c \leqslant 2.0 X_{1/2}$
Horizontal cylinder (line of dipoles)	$Z_c \leqslant 2.0 X_{1/2}$
Vertical cylinder (single monopole)	$Z_t \leqslant 1.3 X_{1/2}$
Edge of narrow dike (line of monopoles)	$Z_t \leqslant 1.0 X_{1/2}$

magnetic source geometries increase, respectively, from a concentrated spherical body to large tabular features of great depth extent.

The effect of observation elevation on magnetic anomalies is particularly well illustrated in Fig. 9. The plot shows vertical contours of the total intensity magnetic anomaly in gammas (nT) of an infinite vertical prism (dike) with a magnetic susceptibility contrast of 0.0025 emu/cm^3 and oriented perpendicular to the magnetic meridian at 75° magnetic inclination. The change in magnetic anomaly with elevation above the source can be readily visualized by considering the anomaly profiles indicated by the intersection of the contour lines with horizontal lines at a specified elevation.

Numerous techniques have been developed for approximating the depth to sources from a measure of the gradient of observed anomalies. These techniques provide maximum depth to the top or center of the source and are based upon recognizing the geometric form of the anomaly source from the anomaly characteristics. In general, the magnetic method provides greater depth resolution than the gravity method and thus is preferred wherever possible. The greater resolution is a result of the higher exponent in the decay function and the relative insensitivity of the magnetic method to depth extent. One of the useful depth techniques is the half-width measurement where one-half the width of the anomaly at one-half the amplitude is related to maximum depth (Nettleton, 1940). The relationships in the magnetic case are given in Table 3, based upon an assumption of vertical magnetic polarization.

The general inversion problem of estimating quantitative parameters of the source from the anomaly data is completely analogous to the gravity case, and the reader is referred to Section 2.8 for a more detailed discussion of the process. The quantitative development of forward modeling in magnetics is slightly more complex than that for gravity applications because of the dipolar formalism. This is exemplified in Table 4, which gives the equations for computing magnetic anomalies of simplified sources assuming vertical magnetic polarization. Tables 2 and 4 can be used together in joint inversions of gravity and magnetic anomalies involving common sources.

Table 4. Equations for computing magnetic anomalies of ideal sources. Here T is the magnetic anomaly in oersteds (teslas) in a vertical polarizing magnetic field caused by a magnetic susceptibility contrast k in emu/cm^3; k_m is the susceptibility of magnetite ($\simeq 0.25$); H is the vertical magnetic field in oersteds; V is volume; R is the distance between observation point and center (sphere) or axis (cylinder) or center line; x is the horizontal distance from observation point to center (sphere) or axis (cylinder) or center line (sheet) or edge (fault); d is depth to center (sphere) or axis (cylinder) or top (d_1) or bottom (d_2) of sheet or center line (fault); t is thickness; r is radius; E is depth extent; θ is angle from horizontal. All distances are measured in common linear units (e.g., centimeters, meters, kilometers, inches, feet, yards, kilofeet, miles, etc.)

Source	Magnetic anomaly
Basic	$T = kHV/R^n$, where $k = k_m \times$ (percentage magnetite)
Sphere	$T = (8\pi k H r^3 / 3d^3)(1 - x^2/2d^2)(1 + x^2/d^2)^{-5/2}$
Vertical cylinder (infinite)	$T = \pi d k H r^2 (x^2 + d^2)^{-3/2}, \quad E \gg d$
Horizontal cylinder (infinite)	$T = 2\pi k H r^2 (d^2 - x^2)(x^2 + d^2)^{-2}$
Narrow vertical sheet	$T = (2kHt)[d_1/(x^2 + d_1^2) - d_2/(x^2 + d_2^2)]$
Vertical fault	$T = 2kHtx/(x^2 + d^2)$
Finite slab	$T = 2kH(\theta_1 - \theta_2), \quad E \ll d$

4. ELECTRICAL EXPLORATION

As a major branch of geophysics, electrical exploration invokes the principles of geoelectricity for mapping subsurface structures of significance to prospecting for mineral and energy resources, and for solving hydrogeological, engineering, and archaeological problems. A considerable diversity of methods is available for geological exploration. These methods may be broadly classified according to whether they measure the ground's electrostatic (i.e., time-invariant) or electrodynamic response.

Steady-state techniques include the spontaneous-polarization (SP), resistivity, and induced-polarization (IP) methods. The results of SP and IP surveys are interpreted in terms of electrochemical potential differences in the subsurface that depend on the mineralogy of the rocks and on the composition and concentration of electrolytes dissolved in the ground water with which the rocks are in contact. Resistivity surveys map vertical and horizontal variations of subsurface electrical resistivity, or its reciprocal property, conductivity, which are related mostly to the distribution and salinity of the ground water and the resistivities of the subsurface materials.

Electrodynamic techniques include inductive electromagnetic (em) surveys and the telluric and magnetotelluric methods. The results of these methods are interpreted primarily in terms of the subsurface resistivity and dielectric properties, although magnetic permeability can also become a factor when significant concentrations of highly magnetic material such as magnetite occur within the subsurface.

4.1 Self-Potential Method

The self-polarization (or spontaneous polarization) method is a passive technique that involves measuring naturally occurring potential differences at the Earth's surface due to subsurface electrochemical activities that govern the magnitude and sign of the voltage developed when the subsurface materials are in equilibrium with an electrolyte. SP anomalies are observed over electrically conductive bodies that cut across the water table below the surface. Such conditions of the subsurface region tend to be characterized by SP anomalies that are minima with magnitudes that can reach up to several hundred millivolts.

A widely accepted model for the generation of SP anomalies at the Earth's surface is shown in Fig. 10. Electrolytes in the pore fluids below the water table release electrons through oxidation, which migrate to the top of the conductive body. These electrons reduce the electrolytes at the top of the body to produce negative ions, which may be electrolytically conducted down the system in the pore fluids. This model of electronic and electrolytic currents can polarize the body as shown in Fig. 10 for the sign and general magnitude of observed SP anomalies. The model is also consistent with the general temporal stability of SP anomalies because the body is fundamentally unaltered, serving only to transport electrons from depth.

Field procedures involve the use of nonpolarizing electrodes connected to a high-impedance millivoltmeter. Surveys commonly involve profiling at a fixed station spacing (often less than 30 m), or by maintaining one electrode in a fixed position and maneuvering the roving electrode over the survey area.

SP anomalies most often are interpreted on a qualitative basis, where the anomalous body is presumed to occur directly beneath the anomaly minimum. However, quantitative modeling can be readily implemented to estimate the depth, shape, and other parameters of the body in the subsurface using fundamental electrostatic theory.

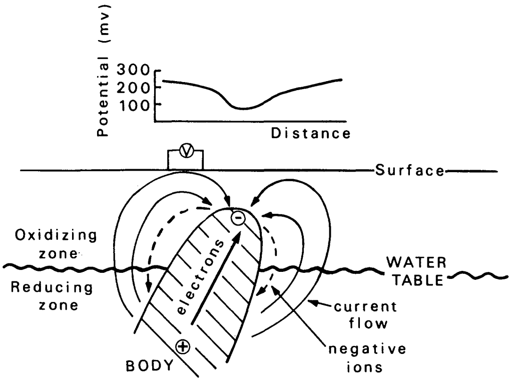

FIG. 10. The mechanism of self-potential anomalies (modified from Sato and Mooney, 1960 by Keary and Brooks, 1984). Natural potential profile and current pattern where sulfide body penetrates oxidizing zone above the water table are also illustrated.

4.2 Resistivity Methods

The resistivity method is routinely implemented in engineering, hydrogeological, and archaeological studies to investigate the shallow subsurface region in terms of vertical and horizontal variations of its resistivity properties. This is an active method whereby electric currents are introduced into the ground and the resulting potential differences are measured at the surface. By Ohm's law for zero frequency or direct current (dc), the potential difference ΔV (volts) between any two points in a circuit is related to the resistance R (ohms) of the medium between the two points and the current I (amperes) flowing in the conductive medium between the two points by

$$\Delta V = IR. \tag{16}$$

Experimentally, however, we also observe that the resistance (R) of a three-dimensional unit element of a material increases with its length L and decreases with its cross-sectional area A, according to

$$R = \rho(L/A), \tag{17}$$

where the proportionality constant ρ is defined as the resistivity (Ω m) of the material. Resistivity is the resistance of a unit element of the material. For some problems it is convenient to consider the reciprocal of resistivity which is called conductivity (S/m, where S denotes siemens). Resistivity surveying is grounded on Eqs. (16) and (17), where Eq. (16) is the basis of the field measurements, and Eq. (17) is the basis for interpreting the results of the survey.

Earth resistivities are usually measured by use of four-terminal electrode arrays positioned at the Earth's surface, where two of the electrodes galvanically drive dc current into the ground and the remaining two electrodes measure the potential difference over the surface. Electrode arrays are used to eliminate the effect of contact resistance in the measurements, which are obtained by averaging field observations made from normal and reversed-polarity input currents. Modern field systems also use very low-frequency ac current to cancel contact resistances around the electrodes. Laboratory studies have shown that resistivities observed at frequencies less than about 10 Hz are essentially the same as those obtained with dc measuring currents.

In resistivity surveying, several arrays are commonly implemented including the Wenner, Schlumberger, dipole-dipole, and pole-dipole arrays, which are illustrated in Fig. 11. The quantities measured in a field determination of resistivity are the current I flowing between the two current electrodes, the difference in potential ΔV between the potential-measuring electrodes, and the distances between the various electrodes. Accordingly, Earth resistivity as measured by four-terminal electrode arrays is given by

$$\rho = (\Delta V/I)K \equiv \rho_A, \tag{18}$$

where K is called the geometric factor of the array (Fig. 11). This equation may be used to compute the resistivity of the Earth only where the Earth is completely homogeneous. In a heterogeneous Earth, this equation is used as a definition for the apparent resistivity ρ_A of the subsurface. Values of the apparent resistivity may bear no relation to any actual value of resistivity in a heterogeneous Earth. However, the variations of apparent resistivity are indicative of how subsurface resistivities vary with depth or horizontally, so that considerable subsurface insight is revealed by obtaining and analyzing apparent resistivity.

The manner in which subsurface information is obtained from resistivity surveys can be shown using Fig. 12. The upper panel illustrates current flow and associated equipotentials for the Wenner electrode array on the

surface of a homogeneous material with resistivity given by ρ_1. The distribution of current within the three-dimensional subsurface may be grossly generalized in terms of the distance between the current electrodes (C_1C_2) as shown in the lower panel of Fig. 12. For the case considered here, the apparent resistivity obtained by the array will equal the resistivity of the subsurface to within the precision of the survey measurements. However, by making the array size larger, we can investigate a larger and deeper volume of the subsurface, so that if the subsurface were characterized by zones of increasing or decreasing resistivity, the apparent resistivity would increase or decrease, respectively. This mode of surveying is called *vertical electrical sounding* (VES), where we map vertical resistivity variations by measuring ρ_A as a function of changing the spacing a of the electrodes while holding the center of the array fixed.

Interpretations are based on plots of ρ_A versus the electrode spacing a as illustrated in Fig. 13. Inversion of VES data is most commonly quantified in terms of multiple horizontal resistivity layering of the subsurface. First-order estimates of layer interface depths are obtained by curve matching, where the VES data are normalized for comparison with a master set of curves to identify possible layered models of the subsurface. These estimates may be further refined by trial-and-error inversion using computer modeling.

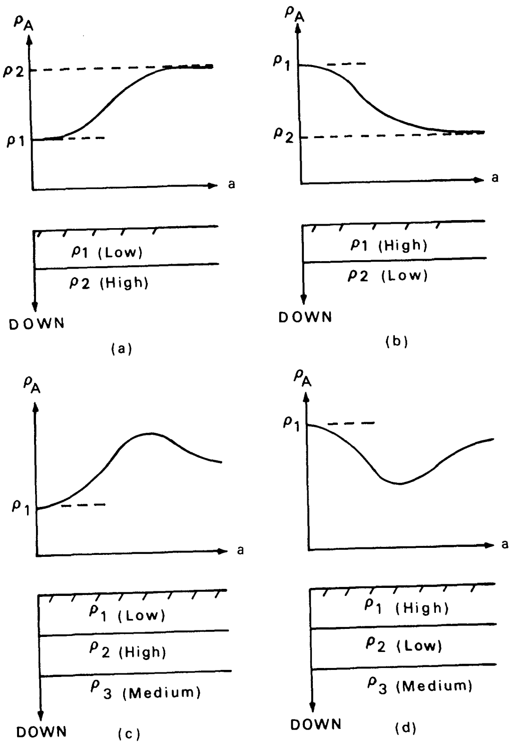

FIG. 13. Vertical electrical soundings (VES) over various layered subsurface structures.

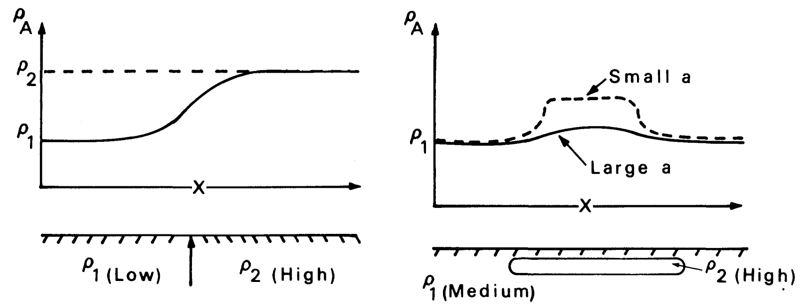
The VES profiles are most commonly obtained using the Wenner and Schlumberger arrays. In surveying with the Wenner array, all four electrodes need to be moved between successive measurements of the apparent resistivity. The field effort to move the electrodes can be minimized with the use of Schlumberger array, where the inner potential electrodes may remain fixed and the current electrodes are expanded symmetrically about the center of the spread to obtain successive measurements of the apparent resistivity. However, when the distance between the current electrodes becomes very large, it may be necessary to increase the separation distance between the potential electrodes to obtain a measurable potential difference.

A second major mode of resistivity surveying is called *horizontal profiling*, where apparent resistivity is mapped as a function of changing offset distance of the center of the array while holding the spacing a of the electrodes constant. Lateral resistivity variations occurring within the depth range of the array will be reflected by similar variations in the apparent resistivity values. Horizontal profiling interpretations are based on plots of the apparent resistivity versus offset distance (x) such as illustrated by the examples given in Fig. 14. In these applications, horizontal profiles for different electrode spacings may be differenced to resolve further details on the lateral resistivity structure of the subsurface.

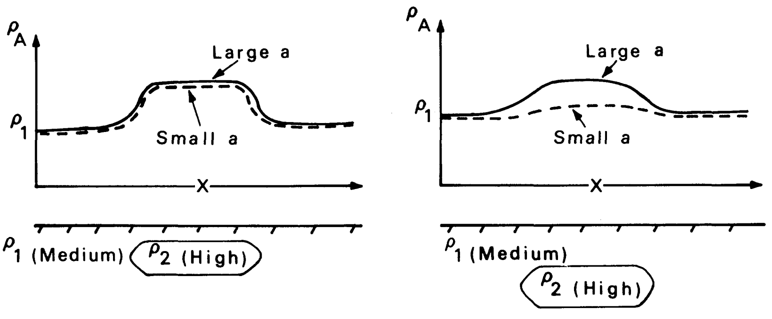
Horizontal profiling known as the *mise à la masse* method can be employed when a portion of the target ore body has been located either at outcrop or by drilling. For this application, the pole-dipole array is used where a single current electrode is placed within the body while the other current electrode is placed outside the body and far away, and the potential electrodes are moved over the Earth's surface mapping equipotential lines. In contrast to horizontal profiling, this method can provide much more information on the extent, dip, strike, and continuity of the body in the subsurface.

The interpretation of apparent resistivity in terms of the resistivity properties of the subsurface is very complex because of the extreme variability and sensitivity of resistivity to the composition and fluids of the subsurface. Electrical resistivity shows the greatest variability of the physical properties of rocks. There is broad overlap between rock types, and hence identifying a rock type solely on the basis of resistivity is generally impossible. Certain minerals such as native metals and graphite conduct currents by the movement of electrons. However, most rock-forming minerals are insulators, and electrical current is carried through a rock mainly by electrolytic conduction involving the movement of ions in the pore waters. Thus, for most rock materials the porosity and salinity of the water in the pores are the most important factors governing subsurface resistivity. An empirical relationship for the dependence of resistivity on these factors is given by Archie's law,

$$\rho = aV_c^{-m}S^{-n}\rho_w, \tag{19}$$



(a) Profiling across a vertical contact (b) Profiling across a shallow thin gravel deposit



(c) Profiling across a shallow thick gravel deposit (d) Profiling across a deep thick gravel deposit

FIG. 14. Horizontal electrical profiling across various subsurface structures.

where ρ_w is the resistivity of the pore water, V_c is the fractional void content (porosity), S is the fraction of pores that are fluid filled, n is approximately 2, and $0.6 < a < 2.5$ and $1.3 < m < 2.5$, generally.

When porous rocks lie above the water table at shallow depths or when they occur at sufficiently great depths that all pore spaces are closed by the ambient pressure, the current flowing through them is maintained by electronic conduction in the mineral grains with relatively high apparent resistivities compared to the intervening zone of saturation. However, even igneous and metamorphic crystalline rock with negligible intergranular porosity and conductivity can become highly conductive in zones where they are cracked and fissured and partially filled by fluids or clay.

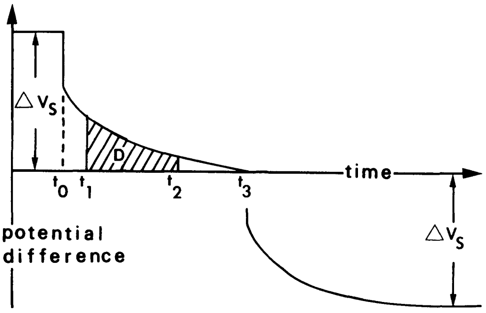


FIG. 15. The induced-polarization effect (after Kearey and Brooks, 1984). At time t_0 the current is turned off and the measured potential difference, after an initial drop from the steady state value ΔV_S, decays gradually to zero. A similar sequence occurs when the current is turned on again, but with opposite polarity to cancel electrode polarization effects. D represents the area under the decay curve for the time interval t_1–t_2.

4.3 Induced-Polarization Method

The induced-polarization (IP) method is principally used for locating disseminated sulfide ores of copper, silver, and other base metals. The method makes use of the capacitive action of the subsurface to locate zones where conductive minerals are disseminated within their host rocks.

During the course of standard resistivity surveying, it is commonly observed that the potential difference may take several seconds to several minutes to reach a stable peak value when the current is turned on, and when the current is turned off it takes a comparable amount of time for the potential difference to decay to zero, as shown in Fig. 15. This effect is called induced polarization and is particularly pronounced where electronically conducting minerals (e.g., metallic sulfides and oxides, graphite) or clay minerals are present in the subsurface. At the time scales involved, this phenomenon reflects the integrated effects of various mechanisms of interfacial polarization that occur whenever the subsurface involves electrically heterogeneous materials where charge concentrations build up at the boundaries of the heterogeneities. Mechanisms of interfacial polarization that are of particular concern to induced-polarization studies include electrode polarization or overvoltage and membrane polarization or electrolytic polarization.

Electrode polarization refers to the well-known effect of charge buildup that occurs at the interface of a conductor immersed in an electrolyte where a current is being driven through the system. This effect inhibits current flow and hence increases the apparent resistivity by an amount termed the *overvoltage* of the system. It can occur within the subsurface wherever an electronically conducting mineral grain boundary is in contact with an electrolytic pore fluid. When the current is applied, charge builds up slowly at these interfaces until saturation, where the potential difference measured by the array is maximum. When the current is turned off, the charge buildup at the interfaces slowly diffuses to cause a transitory decay of the potential difference measurements. This effect is particularly strong where the metallic minerals are individually dispersed within the subsurface so that the area of these interfaces is maximum.

Electrode polarization is the principal effect of interest in IP prospecting for metallic ores. However, other polarization effects may contribute to complicate the interpretation of IP surveys. In particular, membrane polarization effects can occur and may contribute overvoltages equivalent to those observed for a rock with up to 2% metallic minerals. Most subsurface geologic materials have a net negative charge at their interface with the pore fluid, and hence attract positive ions onto the surface. Where the diameters of the interconnecting pore throats are of the same order as the thickness of these charge buildups, negative and positive ions may build up around the blockages to inhibit current flow in the system. Membrane polarization is particularly pronounced in the presence of clay or silt particles that can block the flow of electrolyte-bearing fluid through pore spaces. In situations where membrane polarization is the primary effect, IP surveys can be interpreted for the position of the water table in the subsurface.

IP measurements are obtained as by-products of resistivity surveys, where the resistivity equipment has been upgraded to monitor the transitory behavior of potential differences over time intervals of 1–20 s or more. In practice, Schlumberger, dipole–dipole, and pole–dipole arrays are used, although in principle any standard configuration of electrodes may be employed to obtain IP measurements. IP observations are broadly classified into time-domain and frequency-domain measurements.

Time-domain IP observations involve measuring the transient behavior of potential differences as dc current is being galvanically driven into the ground from metal electrodes. The most common parameter determined is the area D beneath the decay curve over a time interval t_1–t_2 as shown in Fig. 15. Normalizing this area by the steady-state potential difference ΔV_s yields the chargeability M which is defined by

$$M=\frac{D}{\Delta V_s}=\frac{1}{\Delta V_s}\int_{t_1}^{t_2} V(t)\,dt \qquad (20)$$

in mV s/V or ms. Chargeability is commonly expressed in terms of the time interval t_1–t_2 and can be diagnostic of the presence of different minerals. For example, the chargeabilities over an interval of 1 s for pyrite and magnetite are 13.4 and 2.2 ms, respectively (Kearey and Brooks, 1984).

Frequency-domain IP observations are obtained by measuring apparent resistivities using ac current at two or more frequencies. To avoid electromagnetic induction effects, IP measurements are normally made at frequencies of 10 Hz or less where laboratory studies indicate that resistivity is essentially independent of the measuring-current frequency. They are obtained by measuring the apparent resistivity of the ground at two frequencies F and $f<F$, and expressed as the percentage frequency effect (PFE), which is defined by

$$\mathrm{PFE}=100[\rho_A(f)-\rho_A(F)]/\rho_A(F). \qquad (21)$$

Another measure of frequency-domain IP normalizes the PFE with respect to the dc or lower-frequency apparent resistivity. This measure is called the metal factor (MF), which is defined by

$$\mathrm{MF}=2\pi\times 10^5[\rho_A(f)-\rho_A(F)]/\rho_A(f)\rho_A(F), \qquad (22)$$

with units S/m.

The IP method is by far the most effective geophysical tool for locating low-grade ore deposits such as disseminated sulfides. These base-metal deposits have a strong IP effect, but they are nonconducting and hence are difficult to map by other electrical methods. IP data for the most part are interpreted on a qualitative basis, although analytical IP responses have been computed for idealized bodies such as spheres, ellipsoids, dikes, vertical contacts, and horizontal layers for more quantative interpretation.

An example of the results for a time-domain IP survey using a pole–dipole array across the Gortdrum copper–silver ore body in Ireland is shown in Fig. 16. A well-defined chargeability anomaly is observed over the ore body, although the deposit is low grade with less than 2% metallic conducting minerals. The corresponding apparent resistivity profile gives no indication of the presence of mineralization, reflecting rather the large resistivity contrast between the sandstone and dolomitic limestone with a minimum directly over the fault.

4.4 Electromagnetic Methods

With the exception of the magnetic method, the electromagnetic-induction techniques are the most widely used geophysical methods for mineral exploration. These methods are based on the induction of electric currents in buried conductive bodies by the magnetic components of electromagnetic waves generated at or near the Earth's surface. The source or primary waves originate from alternating currents generated at frequencies ranging from a few hertz to a few megahertz through loops of wire on the ground or in the air. The primary electromagnetic field attenuates as it is propagated into the Earth at a rate that depends on its frequency and the electrical properties of

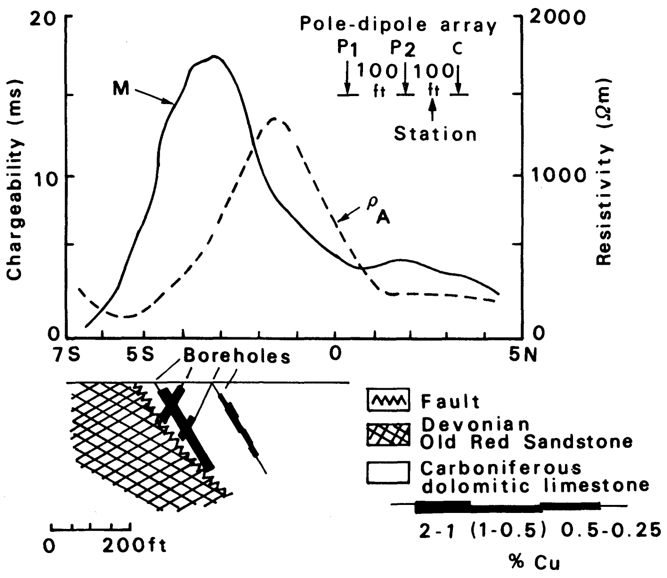

FIG. 16. Time-domain IP over Gortdrum copper-silver body (modified from Seigel, 1967, by Keary and Brooks, 1984).

the subsurface materials. The depth of penetration of the primary electromagnetic field is given by

$$Z_m = 503.8(f/\rho)^{-1/2}, \qquad (23)$$

where Z_m is in meters, the resistivity (ρ) of the Earth is in Ω m, and the frequency (f) of the primary field is in Hz. When the primary electromagnetic field waves pass through a conducting body, they induce eddy currents in the conductive materials (Fig. 17) These currents become the source of secondary electromagnetic waves that can be detected by suitable receiver coils at the Earth's surface again.

A variety of procedures are used to map anomalous electromagnetic-fields. A conventional and straightforward technique involves the use of a small receiver coil to map spatial variations of electromagnetic field inclination or dip. The current induced in the search coil by an electromagnetic wave is maximum or minimum when the plane of the coil is oriented respectively perpendicular or parallel to the direction of the electromagnetic wave. Over barren (nonconductive) ground, the plane of the search coil will be oriented perpendicular or parallel to the transmitter coil to indicate the dip properties of the primary electromagnetic wave. However, where a conductor exists within the subsurface, secondary electromagnetic signals are produced, which add vectorially to the primary electromagnetic signal to yield a resultant electromagnetic signal at the search-coil position. For good conductors the resultant electromagnetic signal can have inclination properties that are significantly different from the dip of the primary electromagnetic signal from the transmitter.

Commonly applied tilt-angle procedures include VLF and AFMAG methods, which are widely used because equipment requirements are simple and their implementation in the field is cost effective and rapid. For the very low-frequency (VLF) method, low-frequency electromagnetic waves generated by powerful radio transmitters used in long-range communications and navigational systems are implemented. Several stations around the world broadcast in the frequency range of 15–25 kHz signals that may be used for surveying

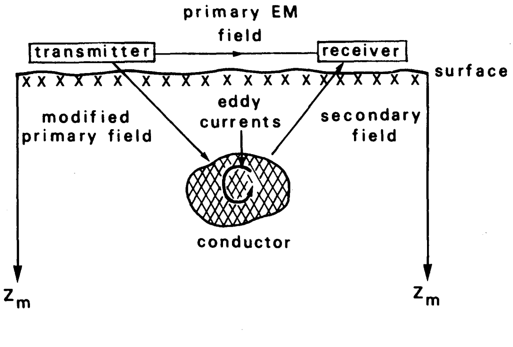

FIG. 17. General principle of electromagnetic surveying for subsurface conductors within the skin depth Z_m.

regions at distances of up to several thousand kilometers from the transmitter.

The primary electromagnetic field generated from the transmitter is essentially planar and horizontal at large distances. The magnetic component *H* lies at right angles to the direction of propagation in the horizontal plane with the electric component *E* lying in the vertical plane. A conductor that strikes in the direction of the transmitter optimally interferes with the magnetic field vector so that the induced eddy currents produce a maximum secondary electromagnetic field, whereas conductors striking at right angles to the direction of primary field propagation yield marginal to undetectable secondary electromagnetic field responses.

The audio-frequency magnetic-field (AFMAG) method utilizes the natural electromagnetic fields generated by thunderstorms, called "sferics," which propagate around the Earth between the ground surface and the ionosphere. This space constitutes an efficient electromagnetic waveguide with low attenuation so that thunderstorms anywhere in the world make an effective contribution to the field at any given point on the Earth. The field also penetrates the subsurface region, where, in the absence of electrically conducting bodies, it is essentially horizontal. Sferic sources are random so that the signal is broadband between 1 and 1000 Hz. This frequency range extends an order of magnitude lower than can be produced with conventional transmitters so that depths of investigation of several hundred meters are feasible.

Random variations in the direction and intensity of the primary field preclude the use of a single coil for determining the direction of the arriving field. Hence, the AFMAG receiver uses two orthogonal coils each inclined at 45° to the horizontal. In the absence of a secondary field, the components of the horizontal primary field perpendicular to the coils are equal so that their subtracted output will be zero. When a conductor is present, a secondary field that causes deflection of the resultant field from the horizontal occurs so that the combined output is no longer zero and is indicative of the tilt.

Tilt-angle methods such as VLF and AFMAG provide semiquantitative information on the horizontal distribution, depth, and dip orientation of conductive bodies within the subsurface. More quantitative information on the conductors can be obtained with em prospecting systems, which measure the phase and amplitude relationships between primary, secondary, and resultant electromagnetic fields. These sophisticated exploration systems commonly involve precisely located and oriented transmitters and receivers that are normally separated by distances of between 30 and 100 m. Over these distances, the primary field suffers minimal modification as it travels within both the air and the subsurface. Hence, a good estimate of the secondary wave may be obtained by subtracting the primary alternating wave from the resultant alternating wave field observed by the receiver. Modern instruments can separate the secondary electromagnetic wave into its real and imaginary components. Figure 18 generalizes the real and imaginary properties of the secondary signal induced in the conductor by primary sinusoidal fields.

The qualitative results presented in Fig. 18 suggest simple rules for characterizing conductors. A good conductor, for example, yields a large real component relative to a smaller imaginary component, whereas a poor conductor produces a relatively large imaginary component in contrast to a small real component. The ratio of the magnitudes of the real to imaginary components is commonly used to quantify the conductor, where a good conductor yields a ratio greater than unity and a poor conductor yields a ratio smaller than unity.

An example showing the results of a mobile transmitter–receiver em profile collected across a sheetlike conductor is given in Fig. 19. The conducting bodies produce negative anomalies in both the real and imaginary components, with maximum amplitudes immediately above the conductor as a consequence of

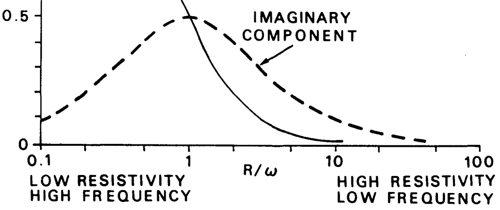

FIG. 18. Response of a single-turn conductor loop of resistance *R* to a primary sinusoidal field with angular frequency ω (after Parasnis, 1979).

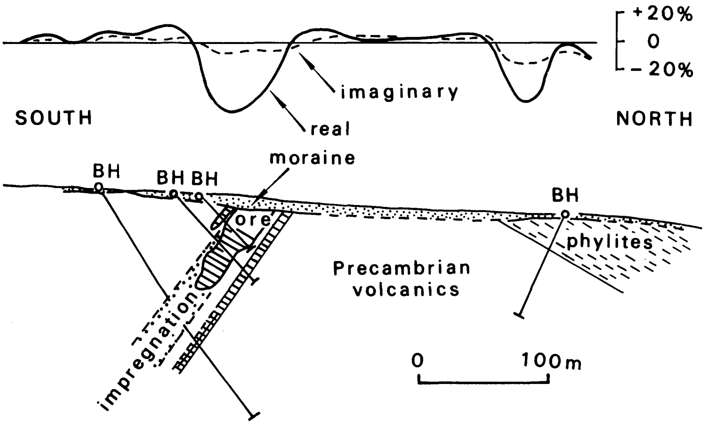

FIG. 19. Mobile transmitter-receiver profile using horizontal coplanar coils separated by 60 m and an operating frequency of 3.6 kHz in the Kankberg area of northern Sweden. Real and imaginary components are given in a percentage of the primary field. BH indicates borehole locations (modified from Parasnis, 1973, by Keary and Brooks, 1984).

the coplanar or horizontal coil system that was employed in this survey. The inclination of the body is suggested by the asymmetry of the anomalies, where the maximum anomaly gradient lies on the down-dip side. The presence of a very good conductor is indicated by the large ratio of the real to imaginary components over the ore body, whereas a smaller ratio is observed over the more resistant sequence of graphite-bearing phyllites to the north.

Mobile transmitter–receiver em surveys are conducted both on the ground and from airborne platforms such as fixed-wing aircraft and helicopters. Maximum penetration in ground surveys is limited to roughly 500 m, whereas for airborne work only about 50 m or less is common because of the weak electromagnetic coupling of the primary signal with the ground from a distant and moving airborne transmitter. Electromagnetic prospecting data are generally presented in the form of cross sections showing the amplitudes of the signals recorded by the receiver versus the horizontal position. Offset is expressed in terms of distance in ground surveys and in terms of time for airborne surveys. In general, the components of the secondary signal that are in phase (real) and out of phase (imaginary) with the primary signal are plotted separately and compared for interpretation.

Quantitative interpretation of electromagnetic data is commonly very complex because of the many factors that can influence the inductive response of the subsurface. Because of the complexity of theoretical calculations, laboratory modeling and simulations are often used to interpret em survey results. Simplified interpretation of mobile transmitter–receiver data may be accomplished for simplistic conductor geometries using master curves. However, much electromagnetic interpretation is only qualitative, especially for airborne data.

4.5 Telluric and Magnetotelluric Methods

Telluric currents flow in vast sheets parallel to the Earth's surface to depths of several kilometers. These currents flow over the whole Earth in a pattern of circular cells where each cell covers millions of square kilometers and remains essentially fixed with respect to the Sun. The source of telluric currents is ascribed to the inductive effects of magnetotelluric fields, which exist as standing waves in the space between the ionosphere and the Earth's surface. Magnetotelluric fields at the Earth's surface are essentially plane waves, with frequencies from about 10^{-5} Hz to at least the audio range, which penetrate the Earth's surface to produce the telluric currents. Ionospheric current systems are believed to be the source of magnetotelluric and telluric fields because periodic and transient fluctuations of the fields can be correlated with diurnal variations in the Earth's magnetic field resulting from solar emissions.

Telluric electric fields cause a mean potential gradient at the Earth's surface of about 10 mV/km and are constantly fluctuating in direction and magnitude at any point. However, systematic horizontal perturbations of telluric potential differences will be found at the Earth's surface when geologic structures disturb the horizontal flow of the telluric current sheets. These geological structures will represent lateral or horizontal resistivity contrasts within the subsurface such as, for example, high-resistivity salt domes or folded strata.

Telluric potential differences are measured using orthogonal pairs of electrodes made of a chemically inert substance like lead, which is nonpolarizing. The position of each station is marked by the coordinates where the line segments between the two electrode pairs bisect each other. The spacing of measurements varies from a few tens of meters to up to several hundred meters depending upon the depth of interest. The survey involves measurements collected with a mobile array, which are referenced to simultaneous readings at a spatially fixed base station. Base-station observations are required to account for temporal variations of the telluric currents.

Magnetotelluric surveying is an extension of the telluric method where one of the potential electrodes is replaced by a highly sensitive magnetometer to measure the associated magnetic field, which is in the picotesla range. The technique involves only mobile arrays (no base station is required) consisting of two electrodes to measure telluric potential differences in one direction and a sensitive magnetometer (e.g., fluxgate) to measure the magnetic field component in the orthogonal direction. In general, it can be shown that the amplitudes of orthogonal electric and magnetic field components are related according to

$$\rho_A = (0.2/f)(E/H)^2, \tag{24}$$

where f is in Hz, E is in mV/km, and H is in nT. This result shows that the apparent resistivity ρ_A varies inversely with frequency, which governs the depth of penetration of the magnetotelluric wave according to relations such as that described in Eq. (23). Hence, by breaking up the observations into their various frequency components and computing the apparent resistivities, it is possible to obtain insight on the vertical variations of resistivity within the subsurface region. Furthermore, these results can be compared at different points on the Earth's surface to establish large-scale horizontal variations of subsurface resistivity.

Magnetotelluric data are used mostly to investigate the large-scale vertical and horizontal resistivity variations of the crust and upper mantle. Interpretation of magnetotelluric data is facilitated by master curves of apparent resistivity versus frequency that are available for simplified features such as two and three horizontal layers, vertical contacts, and dikes. Numerical modeling and inversion of more detailed two-dimensional structures is also possible.

5. APPLICATIONS OF GEOPHYSICS TO LITHOSPHERIC INVESTIGATIONS

Solid-Earth geophysical methods were largely developed from basic physics principles and the investigations of Earth materials. Although the methods were used on an occasional basis for a century or more, the growth of the applications of geophysics really began in the years following World War I and grew rapidly, as did all of science, following World War II. We have seen an exponential growth in recent decades because of societal pressure to solve Earth-related problems such as mineral-resource depletion, natural-hazard mitigation, and environmental restoration, as well as the availability of high-speed computers to control instrumental observations, process numerical data, and present results of computations in graphic form. The following examples of the application of geophysics to lithospheric investigations are selected to illustrate the range of impact of geophysical methods on science and society over a range of scales.

5.1 Mantle and Crustal Processes

Problems dealing with the origin of major Earth land forms—such as continents, oceans, and mountains—have been the subject of intensive inquiry and speculation by geoscientists for many years. Unfortunately, these studies were based on a minimum of information derived primarily from surface geological observations. As a result, no hypothesis survived close scrutiny. This situation changed dramatically and quite quickly as a result of the confluence of geophysical observations following World War II.

Measurement of the spatial variation of the geomagnetic field over oceanic regions showed a pattern of linear magnetic anomalies (Raff and Mason, 1961) that were soon recognized to be symmetrical to midocean ridges that were identified by bathymetric observations. As subsequent studies have proven, Vine and Matthews (1963) correctly identified these lineations as the result of seafloor spreading from the oceanic ridges that cause magma to upwell into the crack or rift along the crest of the ridge (Fig. 20). As the spreading continues over millions of years, the cooling magma acquires a permanent magnetism in the direction of the geomagnetic field. Independent geophysical research has shown that the geomagnetic field reverses polarity occasionally. The reversals are frozen into the newly formed crust, causing the highs and lows in the magnetic field that are observed as magnetic lineations symmetric with oceanic ridges. By dating the reversals from continental rocks, it is possible to date the lineations in the oceans and thus to determine that the velocity of seafloor spreading is millimeters to centimeters per year.

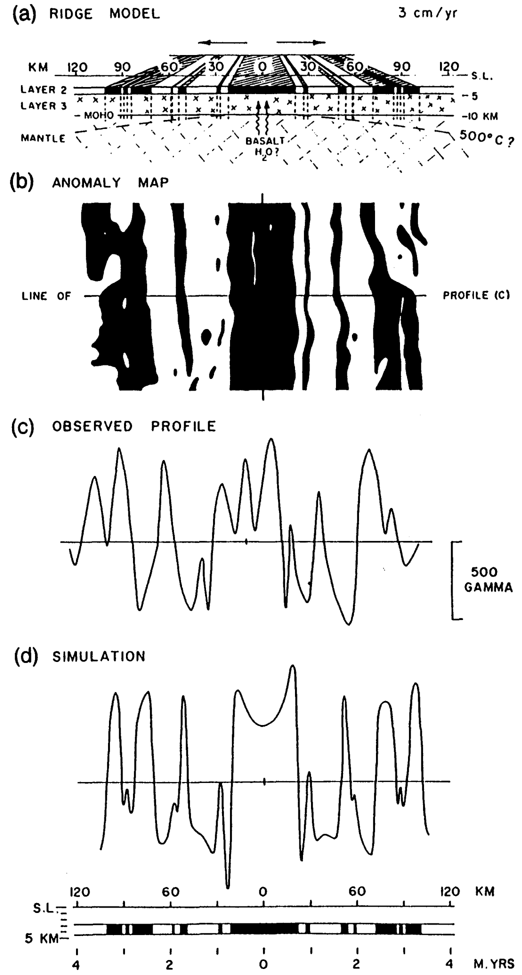

FIG. 20. The principle of seafloor spreading summarized by Vine (1968). (a) Schematic representation of the crustal model, applied to the Juan de Fuca Ridge, southwest of Vancouver Island. Shaded material in layer 2, normally magnetized; unshaded, reversely magnetized. (b) Part of the summary map of magnetic anomalies recorded over the Juan de Fuca Ridge. Black, areas of positive anomalies; white, areas of negative anomalies. (c) A total-field magnetic anomaly profile along the line indicated in (b). (d) A computed magnetic profile assuming the model and reversal time scale.

Seafloor spreading, as derived from magnetic observations in the oceans, explained the youthful nature of the oceans (< 200 Ma) as compared to the continents ($\simeq$ 4000 Ma), but conservation of space required destruction or compression of older crust if new crust was being generated in the oceans. This led to the concept of plate tectonics wherein the surface of the Earth is divided into about 20 plates that are defined by lithospheric earthquake epicenters (Morgan, 1968). Along boundaries between the plates, one of the following processes is going on:

1. crust is produced at oceanic ridges;
2. crust is destroyed by being dragged into the Earth at island arc trenches, and/or crumpled into mountain ranges on the edges of continents causing the ranges to grow; or
3. crustal plates are simply moved past each other with minimal modification and thus the continents drift over the Earth's surface.

The concepts of seafloor spreading and plate tectonics, which are accepted in the geoscience world as facts today, have revolutionized the entire geoscience discipline by providing a unifying concept for most geological processes. Its effect upon science is likened to the impact of the Copernican and atomic theories upon our understanding of the universe. Sophisticated geophysical observations and interpretations over the past quarter of a century have continued to support the initial theories and have done much to refine them, but their origin is in simple geophysical observations of the oceanic geomagnetic field, the distribution of earthquakes over the Earth, and the recognition of the reversal of the polarity of the geomagnetic field through geological time.

5.2 Crustal Studies

The continental crust is a complex mosaic of rock units of varying composition that reflect the multitude of processes that make up the geologic history of the Earth over roughly the past 4600 Ma. Surface geologic studies in the Lake Superior region of mid-North America have identified a complex geologic structure consisting of rock units of contrasting physical properties that originated 1100 Ma ago when the Earth's crust was split over a length in excess of 2000 km (Van Schmus and Hinze, 1985). This structure, the Midcontinent Rift System, is poorly known because over most of its length it is covered by younger rock strata, and even in the Lake Superior region where it crops out, the vertical range of our direct observations is extremely limited. Recent seismic reflection studies on the south shore of Lake Superior in western Michigan have mapped the strata of the rift system to depths of the order of 18 km. Hinze *et al.* (1990) have used a seismic reflection profile together with other geophysical data and surface geologic information to map the distribution of the rock formations to midcrustal levels. Knowledge of this structure makes it possible to suggest the sequence of geologic events involved in the rift and thus to interpret the geologic history of this region over a billion years ago.

Figure 21 shows a small segment of the seismic reflection profile with time of arrival of seismic waves at the surface plotted on the vertical scale as a function of distance along the profile. The coherent (continuous) events are identified as reflections from interfaces between rock strata of differing physical properties. The lack of clearly identifiable reflections within the first few seconds in the central part of this figure where the Portage Lake volcanic rocks crop out is interpreted not as a lack of reflectors, but rather as a result of their steep dip that prevents the reflections from being imaged at the surface. The reflectors of this figure and similar reflections along the profile have been used to chart the distribution of the layered strata as shown in Fig. 22. This figure also presents profiles of the anomalous geomagnetic and gravity fields. Variations in these profiles reflect, respectively, differing magnetization and mass (density) of the underlying rock formations. These are useful in identifying the rock strata imaged by the seismic method and assist in removing ambiguity in the interpretation.

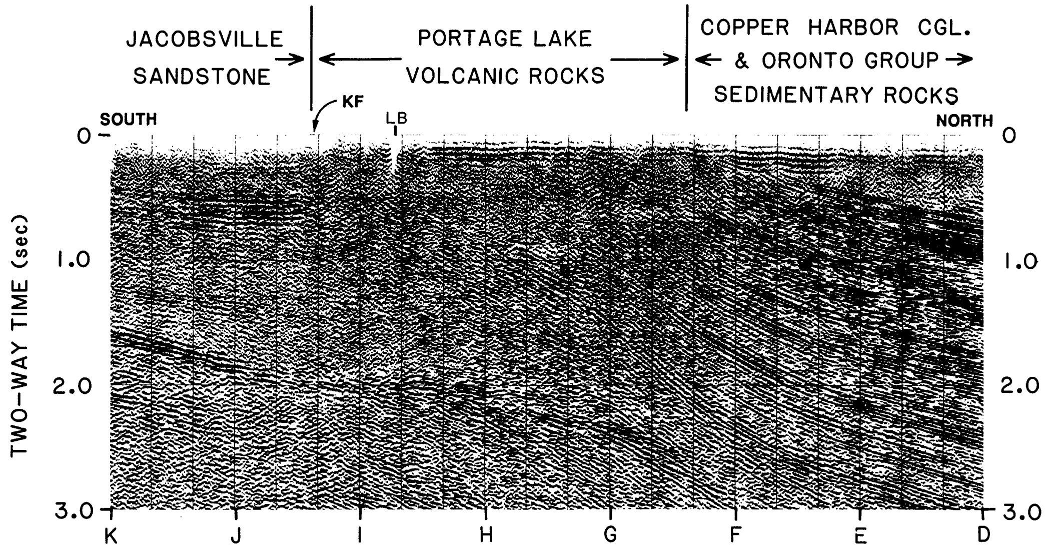

FIG. 21. Portion of migrated seismic reflection record centered on outcrop of Portage Lake volcanic rocks on the south shore of Lake Superior in western Michigan. Interpretation is presented in Fig. 22. No vertical exaggeration; 1 s of two-way time is about 3 km. KF is the observed position of the Keweenaw fault (Fig. 22). LB is position of line break in seismic profile (after Hinze et al., 1990).

Densities of geologic units are in g/cm^3. Geologic column is from oldest to youngest from bottom to top (after Hinze *et al.*, 1990).

In Fig. 22, the positive anomalous areas in the vicinity of 16 and 48 km reflect the strong magnetization of the underlying volcanic rocks of the Midcontinent Rift System that were originally laid down horizontally, but subsequently, during the rifting process, have been structurally disturbed. The positive magnetic anomalies are critical to locating the magnetic volcanic rock. The relative negative gravity anomaly from 20 to 40 km and the strong positive gravity anomaly to the north of the 40-km position results from variations in the density and volume of the underlying rock materials. The negative anomaly from 20 to 40 km is primarily caused by the presence of low-density Jacobsville sandstone that reaches depths of up to 2 km. In contrast, the positive gravity anomaly is caused by an immense volume of relatively high-density volcanic rocks extending to depths of 18 km on this section. Confirmation of the feasibility of this interpretation is provided by the forward modeling of the gravity effect of the profile that is shown on the figure to correspond closely with the observed gravity anomaly. Furthermore, the abruptness of the change in rock type between the negative and positive gravity anomalies and the attitude of the change confirm the presence of a fault. Evaluation of the fault shows that it was caused by compressional forces, quite in contrast to the extensional stress regime required for the rifting process. By considering the types of rocks and their ages, it is thus possible to deduce that the rifting event was terminated by a change in the stress field of the Earth that caused compression of the rift structure.

This is just one small segment of a very large crustal structure that continues to be under intensive geophysical investigation. The results of these studies are not only important in deciphering geologic history, but also are useful in identifying potential earthquake hazards due to reactivation of the associated ancient zones of weakness and in localizing areas for exploration for the copper minerals that are found within the rift rocks.

5.3 Hydrocarbon Exploration

The major expenditures in solid-Earth geophysics are in the search for petroleum—oil and gas—that occur within geologic traps or reservoirs in sedimentary rocks of the continents and their shelves. Numerous requirements are necessary for the accumulation of commercial petroleum deposits, but primary among these are rocks that contain interconnected pore space and include a geological condition that will entrap the lighter-than-water hydrocarbons to prevent them from escaping to the surface and dispersing into the environment. All geophysical methods have a role in exploring sedimentary basins for these conditions. However, in excess of 95% of all petroleum geophysical expenditures are directed toward reflection seismic investigations. This method is capable of providing a subsurface image of sedimentary basins that reveals structural features such as folds, faults, domes, and unconformities. Furthermore, in some cases the seismic method can give insight into lithology, porosity, and hydrocarbon content. The resolution of this method far surpasses other geophysical techniques and thus is particularly important in pinpointing locations that are favorable for drilling in the search for hydrocarbons. The use of the seismic exploration method together with geological information is the key to decreasing the risk of wildcat drilling and providing the energy resources for the world's economy.

The success of seismic reflection in petroleum exploration is a function of increasing the signal-to-noise ratio of the received seismic pulses so that reflections from interfaces can be identified and mapped. This requires favorable geologic conditions and the application of advanced signal processing techniques. Under these conditions, it is possible not only to image the lithologic interfaces, but also to identify contacts between elements of an oil–gas pool. This is illustrated in Fig. 23. The upper portion of the figure shows an idealized anticlinal hydrocarbon deposit with a model seismic profile above it. The water (brine)–gas, the gas–oil, and the oil–water contacts are all apparent in the model. The lower portion of Fig. 23 is an actual seismic profile of a similar geological situation. The darkened coherent events in the actual seismic profile, referred to as "bright spots" by petroleum seismologists, reflect the strong acoustic impedance contrast between the gas-charged rocks and their enclosing materials. Thus, under proper conditions, it is feasible to use the seismic method as a direct hydrocarbon indicator.

Much of the world's petroleum exploration today occurs in the continental shelves. Figure 24 is a seismic reflection profile off the Grand Banks of Newfoundland with a geological interpretation of the data superimposed. The vertical line P-15 is the location of the discovery well of the Hibernia oilfield. The productive capability of this well was estimated to be in excess of 20 000 barrels per day, and the oilfield is estimated to contain in excess of 1 billion barrels of oil (Arthur *et al.*, 1982).

5.4 Mineral Exploration

As is the case for hydrocarbon exploration, mineral exploration may involve any of the solid-earth geophysical exploration methods. However, there are, in general, major differences between hydrocarbon and mineral exploration—in mineral exploration the targets are smaller and shallower, the geology is more complex and varied, and the financial resources are usually considerably less. As a result, the exploration methods based on potential-field theory—magnetic, electrical, gravitational—are most widely employed, and they tend to focus on direct detection of the mineral deposits on the basis of the physical property difference between the deposits and the barren enclosing rock formations.

In mineral exploration, it is often necessary to cover extensive regions of the continents quickly and inexpensively. As a result, many of the mineral exploration methods have been adapted to airborne measurements. The most widely used and versatile of the methods are airborne magnetic and electromagnetic methods. These methods are respectively most appropriately used for identifying and mapping strongly magnetic deposits that contain iron oxide and magnetite, and ores of high electrical conductivity consisting prima-

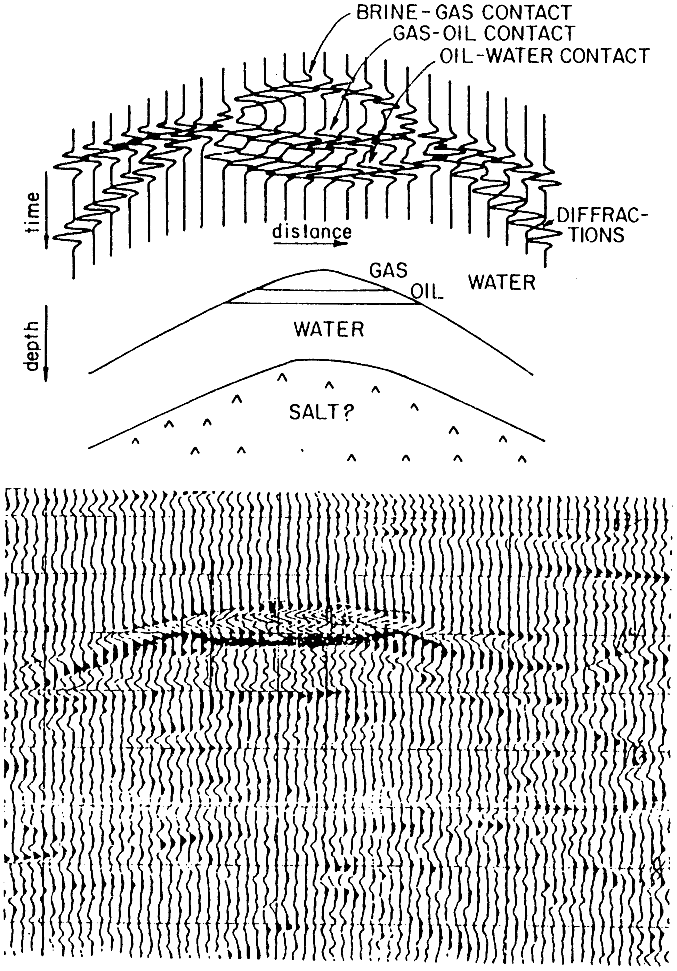

FIG. 23. (Top) Geologic and seismic reflection model of a hydrocarbon reservoir. (Bottom) Seismic reflection profile of a hydrocarbon reservoir that is an analog of model in top figure (modified from Wood, 1982).

rily of metallic sulfides. An illustration of the use of these methods in mapping diamond-bearing kimberlite pipes in Tanzania is shown in Fig. 25. On the left are shown the contours of equal magnetic intensity. Two of the known kimberlites in the region are located by intense magnetic anomalies. On the right of the figure the apparent conductivity of the surface material, as determined by an airborne electromagnetic survey, is shown for the same region as the magnetic map. All three kimberlite pipes are associated with high electrical conductivity. In this case the anomalous conductivity is not due to metallic sulfides, but rather to a clay-rich layer that forms above the kimberlite from weathering of the pipes (Palacky, 1990). The clay layer is more conducting than the weathered material from the adjacent barren rock.

5.5 Ground-Water Investigations

Ground water is a critical resource for mankind in many areas of the Earth. Although this is true in many humid regions that do not have ready access to surface waters for human consumption, irrigation, and industrial uses, it is particularly true in arid regions where ground water is the only source of water for much of the year. Thus the location of water in the subsurface that is readily available and potable is a major source of concern. In order to enhance the efficiency of the ground-water exploration process, wherein the number of wells is minimized, geophysical exploration techniques are commonly applied to the problem. Essentially all geophysical methods adapted to the shallow subsurface are used in ground-water investigations. Some methods, like the commonly used electrical

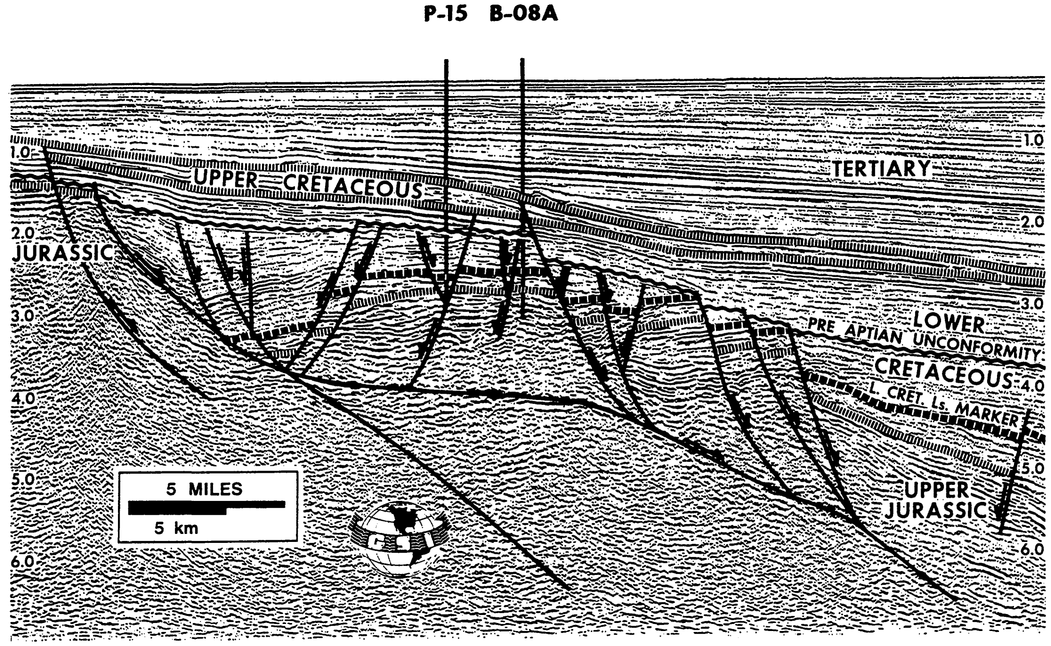

FIG. 24. Migrated seismic profile off the Grand Banks of Newfoundland with interpreted geology. P-15 and B-08A are nearby offshore drill holes. (Line provided courtesy of Geophysical Service, Inc., after Arthur *et al.*, 1982).

resistivity and electromagnetic techniques, are generally used in a direct manner, searching out the modification of the electrical properties caused by the presence of water and water of varying quality. In contrast, other methods, such as the seismic and gravity methods, are used to determine the stratigraphy and structure of the water-saturated Earth materials and thus indirectly the most favorable subsurface regions for ground-water production. These methods provide no direct information on water quality.

In recent years, geophysical methods have had an increasing role in delimiting the extent of pollution of ground-water resources. Generally, this pollution resulting from human activities is detected by electrical methods that measure the decrease in electrical resistivity brought about by the increasing ion content of polluted waters. Such is the case of salt-water intrusion near the Cross-Florida Barge Canal that was initiated to provide a shortened, navigable waterway across northern Florida between the Atlantic Ocean and the Gulf of Mexico. The sea-level canal was cut several meters into the surface carbonate rocks that comprise the Floridan aquifer (Hagemeyer and Stewart, 1990). Surface resistivity measurements (Fig. 26) indicate that low resistivity values are found in the subsurface along the course of the canal, suggesting that sea-water intrusion by the waters of the canal is polluting the aquifer. The degree and extent of the salt-water intrusion can be estimated from the values of resistivity if related geological and ground-water chemical data are available.

5.6 Environmental and Engineering Investigations

Geophysical methods have for several decades had an important role in determining various physical characteristics of the subsurface that are required for engineering designs. In recent years, with the accelerating concern for the environment and especially for maintaining the quality of ground water, there has been an increasing use of geophysical techniques. Geophysical techniques are usually much more rapid and less expensive than direct measurements in drill holes, but they have neither the sensitivity nor the resolution of direct subsurface measurements. Nonetheless, geophysical methods are often employed

in environmental and engineering investigations to aid in selecting optimum sites for drilling and in many cases to avoid the potential pollution hazards related to direct investigations. As in ground-water investigations, a wide range of methods is employed in environmental and engineering studies; the best method for a particular problem is often decided upon by relative costs rather than by a desire to maximize information from the study.

An illustration of the efficient use of a geophysical method to solve an environmental problem is shown in Fig. 27. A landfill

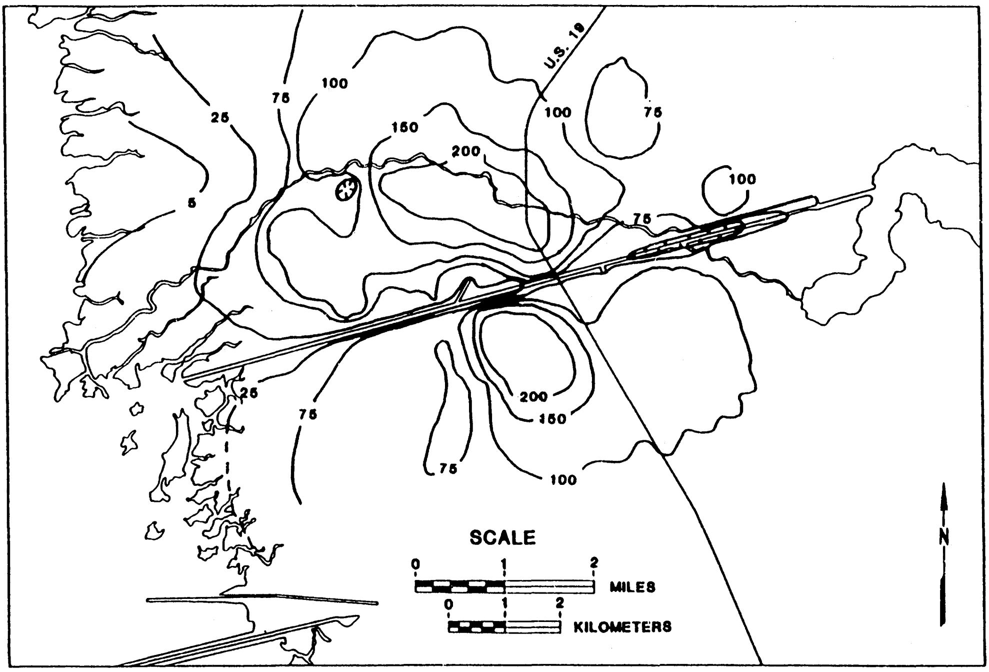

FIG. 26. Contour map of interpreted resistivity in Ω m at 30 m below land surface from vertical resistivity soundings in the vicinity of the Cross-Florida Barge Canal, northern Florida (after Hagemeyer and Stewart, 1990).

approximately 60×150 m^2 located in northwest Indiana (Roberts *et al.*, 1990) was the subject of an intensive investigation to determine its potential impact upon the groundwater resources of the region. One of the required site characteristics is the configuration of the bottom of the landfill, which was the original land surface of a ravine that was filled during the dumping process. Figure 27 shows the residual gravity-anomaly contour map of the landfill. The negative anomaly supports the assumption that the landfill is less dense than the enclosing glacial till. Figure 28 is an isopach map of the landfill derived by subtracting the prelandfill surface from the present surface landform. Comparison of these two figures illustrates how well the gravity method can be used to predict the thickness of the landfill. Furthermore, with constraints on the dimensions of the landfill from collateral data, interpreted density variations within the landfill can be used to characterize the nature of the solid waste material. In the case of the mapped landfill, Roberts *et al.* (1990) discriminated regions within the landfill composed of primarily domestic-type trash from lower-density construction and vegetation refuse.

6. SUMMARY

Solid-Earth geophysics has grown tremendously in acceptance, utilization, and effectiveness over the past half century. This science, which is thoroughly grounded in classical physics, has thrived because of improvements in instrumentation and numerical processing, but has been successful because of the effective integration of geology and physics. The problems solved by solid-Earth geophysics are largely geological; thus geological information and principles are necessary constraints in the application of the science. This is especially true because of the ambiguity inherent in the interpretation of solid-Earth geophysical data. Numerous geophysical techniques have been developed to sense remotely the variety of physical properties of Earth materials. They all have their unique uses, but solid-Earth geophysics is most successful where

multiple methods, as well as geology, are synergistically combined.

Solid-Earth geophysical studies have been unusually successful in that they provided the basic building blocks for the new paradigm of geoscience, plate tectonics and seafloor spreading, which have made it possible to establish a unifying concept for most Earth processes. However, solid-Earth geophysics as applied to studies of the lithosphere have far-ranging applications beyond that of understanding the basic nature, composition, and structure of this Earth shell. Geophysics has an important role in solving numerous societal problems such as contamination of the subsurface environment, maintaining adequate Earth resources to sustain the world's quality of life, and predicting earthquakes and volcanic activity. With the stress placed upon the Earth by a booming world population and the desire

to enhance the quality of life in all regions of the Earth, we can anticipate that solid-Earth geophysics will need to expand its horizons and improve its effectiveness.

GLOSSARY

Aliasing: A frequency ambiguity introduced in the representation of digital data where the sampling rate involves fewer than two samples per cycle. In this case, an input signal at one frequency yields the same sample values as a lower frequency at the output of the system. The lower frequency is an alias of the input frequency and is completely erroneous.

Curie Point: The temperature at which a material loses its magnetization.

Ma: Million years (of geologic age).

Offset: The distance between the point of disturbance (source point) and the position of a detector or the center of an array of detectors.

resonances, so that the precession signal output changes continuously with the ambient magnetic field. In addition to continuous precession signal, the method increases the signal strength and signal-to-noise ratio.

Spherical Divergence: The decrease in signal strength (energy per unit area of wave front) with distance as the wave spreads out.

Zero-Length Spring: A spring whose effective length, as referred to a fixed point of support, is zero when the external forces acting upon it are zero.

INTRODUCTION

In the widest sense, geothermal energy refers to all heat energy stored in the rocks and fluids of the Earth. It has been well known for over a century that the temperature of the Earth's crust increases with depth. It had been observed by ancient peoples that in certain places the Earth's heat is near the surface; volcanos, lava flows, hot springs, geysers, and hot mud pools are manifestations of the heat. These surface manifestations were used by early mankind for domestic chores such as cooking. These geothermal regions were often treated as sacred places and served as sanctuaries after battles. History tells us that hot baths were very popular as social gathering places, and for relaxation and recreation in early Greek, Turkish, and Roman times. This use is still widespread in the world, and hot-spring spas are especially well developed and patronized in several European and Asian countries; Japan is a notable example.

Industrial uses of steam vents, hot mineral-laden waters, and surface heat occurred in ancient times. One of the most significant of these early developments was beneficiation of salt and chemicals. The concentration of metal ores and chemicals such as borates and borax is well known. In what is now Tuscany, Italy, the Etruscans early engaged in trade in borax products from hot springs. Most of the subsequent development of geothermal energy worldwide has focused on such areas of surface manifestations and has involved simply drilling into reservoirs of naturally occurring fluids. Initially these developments focused on enhancement of the steam flows for chemical concentration and for expansion of hot-spring spas. The earliest exploitations of the so-called hydrothermal resources were similar to mankind's use of coal outcrops and the seeps of hydrocarbons. However, geothermal heat, unlike fossil fuels, cannot be transported great distances and must be used near the resource or converted to electric power for transmission to the users. At the turn of the century, the geothermal area at Larderello in Italy was the location of one of the first applications of natural steam to drive prime movers and produce electricity.

This article first provides a brief review of the history of geothermal energy uses and development. Then follows a section that de-

fines the classifications and uses of geothermal energy and provides an overview of resource assessment. Basic sections on the geology and hydrology of hydrothermal systems set the stage for a description of nonhydrothermal resources and some advanced research projects on what is termed "heat mining." Finally, sections on technologies, environmental matters, and economic issues are presented.

1. HISTORY

Early peoples often settled or camped around the thermal areas of our planet. In these settlements the hot springs, steam and gas vents, and mud pools were used for domestic chores such as cooking, bathing, and heating. An example of users of these sources of geothermal energy are the Maori people of New Zealand. Some of these people settled in the volcanic regions of the North Island beginning in the 14th century. Their uses of the energy are recorded in legends and are practiced today, especially within the town of Rotorua (Cooke, 1970) and the extensive Taupo volcanic zone. This area subsequently was the location of the first geothermal electric-power production in New Zealand, from a 160-MW(e) power station at Wairaki in 1958 (New Zealand Electricity Department, 1970). The industrial development in that area was typical of how geothermal energy has developed: considerable drilling of wells for domestic uses and especially for resort hotels, baths, health spas, and other commercial ventures preceded the power development and thus provided a continuity of beneficial uses.

Italian thermal areas are the earliest and most widely reported. Invasion and occupation of Italy by the Etruscans occurred about 3500 years ago. Tuscany, where they settled, has numerous thermal areas. These early peoples used the borates found in the thermal waters to produce beautiful pottery glazes. The Etruscans developed trade in medicinal muds from thermal pools and developed therapeutic baths. Both enterprises continued when the Romans later came to dominate the regions. The use of steam vents to concentrate and beneficiate ores was mentioned early in the first definitive text on mining technology (Agricola, 1556). Agricola specifically mentions the production of borax and other borates from the hot pools and vents. The uses of borates as soldering fluxes for silver and gold work, as medicinal applications for eye and skin diseases, and as agents to process wool are recorded in old Greek and Roman writings. The Conte de Lederel used steam from the vents to evaporate vats of boric acid in 1818. Initially, heat for concentration was provided by wood fires under the vats, but destruction of the forests and a need to increase production led to the use of geothermal steam for borate processing. Invention of masonry domes that covered the pools (*lagone coperio*) and a system of pipes resulted in a unique gathering system to concentrate the steam. The town and region were named Larderello in honor of this developer of geothermal energy. The Larderello firm first introduced water-well drilling technology. Then the firm adopted drilling technology from the German mining industry to expand steam supply and chemical production vastly. This profitable firm and its use of the abundant geothermal energy stimulated invention of tools that increased productivity even more. Effective tools included shell-and-tube heat exchangers for production of clean steam, steam piston pumps, and motors for drill-rig winches. Near the beginning of the 20th century experiments were conducted on additional applications of steam-driven motors. In 1904, P. G. Conti, then director at Larderello, put into use the world's first geothermal steam-driven 10-kW electric dynamo to provide lighting in the plant. By 1913, the world's first commercial electric power was being generated to light all the facilities at Larderello, and a network of transmission lines had been established to provide electricity to the towns in the area. This first geothermal electric utility used a 250-kW turbogenerator (Mazzoni, 1954; Villa, 1975; Burgassi, 1987).

Japan has an abundance of heat sources provided by the young volcanism that dominates its geologic setting. Early inhabitants used the hot springs intensively; these sites were the centers of many villages, shrines, and spas. Today there are thousands of resort and health spas located at nearly all the thermal areas (Japan Spa Association, 1983). The development of the many high-grade (that is, high-temperature) hydrothermal fluid resources long recognized to exist in Japan was paced by expansion of resort and therapeutic spa areas. This required drilling of wells to expand production, and development and advancement of the expertise and technologies in exploration and drilling. Table 1 records the early development of electric power (Japan Geothermal Energy Association, 1974), which began in 1919 in the Beppu tourist thermal area of the southern island of Kyushu. Development in that region (see Table 1) was hampered because the reservoirs produced a mixture of hot water and steam, not dry steam as in Italy.

Table 1. Early history of geothermal electric-power development in Japan.[a]

1919	Vice-Admiral Y. Masuji drilled a steam well in Beppu, Kyushu.
1925	Dr. T. Heiji commenced research on geothermal development by building an experimental 1-kW(e) steam generator in Beppu.
1927	Dr. Heiji drilled a steam well at Otake, Kyushu.
1947	Tone Boring Co. drilled steam wells at Yunosawa, Shizuoka Prefecture, and Narugo, Miyagi Prefecture.
1948	Tone Boring Co. built an experimental 3-kW(e) power plant at Yunosawa near Atagawa, Isu Peninsula.
1951	The Industrial Technology Agency of Japan built an experimental 30-kW(e) power plant at Beppu. The Geological Survey of Japan initiated basic surveys of various geothermal areas in Kyushu.
1953	Kyushu Electric Power Co. commenced research work on the Otake Geothermal Field, Oita Prefecture, Kyushu.
1957	Azaumakako Co. and the Geological Survey of Japan commenced cooperative research work at Matsukawa, Iwate Prefecture.
1960	Fuijita Kanko (tourist) Co. operated a 30-kW(e) nonutility geothermal power plant at Kowakudani, Hakone, Kanagawa Prefecture.
1965	Mitsubishi Metal Mining Co. started research work in the Onuma area of Hachimantai, Iwate Prefecture.
1966	A 22-MW(e) geothermal power plant was completed at the Matsukawa field by the Japan Metals & Chemical Co.
1967	A 13-MW(e) geothermal power plant was completed at the Otake Field by the Kyushu Electric Power Co.
1974	A 10-MW(e) geothermal power plant was completed at the Onuma Field by the Mitsubishi Metal Mining Co.

[a] Japan Geothermal Energy Association (1974).

The Japanese did not continue developing the liquid-dominated reservoirs until they heard of successes in New Zealand and the discovery in 1959 of a dry steam field at Matsukawa in northern Japan. The 1959 discovery well at Matsukawa had a 4-MW(e) potential steam production. The first geothermal electric power plant was established there in 1966. The Japanese resumed development of liquid-dominated reservoirs with the Otake plant in 1967. Following these early efforts, electric-power development grew steadily. However, in Japan today more geothermal energy is used directly for such things as bathing, melting snow from roads, washing clothes, and making sake than is converted to electricity, with only 214.6 MW(e) installed electric power capacity (Huttrer, 1990) and 2686 MW(t) consumed in direct use (Freeston, 1990). Following the first "oil shock" in 1973, the Japanese government expanded its support of research and development for geothermal energy and has encouraged industry to expand development of the country's vast high-grade hydrothermal resources. It has also supported projects in exploration and drilling technology, advanced electric conversion cycles for turbines using organic fluid, and experimental programs to develop direct heat mining of subsurface hot rocks (NEDO, 1991).

The pattern of development of geothermal energy in the United States has been much like that in other parts of the world. Use by aboriginal peoples was widespread. When European colonists and settlers displaced these people, the initial uses for public resorts, therapeutic baths, and private use by individual land owners remained. The use of water-well drilling rigs to augment naturally occurring hot springs was practiced from the 19th century. Thus, the warm springs of the eastern regions and hot springs and volcanic zones in the western United States were rapidly exploited, much as they had been in Europe. The thermal areas in the state of Wyoming, now Yellowstone Park, and the thermal areas of California and the volcanic zone along the west coast were noted by early explorers and settlers. The Big Geysers area, about 135 km north of San Francisco, was discovered by a hunter in 1847 (Koenig, 1992), and a hot-spring spa hotel was developed on the site soon thereafter. Exploratory coring and drilling commenced in 1921, and by 1923 the first two wells drilled near the hotel had been completed and a 35-kW turbogenerator was supplying electric power for the resort and for subsequent drilling operations. Drilling equipment was adapted from water-well rigs, but as this equipment proved inadequate, subsequent drilling used a rotary rig with a large-capacity, steam-driven fluid pump. The next four wells were completed by 1925. Analysis of the flow, temperature, and production data (Geiger, 1926) demonstrated the potential for the Big Geysers area; however, there was no market for electric power at that time. Finally, in 1955 drilling was initiated for a power plant of 125 MW(e), which went on line as utility power in 1960 (Rintoul, 1990). This plant used production from a four-well field of about 240 000 lb/h of dry steam. Subsequent exploration and development proceeded apace (Koenig, 1992). Today this mature steam reservoir produces over 2000 MW(e) from some 30 separate power plants. The Big Geysers field development was thus the second commercial development of geothermal energy for electric power generation after Italy. The dry-steam hydrothermal reservoirs at Larderello, Italy, Matsukawa, Japan, and the Big Geysers, United States, had firmly established the viability of this type of energy source by the middle of the 20th century.

The successful development of the liquid-dominated, high-grade, hydrothermal reservoirs at Wairaki, New Zealand (1959), Otake, Japan (1967), and Cerro Prieto, Mexico (1973), had extended the range of case histories to the mixed water and steam reservoirs found worldwide (DiPippo, 1987). These three case histories formed the basis for a much wider development of geothermal energy. Figure 1 illustrates the historical progress of that development, and Table 2 summarizes the total installed capacity of 5828 MW(e) by country for 1990.

The use of natural geothermal fluids in direct domestic and industrial applications has increased rapidly worldwide. In 1992, use of geothermal energy is estimated to be at a rate of 11 385 MW(t). Advances in direct-use technology are outpacing improvements in large power plants. Recent experience shows that development of small power plants probably will increase more rapidly than development of large, conventional steam-turbine plants.

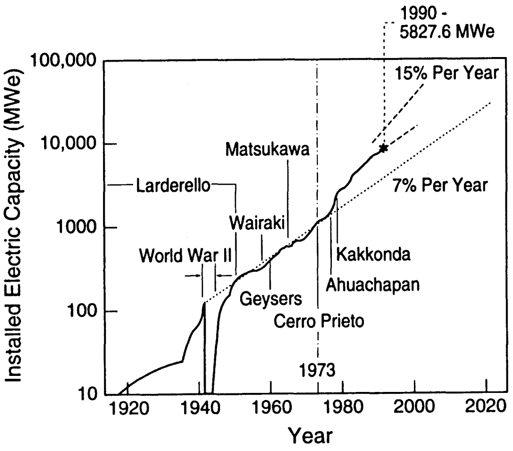

FIG. 1. Worldwide growth trend of geothermal power plants. A relatively steady growth rate of 7% per year of growth can be observed in this figure except for two noticeable perturbations. First was the interruption of growth (in Italy) during World War II, and the second was the surge of growth caused by the oil supply restrictions in the early 1970s.

2. RESOURCE TYPES AND ASSESSMENTS

Descriptions and definitions of geothermal energy types evolve continuously. Elder (1981) states that exploitation of the Earth's internal heat is still in its infancy. But acceleration of resource development has been aided by the efforts of the United Nations, which has focused on education of scientists and technicians from developing nations. The development of local energy sources is especially valuable and beneficial as it reduces problems of foreign exchange and offers some immunity to fossil-fuel supply crises. This has been true for Mexico (Lippman and Manon, 1987) and the Philippines (Otte, 1991). Introduction of new concepts and methods of heat mining (Armstead and Tester, 1987) and accumulation of case histories of successful exploration and exploitation have led to two important results. First, the increasing number of successful projects has accelerated development. Second, introduction of new resource concepts and methods of heat mining has greatly expanded our perception of the extent of geothermal resources.

2.1 Geothermal Resource Types

Temperature increases with depth in the Earth, as shown by the current model of the Earth's interior [Fig. 2(a)] (see EARTH, INTERIOR STRUCTURE OF). The average or normal temperature distribution nearer the surface is shown in Fig. 2(b). Sufficient global data have revealed that the average temperature gradient at the surface, that is, the rate at which the temperature increases, is about 25 °C/km, and the average surface heat flux is about 50 mW/m^2. This heat flux, q_s, is related to a nominal thermal conductivity according to the equation

$$q_s = -\bar{\lambda}\frac{dT}{dz}, \tag{1}$$

where $\bar{\lambda}$ is an average value of the thermal conductivity of the material near the surface. This heat flow from the Earth's interior is small compared to the incoming average solar heat flux on the illuminated side of the Earth, which is 175 W/m^2, a factor some 3500 times greater than the surface heat flux. The solar flux is absorbed in the atmosphere and surface features, distributed around the globe, and reradiated. The average surface temperature is set by this radiative balance at about 15 °C (Elder, 1981).

The nominal heated global volume contains an enormous amount of stored heat energy. The heat is due to the energy from

1. its original gravitational accumulation;
2. the differentiation of the core, mantle, and crustal components; and

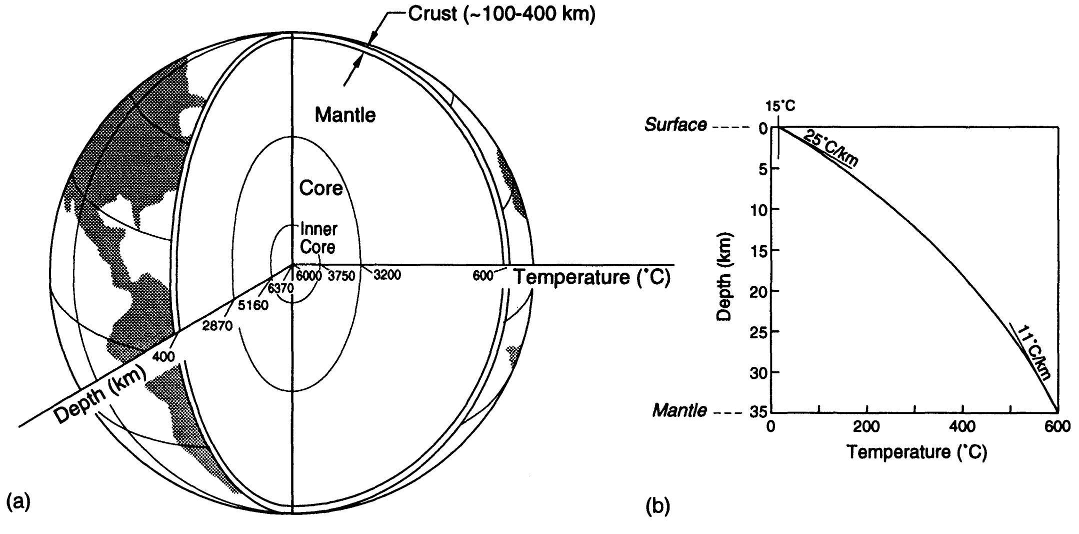

FIG. 2. Temperature distribution within the Earth (Mustoe, 1984). (a) Nominal thermal structure of the Earth. (b) Nominal temperature profile near the Earth's surface.

3. radioactive heating from natural uranium, thorium, and potassium (Bowen, 1989).

There is estimated to be some 1.3×10^{27} J stored in the crust to a depth of 10 km (Armstead and Tester, 1987). This amount is derived by integrating the temperature curve in Fig. 2(b) to a depth of 10 km and using average values of crustal rock properties. The heat content $Q(z_f)$ contained in the volume beneath the surface area A is given by

$$Q(Z_f) = A \int_0^{Z_f} \bar{\rho}(z) C(z) T(z) dz, \qquad (2)$$

where Z_f is the depth, $\bar{\rho}(z)$ is the density, $C(z)$ is the volumetric specific heat content, and $T(z)$ is the temperature as a function of depth. The average density is 2500 kg/m^3 and the average specific heat is 770 J/kg °C (Rowley, 1982). This energy, if recovered, would be equivalent to the combustion of about 2.3×10^{17} barrels of oil. This can be compared with the annual U.S. consumption of oil (6.2×10^9 barrels) or the estimated world reserves of oil (1×10^{12} barrels).

However, the easily accessible, shallow, high-grade geothermal energy resources are located in the geothermal belts or zones of the Earth as shown in Fig. 3. These areas make up only 1% or so of the total land area. They are primarily located at the crustal plate boundaries (Rybach and Muffler, 1981), and the occurrences of natural geothermal systems in these zones are often referred to as thermal anomalies. The descriptions and definitions of energy resources set forth in this section are not universal and are introduced or adopted here for convenience of discussion.

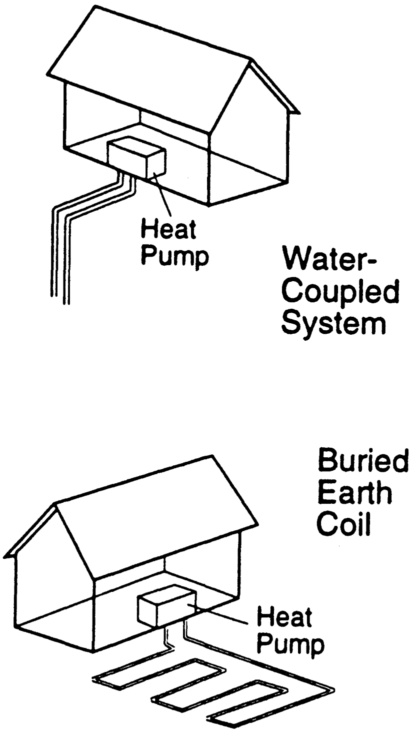

FIG. 4. Use of Earth energy resources for space conditioning.

2.1.1 Earth Energy. This resource type is applied in the United States to the near-surface use of direct soil contact and normal-gradient shallow aquifers for heat-pump installations. The heat-pump sink is either a pumped flow of shallow aquifer water, a heat-exchanger loop inserted in a water well, or a coil of tubing buried in the earth. Figure 4 illustrates these systems (Rafferty, 1989). Perhaps 100 000 units have been installed in the United States and Canada (Pratsch, 1990). These installations have mainly been in the middle west and eastern parts of these countries, but they can be installed essentially anywhere. Heat pumps coupled to the Earth or to water wells have been promoted by electric utilities to relieve peak winter heating and summer cooling loads. This shallow geothermal Earth energy resource is expected to find much wider use worldwide; currently its use is increasing at about 25% per year.

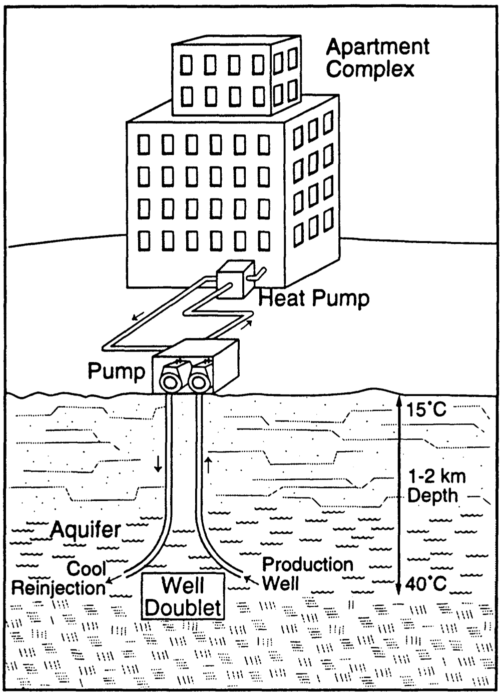

FIG. 5. Hot water from deep aquifers in normal-gradient (25 °C/km) basins is used for space heating. Two-well (doublet) systems depend on sufficient spacing between production and reinjection wells to prevent aquifer cooling. These conditions occur beneath Louisville, Kentucky, U.S.A., and Paris, France.

2.1.2 Normal-Gradient Aquifers. There is an increasing use of deep aquifers that are located in sedimentary basins. The technology consists of a doublet, or two-well system (Fig. 5), that is pumped at large flow rates and uses a heat pump to heat and cool large apartment and industrial complexes (Boisdet *et al.*, 1990). Doublet-source configurations use sufficient separation of the production and reinjection wells to avoid significant cooling of the production well.

2.1.3 Hot and Warm Aquifers. This is a widespread resource and supports direct-use application. It is found especially in thermal zones where hot and warm springs occur naturally. Water-well drilling in these areas produces hot to warm water at relatively shallow depths. Many domestic and industrial heating systems using this resource have been developed; they are rapidly expanding worldwide. A notable example is in Iceland, where Reykjavik, the capital city, has more than 90% of its thermal energy needs serviced by such a system, with a total of 705 hot-water wells supplying some 4600 kg/s. Another high-gradient region occurs in the Carpathian Basin of Hungary, where the heat flux and thermal gradient are about double the world average. This country has long used deep wells drilled into warm-water aquifers for agricultural, public bath, and industrial uses. Nearly 1000 flowing wells produce over 1200 MW(t) with a total flow rate of 12 000 kg/s at temperatures between 50 and 90 °C. Over a year this usage is equivalent to combustion of 24×10^6 barrels of oil. Agricultural use, mainly for greenhouses (29%), is significant to the economy of Hungary. In the United States (Lienau and Lunis, 1989) this resource type is distributed widely throughout the eastern states. Nearly 68 000 individual applications are based on warm or hot aquifers. These displace the combustion of perhaps 3×10^6 barrels of oil a year. District heating in Boise, Idaho, Klamath Falls, Oregon, and Mammoth Lake, California, and enhanced oil recovery and gold leaching enhancement projects have expanded the potential for using this type of resource.

2.1.4 Hydrothermal Convection Resources. In thermal areas, there exist heat sources in the form of magma that intrudes into the shallow crust or extrudes as in volcanic activity. These heat sources are cooled by heat convection to naturally circulating water. These are the resource types that have been given the most intense study and have been most widely and effectively exploited. The high-grade (> 150 °C) fluids in these convection systems are very valuable and form the basis for the conversion of thermal energy into electric power. These resources are characterized by two major subtypes of reservoirs. One is vapor dominated, with dry steam circulating in the reservoir; the other is liquid dominated, with a two-phase mixture of water and steam circulating in the reservoir. There are two essential requirements for reservoir properties: sufficient porosity and permeability, and a convective flow of water to bring the energy toward the surface. Such reservoirs of convecting fluid are tapped by drilling and will produce hot fluids, either as steam or, more commonly, as a mixture of water and steam. Figure 6 is a schematic of a typical hydrothermal system (Muffler, 1985). Exploration and exploitation of this resource type has been rapid in the past half-decade (Huttrer, 1990). Within this period a total of 166 electric power plants were installed worldwide, with 143 in the United States alone. Most hydrothermal resources are liquid dominated (DiPippo, 1987). Most are found in volcanic zones, but some are located in large sedimentary basins. One example is the Imperial Valley, California, U.S.A., which is on the active boundary of the Pacific and North American plates. Here several thermal anomalies that had no surface manifestations were discovered and drilled to develop productive reservoirs. The large development in Mexico south of the Imperial Valley, at the Cerro Prieto field (Lippman and Manon, 1987) is another example of hydrothermal resources in such a geological setting.

2.1.5 Geopressured Resources. Geopressured reservoirs containing hot brine and quantities of dissolved methane (natural gas) are often encountered when drilling in deep basins for hydrocarbon accumulations. These reservoirs are usually associated with undercompaction of sediments that have an imper-

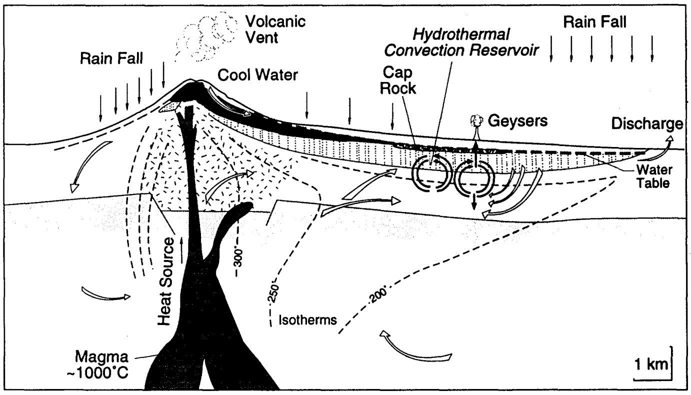

FIG. 6. Hydrothermal system. This illustrates a typical system associated with a volcanic heat source. The system consists of a hot magma, at about 1000 °C, cooled by convectively circulating water that is continually supplied by rainfall. The system contains a reservoir that is a local volume of permeable rock.

meable cap rock (shale). An internal pressure higher than hydrostatic pressure at depth is generated because of the inability of the undercompacted sediments to support the overlying rock mass. The most widely known geopressured zones are found in the Gulf of Mexico regions of Mississippi, Louisiana, and Texas, U.S.A. (Dorfman and Morton, 1985); however, many other deep basins worldwide are known to contain such resources.

2.1.6 Hot Dry Rock Resources. This resource type consists of the vast, pervasive mass of crustal rocks that exist beneath all continents (Smith, 1988). This resource type is therefore not necessarily restricted to the thermal zones or geothermal belts. The access and exploitation of this resource depend on a developing technology that drills a pair, or doublet, of wells into the hot rock, where no significant porosity or permeability exists, creates an artificial fractured reservoir, injects water into and through the artificial fracture system, and in a closed-loop process extracts the energy by the usual heat-exchanger or turbogenerator electric conversion technologies.

This technology has active research and development projects in the U.S., Japan, and Europe (Anderson, 1992). Based upon rather modest extensions of present drilling and reservoir technologies, it may be expected that commercial prototype hot dry rock resources will be in place by the end of the 20th century. Warm dry rock systems, used in conjunction with geothermal heat pumps in Sweden, have displaced nearly 100 MW(e) of needed new electrical capacity.

2.1.7 Magma Resource. Discrete intrusions of molten rock (magma) are being studied in the United States (Hardee, 1988). This concept uses discrete magma bodies close enough to the surface to be drilled into and a heat exchanger installed in the holes. The initial targets are thought to be the large, recent (silicic) calderas (volcanic collapse craters). The magma body that is believed to underlie the Long Valley caldera in California, U.S.A., has been selected for initial drilling and experiments. The magma energy concept requires considerable advances in drilling and materials technology before it can be brought to a demonstration stage. The energy of a large, high-temperature magma body is very great. For example, consider that a 4.0-km^3 volume at about 1000 °C would release about 6.5×10^4 TJ (6.5 Quads) when cooled to 150 °C. If this heat were captured and converted to electricity at a 10% conversion efficiency, it could produce 200 MW(e) for a century.

2.2 Resource Assessments

In present geothermal resource assessments and reserve estimates, it is important that the objectives of the assessments and the basis for the results are understood. At this early stage in geothermal energy development, there is a relatively limited amount of subsurface information and few published well and production data available. Therefore this account serves best as a status report.

A global assessment developed for the 1977 World Energy Conference (Roberts, 1978) calculated and estimated the geothermal energy storage to a depth of 3 km [Table 3 and

Table 3. Global geothermal resource base estimate in 10^{12} TJ, based upon geographic distribution of geothermal zones (3 km integration depth).

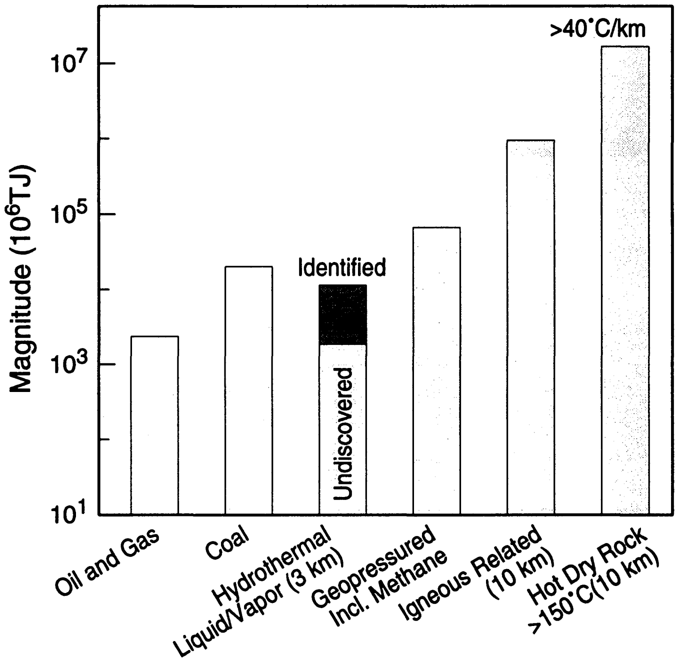

FIG. 7. Comparison of geothermal, coal, oil, and gas resources for the United States (Rowley, 1982). This figure shows that the total of all geothermal resource types is approximately 14 orders of magnitude greater than the total fossil resource base. For reference, 10^6 terajoules (TJ) equals 10^{15} British thermal units (Btu) equals 10^6 tonnes (t) of oil equals 1.4×10^6 tonnes of coal equals 1 megawatt thermal [MW(t)] of power use for one century.

Eq. (2)]. Such assessments are usually restricted to estimates of long-term potentials, priorities for alternative-energy research and development, and comparisons with the resource bases or measured quantities of other energy resources.

A few national and region geothermal resource assessments have been developed, and those for Europe (Haenel and Staroste, 1988), Italy (Muffler and Cataldi,1978), Japan (Yamaguchi, 1992), New Zealand (Donaldson and Grant, 1978), and, most notably, for United States (White and Williams, 1975; Muffler, 1978; Reed, 1983) illustrate the value of such assessments. Figure 7 summarizes these results for the United States and compares geothermal resources with coal and oil resources.

The methods used for regional assessments have been restricted generally to estimates or calculations of the geothermal energy stored in the subsurface rocks and fluids, and are usually restricted to depths of less than 3 km as a judgment of the economically accessible drilling depth. The definitions and philosophy of deriving energy assessments have been very different across the various energy resource types. However, the most definitive and effective methodology for the geothermal types has been developed by Muffler (1978).

The resources assessments of shallow aquifers rely on long-established water resource evaluation techniques. Major sedimentary basins can therefore be relatively easily evaluated for the energy in place. Another assessment method that has been advocated by McNitt (1978) and applied in Central America (Einarsson, 1975) is based on statistical analyses of already explored and drilled resources and producing, high-grade hydrothermal reservoirs. This methodology was used (Einarsson, 1975) with a very preliminary survey of hot-spring areas to project a minimum electric power production for Central America of 8000 MW(e). The value and usefulness of such methodology can only be determined by long-term comparisons with the results of actual geothermal development.

3. GEOLOGY AND HYDROLOGY OF GEOTHERMAL RESOURCES

This section describes only the resource type introduced in Sec. 2.1.4 above, hydrothermal convection resources.

3.1 Nature and Occurrence

Near-surface hydrothermal systems occur as a result of the geologic transport of above-average amounts of heat into the shallow crust. Therefore the occurrences of hydrothermal systems are not random but are determined by geological processes on local, regional, and global scales. Useful hydrothermal reservoirs contain the following elements: heat sources, permeability in the subsurface rocks that provides pathways for the fluid-transport system, water in the interconnected porosity, and usually a cap rock or blanketing overlying structure that limits leakage through natural surface manifestations.

3.2 Geologic Setting

The higher-than-average temperatures that result in so-called geothermal zones are caused by the following five geologic processes:

1. intrusion of magma into shallow levels of the crust,
2. occurrence of thinned crust and resulting higher-than-average heat flow,
3. circulation of heated groundwater along faults to depths of 1 to 5 km,
4. insulating blankets or rock layers of low thermal conductivity above hot aquifers, or
5. high volumetric radioactive heating rates in shallow, buried plutons.

The majority of high-grade resources have been found to be a result of the first process, although reservoirs based on heat sources of types **2** and **3** have been exploited. The blanketing process is typically found in sedimentary basins, which have lower temperatures and are suitable for direct use. The fifth process, radioactive heating, has been explored but as yet not exploited (Costain *et al.*, 1980).

Intrusion of magma is most commonly found within the global volcanic belts, Fig. 3, and associated with the margins of crustal plates. Intraplate heat sources, usually associated with mantle plumes, also produce near-surface hot spots. These latter geologic processes often produce large magma bodies and associated silicic calderas. In the United States, such calderas are found in the Yellowstone complex in Wyoming, Long Valley in California, and the Valles in New Mexico. The relationships of geothermal systems to volcano heat sources have been discussed extensively by Wohletz and Heiken (1992). The schematic geologic cross section in Fig. 6 typifies hydrothermal systems generated by volcanic heat sources.

3.3 Permeability and Hydrology

In most geothermal systems, porosity and permeability result from fracture networks in the brittle, crystalline rocks associated with thermal zones, tectonic stress caused by crustal plate interactions, and the forces induced by intrusion of hot magma. Even in layered sedimentary basins, the intergranular porosity is filled in by deposition of secondary minerals from the circulating geothermal fluids; the result is densification and the production of secondary, brittle fracture networks. The subsurface fracture networks are frequently associated with major fault zones and form roughly orthogonal fracture systems. Such fracture systems often lead to an elongated zone of permeability and porosity along the fault zone. Such fault and fracture zones also tend to be quite deep relative to the lateral extent of the reservoir.

The subsurface fluids are usually a result of groundwater derived from precipitation and runoff that penetrates into and then circulates within the hydrothermal system as illustrated in Fig. 6. A few reservoirs have a significant fluid component from seawater, as in the Fushime geothermal field at the southern tip of the island of Kyushu, Japan (Yoshimura *et al.*, 1985). However, systems do occur without surface recharge and discharge areas, such as the reservoirs in the Salton Trough in California, U.S., where several reservoirs without any surface manifestations of discharge such as hot springs or gas vents have been found (Elders and Pena, 1979).The hydrological regimes of the hydrothermal systems studied thus far are very diverse, and the location and nature of the reservoir are strongly influenced by the locations of the recharge and discharge areas, as well as by the size, temperature, depth, and age of the heat source. These factors have combined to produce reservoirs with areas ranging from about 0.5 to 200 km^2 as defined by the 180 °C isotherm (McNitt, 1978). The nature of the fracture networks and the hydrologic variables also cause two other commonly encountered situations, namely, the production of a condensing zone at the top of the convection cells within the reservoir, and the often resulting chemical deposition and sealing of the fractures, with subsequent formation of a cap rock.

The nature, spacing, and aperture of the subsurface fracture systems are determined by past tectonic activity and hydrothermal activity (Norton, 1988; Norton and Knight, 1977), lithology (Morse and Thorson, 1978), and local and regional crustal stresses (Nakamura, 1977). Because crystalline rocks have very low matrix permeabilities and porosities, the fracture systems control the volume and circulation of the fluids that provide the removal of heat from the reservoir and the convection of heat toward the Earth's surface. These fractured reservoir conditions are very different from those of the commonly encountered oil and gas reservoirs [although a few fractured petroleum reservoirs have been studied (Aguilera, 1980)]. The fracture porosity found in geothermal systems is generally less than 10%, but the permeability can vary by six orders of magnitude.

4. TECHNOLOGIES

The technologies applied to the development and production of geothermal energy are largely adaptations of those used in the water-well, mineral, and petroleum industries. The fractured nature of geothermal reservoirs influences every aspect of applying the most commonly used technologies to geothermal development and production. The technologies are most conveniently discussed in five categories: exploration, drilling, reservoir engineering and production management, utilization and conversion, and environmental protection. These categories are discussed in the order in which the work is normally conducted in a geothermal project.

4.1 Exploration

Exploration for geothermal resources is a relatively new and still developing area of applied science. Exploration activity and advances in the technology have expanded rapidly in the past decade and a half. Before 1965 the pioneering efforts were carried out primarily by Italy, New Zealand, Japan, Iceland, and France. The methods applied were adapted from those used for water, mineral, and petroleum resource development and the scientific study of volcanos.

Very early exploration programs concentrated on geothermal areas of large extent and abundant surface manifestations. These early efforts were often merely the drilling of step-out wells to enhance the fluid flows as at Larderello, Italy (Burgassi, 1987), and many other locations, but by the early 1970s the exploration activities had expanded until systems with little or no surface indications were being successfully located. At present there is no generally accepted approach to planning and conducting exploration for geothermal resources. However, it is usually conducted by an exploration team of geologists, geochemists, hydrologists, geophysicists, and drilling engineers. The effort usually starts at the regional level (Wright *et al.*, 1989) and as existing field work, principally geologic mapping and geochemical sampling, progresses, the area of investigation is narrowed (Ward *et al.*, 1981). Early in the assessment of the local area, a conceptual model (Elders, 1991) is developed, containing the four basic elements given in Sec. 3.1. The process, diagrammed in Fig. 8, is refined as detailed data are accumulated. The prospecting methods have as their prime objective the location of a hot subsurface volume of fluid contained in rock of sufficient porosity and permeability to sustain circulation. Table 4 lists the techniques typically employed. Very basic are the geothermometers (Henley *et al.*, 1984), data obtained from the hot springs, gas vents (fumaroles), and shallow drill holes that can often determine the base temperature of the system (Truesdell, 1984). These techniques can often determine the base temperature that the fluid reaches at depth and thus set the grade of the resource, i.e., whether it is useful for electric-power generation or, at lower temperatures, direct-use applications. The methods used must be capable of distinguishing between hot dry rocks and hot permeable rocks containing fluids.

As detailed data accumulate, temperature-gradient data from shallow core holes are coordinated with surface geological and geophysical survey results. The initial surface geophysical surveys are usually done with

gravity and dc resistivity measurements (see GEOPHYSICS). These surveys are calibrated by the use of resistivity and density logging in shallow and intermediate-depth holes. These data can provide a sufficient refinement of the subsurface reservoir model to allow a decision to be made: whether to locate and drill a first, deep exploratory well or not to proceed with the exploration (Hill, 1985). Typical results of commonly used geophysical survey of subsurface resistance are illustrated in Fig. 9 and often are prospective for a quantity of hot fluids, because hot brine contained in pores has a considerably lower resistance than the surrounding rock (Goldstein, 1988).

4.2 Drilling

Geothermal drilling equipment and practices have developed from construction, water-well, mineral, and petroleum technologies. Early drilling projects in Italy (Mazzoni, 1954) and the Big Geysers field in California, U.S.A. (Rintoul, 1990), illustrate the progression of the early stages of drilling that used lightweight equipment. Frequently, equipment selection focused on modifications of mining drills. The selection was due to the hard, abrasive, and fractured nature of the coarsely crystalline and volcanic rocks. Equipment must be modified to control blowouts. Even though blowouts are rare (Zvulun, 1989), they do occur when drilling encounters an energetic steam-production zone and the surface valves and other flow-preventor equipment fail to contain the flow. Geothermal blowouts are similar to high-pressure gas blowouts in

Drilling	Intermediate-depth core holes and monitoring wells Deep exploration wells

petroleum drilling, and the geothermal methods and equipment are adaptations from that industry (Goins and Sheffield, 1983). Other modifications are needed to control the wells and to drill large-diameter holes to accommodate large production flows. Drilling for production from direct-use reservoirs (Culver, 1989) requires only adaptations to accommodate the elevated temperatures.

Production drilling usually commences at a geothermal prospect once the deep exploration phase of drilling has been completed and well tests have demonstrated the reservoir potential of the field. As in all subsurface excavation processes, geothermal drilling usually follows a learning curve of improvement as knowledge of subsurface conditions increases through time. Achieving an increasing level of drilling effectiveness is very desirable, as drilling costs can be 40% to 60% of the total project budget. Geothermal drilling is more costly than wells drilled to comparable depths for oil and gas; this cost factor can be 2 to 4 times greater (Kelsey and Carson, 1987). Increased costs are directly related to the severity of subsurface conditions. Also, the average geothermal well is about twice as deep as the average U.S. oil well. These relative cost factors are summarized in Fig. 10 from the U.S. geothermal data base (Rowley, 1988).

Data on the history of geothermal drilling in the United States are presented in Fig. 11, where it is shown that the majority of production wells (over 500) have been drilled at the Big Geysers Field (steam) in California. This drilling is done using air as the drilling fluid,

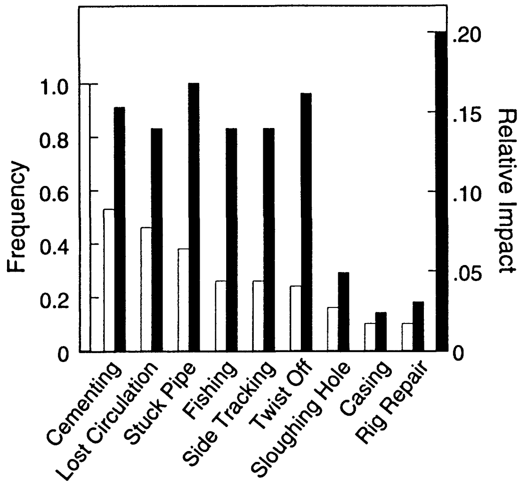

FIG. 10. Summary of frequency (open bar) and relative impact (solid bar) of geothermal drilling problems. Relative impact is a problem's frequency times the number of days' delay it causes.

as is usual for vapor-dominated reservoirs. Air drilling prevents reservoir fracturing, loss of circulating fluids, and plugging of fractures caused by the hydrostatic pressure of a liquid column (Wolke *et al.*, 1990). Directional drilling is used primarily to steer a borehole toward a production-zone target (Burkman and Nickels, 1990). Half of the geothermal wells in the United States are drilled in this way. It can also solve tight topographical constraints, lower the costs of drill pad construction, and allow for alternate drilling of reinjection wells. Directional drilling equipment needs upgrading to high temperatures (Saito, 1992) to incline and steer the wellbore so that it intersects near-vertical and azimuthal fracture trends (Shale and Nickels, 1992). Especially important are high-temperature–rated downhole drilling motors, for both air and liquid, and the steering instruments needed to steer the drilling assembly out of vertical and in a particular azimuthal direction.

FIG. 11. The total number of wells has increased; the percentage of those wells coming from liquid-dominated fields has also increased. The only steam field in the United States is at the Big Geysers field in California.

4.3 Reservoir Engineering and Production Management

Over the past decade, the ability to simulate and provide predictions of hydrothermal reservoirs has progressed rapidly (Bodvarsson and Witherspoon, 1989). The reservoir engineer's tasks are

- prediction of the production potential of the reservoir,
- determination of the number and locations of production wells,
- prediction of declines in total field and individual well production rates,
- determination of the number and locations of reinjection wells to minimize the cooling of production wells by cold injection fluids, and
- projection of the reserves of energy and a production strategy that will sustain production at the needed levels for the lifetime of the project, usually 20 to 30 years.

Simulation methods have been developed from those previously perfected for petroleum- and water-reservoir analyses. The process starts with collection of the properties of both reservoir rocks and fluid. The reservoir engineer then directs

- conduct of temperature- and pressure-logging surveys and other production measurements as the wells are drilled,
- interpretation of pressure transient test results on production wells,
- construction of reservoir computer simulation designed to model the reservoir in its undisturbed natural state, and
- extension of that model to one that simulates, over time, production from the reservoir.

FIG. 12. Cross section of geothermal reservoir model showing rock porosities and permeabilities within the producing zones at Olkaria Field, Kenya (Bodvarsson and Witherspoon, 1989).

The process of reservoir simulator development is illustrated in Fig. 8. Early reservoir models were first established in New Zealand (Grant *et al.*, 1982). Subsequently, they have advanced, and models now include such essential complexities as fracture flow of two-phase fluids, three-dimensional conduction of heat between fractures, and the sweep flows of cooler fluid from both natural recharge and reinjection water. Figure 12 illustrates an example of a typical computer simulation on a well-by-well basis.

Such reservoir engineering activities can provide the basis for production management. This management requires continual updating of the estimated reserves, adjustment of individual well production, and use and decisions about drilling of new wells to maintain the total needed power production.

4.4 Utilization and Conversion

The technologies used for utilization of the geothermal heat of the Earth are primarily adaptations and applications of existing industrial systems for heat exchange or conversion to electric power.

4.4.1 Direct Use. Geothermal heat is used directly for many things (Lienau and Lunis, 1989); its direct use is greater than its use for conversion to electricity (Freeston, 1990). In the United States there are 452 sites that produced 5,466 GWh of energy in 1990. It is reported that 44% is used for enhanced oil

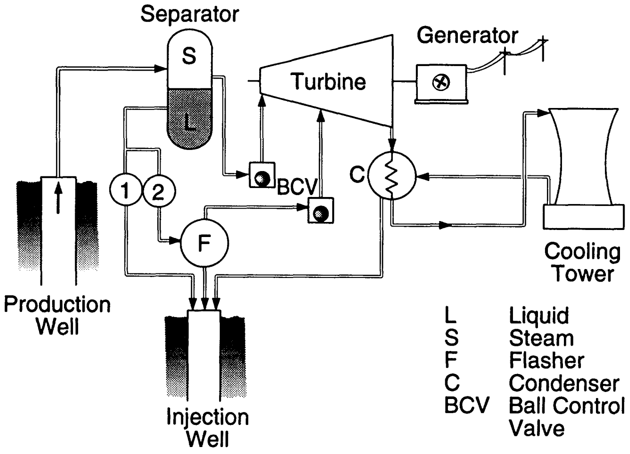

FIG. 13. Schematic of geothermal power plant showing two types. In both types, separated steam is fed to the turbine. Then in the first type (1), separated liquid is reinjected directly into the injection well. In the second type (2), the separated liquid is flashed again in flasher F, and the separated steam enters the turbine's lower pressure stage. The second type increases power plant efficiency.

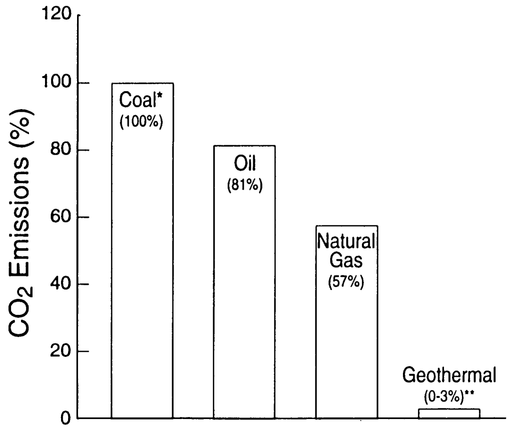
recovery and 30% for earth-coupled heat-pump installations. Twenty-seven new district heating systems that have been developed in the past five years, heap-leaching for gold ore extraction, and various greenhouse, aquaculture, and building heating installations accounted for about 100 MW(t). Very significant is the rapid growth of installed heat pump units for domestic space conditioning growth. About 30 000 of them use groundwater wells and another 50 000 use direct earth-coupled loops. Together they produce 400 MW(t) annually. Japan (Higo, 1990) makes by far the most use of geothermal water with a total estimated thermal power of 3,321 MW(t), with about 90% used for bathing and hot spring resorts. The remaining 10% (Sekioka, 1990) is used for diverse applications; use for greenhouses predominates, and snow melting applications have been recorded.

4.4.2 Electric Power Generation. The technologies and facilities for steam utilization from vapor- or liquid-dominated reservoirs (DiPippo, 1987) can readily be modified from conventional thermal power plants (Kestin, 1980). Major modifications include scrubbing the steam of impurities, especially the noncondensable gases CO, CO_2, and H_2S, and reducing scaling of the pipe lines, valves, and turbines. Also, the cooled condensate fluids and the by-products of the steam-scrubbing process must be disposed of. A simplified schematic of a geothermal power plant with single-flash and double-flash options, Fig. 13, illustrates the other major difference from fossil or nuclear plants. The geothermal system is a steady flow-through process with the hot geothermal fluids being fed directly through the turbine and then reinjected after they cool. In contrast, conventional thermal plants use an external heat source in a boiler and run the fluid in a closed cycle through the turbine.

The optimum size of geothermal power plants is 50 to 100 MW(e) capacity. This has been determined from experience and is related to a tradeoff between the cost of extending the well-field piping, the energy losses in long piping runs, and the incremental costs of locating and constructing another power plant.

An advanced power-generation concept is the organic Rankine cycle, usually termed binary-cycle plants (Milora and Tester, 1976). This system removes the heat from the wellhead fluid by a heat exchanger, and, using an organic fluid tailored to match the temperature of the geothermal fluid production, expands the organic fluid in a turbine that operates on a closed cycle (DiPippo, 1987). The advantages of the new binary plants are that the spent fluids are immediately reinjected back into the subsurface, the turbine generator units are modularized, and the units can be used on resources that are at intermediate temperatures. The binary plant also keeps mineral-laden source fluid separated from the turbine working fluid. A number of binary plant designs have been developed. Several have been installed in the state of Nevada, U.S.A., with considerable commercial success. This development means that



*Coal-fired plant ~500 lb/hr·MW(e) expressed as carbon.

** Newest geothermal plants use reinjection of gases and produce no CO_2.

FIG. 14. Relative carbon dioxide (CO_2) emissions from fossil-fuel and geothermal power plants, with coal taken as 100%.

electric power can be generated from small geothermal reservoirs having relatively low temperatures.

4.5 Environmental Protection

Early consideration of pollution abatement and environmental impacts has led to effective development of abatement practices, equipment, and monitoring and control methods (Hartley, 1980). The environmental sensitivity of the public and the regulatory mechanisms and environmental laws both in California, U.S.A., and in Japan have dictated that the geothermal projects now used as case histories for environmental aspects of geothermal development be given appropriate consideration. The impacts on land, water, and air have been reviewed by Weres (1988), and the nature and details of the control technologies are in place. Major problems were the handling of the large mass-flow rates of the fluids and the mitigation of the noncondensable gases, especially H_2S. The identification of potentially hazardous metals such as mercury, lead, arsenic, vanadium, and boron in the residuals from the power plants has aided the handling and disposal of these wastes. The early development and deployment of H_2S scrubbing technologies has allowed geothermal plants to meet stringent air-quality regulations. Drilling activity has been under strict regulation, and the use of H_2S abatement measures and noise-control mufflers has mitigated significant environmental impacts.

Geothermal development on a per-megawatt basis does not contribute as much to greenhouse gases as conventional thermal plants do (Fig. 14). A new reinjection technology (Hibara *et al.*, 1990) for the noncondensable gases has greatly reduced the total emissions from geothermal power plants. This technology, applied to conventional geothermal power plants, reduces their emissions to nearly zero, as in the case of binary plants.

5. ECONOMICS

The heat energy and electric power generated from geothermal resources are competitive with fossil- and nuclear-fueled heat and electricity in the United States and Japan where the private sector is conducting devel-

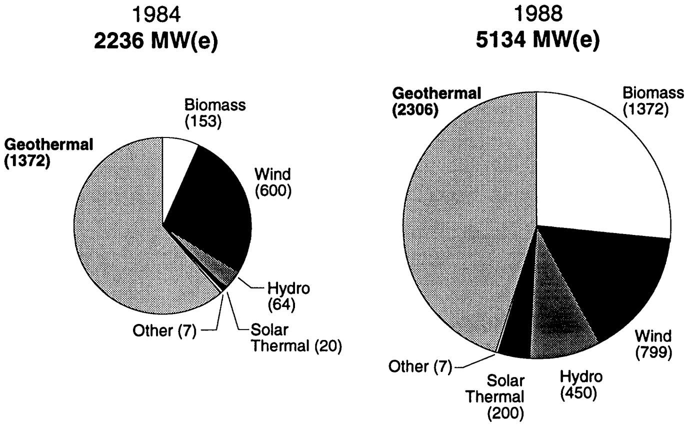


FIG. 15. Total U.S. utility power production from renewable resources.

opments. Outside these countries the national utility organizations usually have responsibility for development of electric generation, and it is difficult to judge whether the projects are competitive. However, in a country where fossil energy resources are scarce or absent, the development of geothermal energy is very attractive. In geothermal energy projects, the required technological level is lower, availability is higher, and the utility infrastructure is less complicated than that for alternative power-generation sources (Otte, 1991). Such geothermal energy projects, because they depend on local energy resources, are especially attractive from a balance-of-payments standpoint in many developing countries.

The economic cost analysis and evaluation of geothermal projects is straightforward and follows from the engineering cost estimating and financial considerations for more familiar fossil energy facilities (Tester, 1982; Blair *et al.*, 1982; Denno, 1990). In the United States the utility industry (Nola and Sioshansi, 1990) consistently produces more energy from geothermal resources than from other renewable alternatives (Fig. 15).

GLOSSARY

Aquifer: A subsurface, porous zone that contains groundwater and from which flow can be produced by a well.

Base Temperature: The maximum rock temperature reached at an unknown depth by the circulation of fluid, usually estimated by geochemical methods.

Binary Geothermal Power Plant: A two-fluid system that transfers heat from the geothermal fluid through a heat exchanger to an organic fluid that vaporizes to drive anorganic Rankine cycle turbine to produce electricity.

Direct Use: The use of geothermal (heat) energy for domestic and commercial applications that do not need conversion to electricity.

Fractured Reservoir: A reservoir of hot fluid with a circulating fluid system driven by geothermal energy occurring in fault and fissure zones that are porous and permeable.

Geothermal Anomaly: A significant deviation from the global average values in the temperature gradient or heat flow.

Geothermal Heat Pump: A heat pump that transfers energy to or from the Earth.

Geothermal Power: The rate at which geothermal energy is delivered; expressed as watts, W; in large amounts as megawatts; in direct use, MW(t); and converted to electricity, MW(e).

Geothermometers: Chemical analysis techniques based on chemical species in geothermal fluids that allow calculation of equilibrium temperatures as a function of their solubility; they indicate the base temperatures of a reservoir.

Geophysical Survey: A survey of such properties as resistivity, gravity, magnetism, and self-potential that probes the subsurface for differences in the rock properties and the presence of hot fluid.

Heat Flow: Geothermal heat flux at the Earth's surface, resulting from heat flowing from the interior.

Hydrothermal Convection System: A geothermal zone where heat is transferred to the near-surface by convective circulation of water or steam, not by the more common conductive mechanism.

Liquid-Dominated Reservoir: A hydrothermal reservoir where the subsurface conditions have caused the fluid to be present as a two-phase mixture of steam and liquid.

Magma: Mass of molten rock within the Earth's crust.

Magma Chamber: A body of magma (molten rock) in the Earth's crust.

Noncondensable Gas: A gas contained in a geothermal fluid that escapes when the fluid is flashed at the Earth's surface; examples are carbon monoxide, carbon dioxide, hydrogen sulfide, hydrogen, and helium.

Pluton: A body of rock that has solidified from magma below the Earth's surface.

Reservoir: A natural underground zone containing a significant accumulation of thermal energy.

Thermal Anomaly: Departure of a local subsurface temperature from the average surrounding temperatures.

Vapor-Dominated Reservoir: A hydrothermal reservoir where subsurface conditions have caused the fluids to be present as steam.

INTRODUCTION

The properties of elemental germanium have been more thoroughly studied than those of any other member of the periodic table, with the possible exception of silicon. In order to review this extensive body of knowledge, various topics have been selected to illustrate the contribution of the study of germanium to semiconductor theory and technology.

The rise and fall of germanium as the commercially most important semiconductor are reviewed, followed by a description of its chemical and physical properties. Figures that summarize experimental and theoretical data have been selected, and they cover electronic and optical properties, technology, and applications. Germanium purification and crystal growth are described, and the more important current uses are listed.

Germanium was first isolated by C. Winkler in 1886 (Winkler, 1886) from the mineral argyrodite but had no commercial use until the second World War (WW II). Efforts to find a suitable material for radar detectors led to an intensive study of the semiconducting properties of germanium and silicon. These studies verified the importance of trace impurities in controlling electrical properties but did not emphasize the importance of crystalline perfection. Because of the different chemical natures of the semiconductors, silicon devices evolved into "cat's whisker" detectors and germanium in "high-voltage" rectifiers, both being made with polycrystalline material (Torrey and Whitmar, 1948).

Immediately after WW II Bell Telephone Laboratories established a solid-state division to begin a coordinated research effort by physicists, chemists, and engineers with the goal of producing a solid-state amplifier. This work led by 1948 to the invention of the point-contact transistor (Bardeen and Brattain, 1948), the field-effect transistor (Shockley and Pearson, 1948), and the junction transistor (Shockley, 1949). These devices were made from germanium single crystals.

Germanium devices remained dominant during the first decade after the invention of the transistor, mainly because of the ease of purification and crystal growth and low-temperature processing when compared to silicon (Biondi, 1958). However, once high-temperature synthesis and processing of sili-

con were developed, germanium devices were rapidly replaced by silicon in almost all applications. This immediate dominance of silicon was due mainly to the outstanding surface-passivating and impurity-masking properties of thermally grown SiO_2 films on silicon and to the larger band gap allowing higher-temperature device operation. The thermal oxide GeO_2 on germanium is water soluble and unstable in air.

The crust of the earth contains about 8×10^{-4} wt % germanium, which is 100 times more abundant than silver, but as there are no rich ores, the supply is very price sensitive. A typical price for the past 30 years has been about US $600 per kg of pure polycrystalline Ge (1992 dollars).

1. PHYSICAL AND CHEMICAL PROPERTIES

Elemental germanium is brittle and harder than glass, a consequence of its purely covalent tetrahedral bonding. The metallic luster is due to the high refractive index and the large free-carrier concentration generated by visible light. The electrical conductivity of pure germanium increases with temperature as a result of the increase in the concentration of thermally generated electrons and holes. Germanium crystallizes from the melt ($T_{melt}=936$ °C) in the diamond lattice structure with a lattice constant of 5.65 Å. The diamond lattice is a very open structure, resulting in the expansion of germanium by 4.9% upon freezing.

Chemically, germanium reacts as would be predicted by its location in the periodic table: a column IV element located between silicon and tin. The absence of clearly distinguishing chemical properties, together with its high cost, accounts for the lack of interest by chemists in studying germanium before its unusual electrical properties were discovered.

Germanium is stable in air up to about 500 °C. It is not attacked by HCl, HF, H_2SO_4, or strong alkalis. Germanium is dissolved slowly by HNO_3, H_2O_2, and sodium hypochlorite (laundry bleach); dissolves rapidly in mixtures containing HF and a strong oxidizer, e.g., HF-HNO_3, HF-H_2O_2; and, when hot, reacts exothermally with Cl_2 to produce $GeCl_4$. Elemental germanium can be melted with negligible reaction in graphite or fused-silica containers in a controlled atmosphere (e.g., N_2, H_2, Ar, He, vacuum). The purity of Ge can be found by measuring its resistivity either at room temperature or at liquid nitrogen temperature (77 K). This simplicity of analysis led to rapid advances in purification (Tannenbaum, 1959). The use of highly purified containers of graphite or silica, together with a controlled atmosphere of H_2 that has been passed through a palladium purifier, has led to germanium crystals of a purity unattained by any other elemental substance. Large, highly perfect germanium single crystals can be grown with a total electrically active impurity concentration of less than 10^{10} cm^{-3}, or, in chemists' terminology, less than 10^{-7} ppm.

A summary of the major properties of germanium is given in Table 1. Extensive data tabulations have been published that attempt a complete survey of the germanium literature (Madelung, 1982; Madelung and Schulz, 1987, 1989).

2. ELECTRONIC PROPERTIES

2.1 Band Structure

The band structure of germanium is shown in Fig. 1. The maximum of the valence band is located at the center of the Brillouin zone, while the four conduction-band minima are located at the L points along the four [111] directions. Semiconductors with the maximum of the valence band located at a different value of k than the minimum (minima) of the conduction band are called indirect band-gap semiconductors. They are characterized by long minority-carrier lifetimes and very inefficient photon emission upon band-to-band electron-hole recombination.

The valence-band edge is derived from the $p_{3/2}$ and $p_{1/2}$ states of the free atom with the $p_{3/2}$ states at the higher energy. The top of the valence band consists of a light- and a heavy-hole band that are degenerate at $k=0$ (the center of the Brillouin zone, called the Γ point), and a third band that is split off by 0.29 eV. The direct and indirect gaps decrease as the temperature is increased, as shown in Fig. 2.

Table 1. Properties of germanium.

Property	Value

heavy	0.28
Refractive index, 2.5–150 μm	4.0
Dielectric constant	16.0

2.2 Impurity and Defect Levels

A large number of impurities, defects, and their combinations (also called complexes) are known to produce energy levels in the forbidden gap of germanium (Fig. 3). These gap states are conveniently characterized as being donor or acceptor type, shallow (near the corresponding band edges) or deep (far from band edges). As in other semiconductors, there exist single, double, and multivalent centers (e.g., double acceptor Be). The energies of the ground states and the excited states of shallow donors [Fig. 4(a)] and shallow acceptors [Fig. 4(b)] can be calculated accurately by advanced effective-mass theory (Faulkner, 1969; Baldereschi and Lipari, 1973, 1974).

The shallow levels that are created by the column III and V impurities and lithium have been studied with a wide variety of techniques. In the temperature range where the thermal energy is sufficient to ionize shallow impurities but is too small to create electrons and holes across the band gap, the free-carrier

concentration corresponds to the difference of majority and minority dopant concentrations, the so-called net dopant concentration. The difference is the consequence of the compensation of donors by acceptors and vice versa. Compensation results from the minimum-energy principle: an electron of a donor impurity occupies an acceptor level that lies much lower in energy rather than being raised into the conduction band. Variable-temperature Hall-effect measurements (Yee *et al.*, 1974) give accurate free-carrier concentration values (Fig. 5). The free-carrier concentration is an accurate measure of the net dopant concentration in the temperature range defined above (also called exhaustion or saturation range).

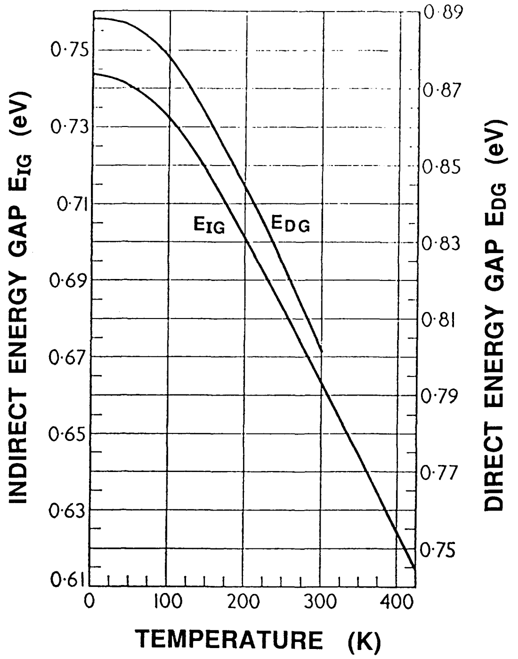

FIG. 2. Indirect (E_{IG}) and (E_{DG}) energy gaps vs temperature (after McLean, 1960).

Low-temperature optical absorption spectroscopy of lightly doped crystals reveals the hydrogenic bound excited-state spectrum of shallow donors and acceptors (Ramdas and Rodriguez, 1981). The development of ultrapure crystals required a highly sensitive and high-resolution characterization technique. Photothermal-ionization spectroscopy (PTIS), a two-step ionization process, can generate photoconductivity spectra with linewidths of the order of 10 μeV in crystal specimens containing less than 10^6 centers/cm^3. PTIS has led to the discovery of a large number of

shallow-level centers that contain hydrogen bound to a neutral or a multivalent impurity (Haller *et al.*, 1981; Haller, 1986).

The very deep impurities, e.g., the transition metals, have small optical cross sections and very low solubility and are more conveniently, but less accurately, studied by deep-level transient spectroscopy (DLTS) (Pearton, 1982) (Fig. 6).

2.3 Electronic Transport

2.3.1 Intrinsic Conduction. The electrical conductivity is proportional to the product of the number of charge carriers and their mobility. In an intrinsic semiconductor one observes bipolar conduction by electrons and holes. The conductivity is given by

$$\sigma = ne\mu_e + pe\mu_p, \qquad (1)$$

where n and p are the electron and hole concentrations and μ_e and μ_p are their respective mobilities. The concentration of charge carriers obeys a mass action law so that at a given temperature $np = n_i^2 = \text{constant}$:

$$np = 4(2\pi kT/h^2)^3(m_e m_h)^{3/2}e^{-E_g/kT}, \qquad (2)$$

where m_e and m_h are the electron and hole effective masses and n_i is the intrinsic carrier concentration. This relation holds over a wide temperature range, as is shown experimentally for germanium in Fig. 7. The strong temperature dependence of n_i dominates σ, and the weaker power dependences of the mobilities do not play a significant role.

2.3.2 Extrinsic Conduction. When germanium is doped with shallow donors or acceptors (column III or V elements), n or p becomes much larger than n_i over a wide temperature range, and the conductivity will be dominated by the temperature dependence of the mobility. Three major mobility regimes

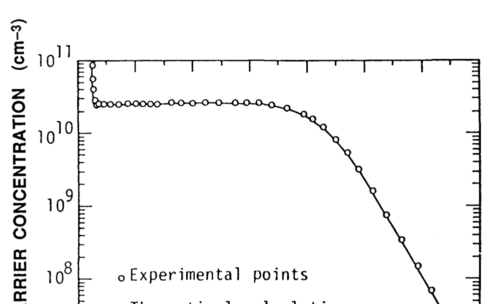

FIG. 5. Free hole concentration in an ultrapure Ge sample as measured by Hall effect (after Yee *et al.*, 1974).

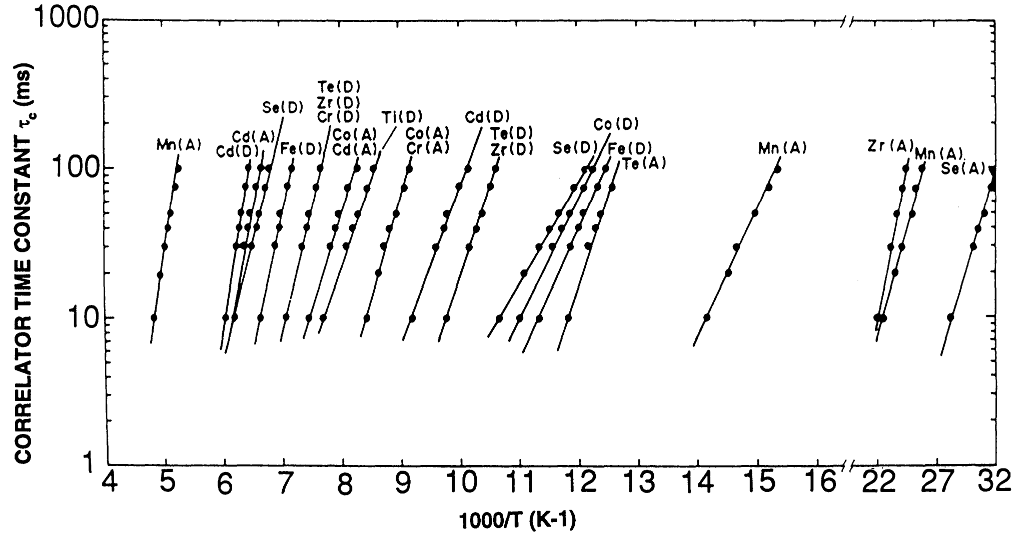

FIG. 6. Detrapping time constants of deep-level impurities thermally diffused into germanium, measured by deep-level transient spectroscopy (after Pearton, 1982).

are observed. At high temperature, lattice phonon scattering dominates:

$$\mu_{\text{phonon}} \propto T^{-3/2}. \tag{3}$$

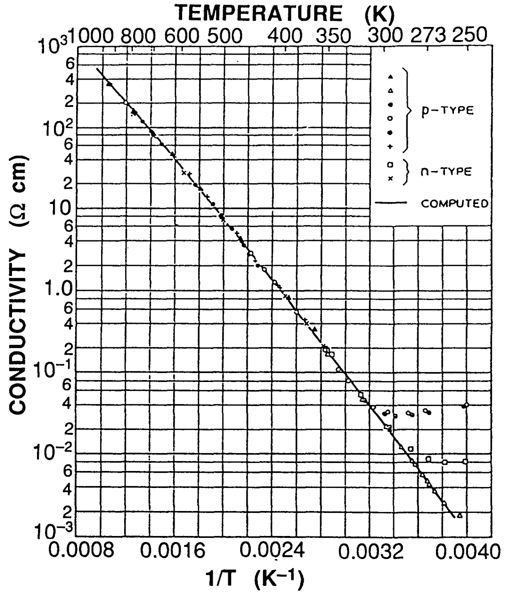

FIG. 7. The conductivity of intrinsic Ge vs temperature (after Morin and Maita, 1954).

At lower temperature, ionized-impurity scattering limits the mobility:

$$\mu_{\text{ionized imp.}} \propto T^{3/2}/Z^2N, \tag{4}$$

with Z=number of charges on the ionized impurity and N=concentration of ionized centers. In crystals with very low compensation (several orders of magnitude larger majority than minority dopant concentration) one observes a low-temperature regime in which neutral-impurity scattering dominates:

$$\mu_{\text{ionized imp.}} \propto 1/N, \tag{5}$$

with N=concentration of neutral centers. The total mobility is obtained by adding the inverse mobilities (Matthiessen's rule):

$$\mu_{\text{total}} = \left(\frac{1}{\mu_{\text{phonon}}} + \frac{1}{\mu_{\text{ionized imp.}}} + \frac{1}{\mu_{\text{neutral imp.}}} \right)^{-1}. \tag{6}$$

Figure 8 shows the hole mobilities in two low-compensation, Ga-doped Ge crystals over a wide temperature range. The onset of ionized-impurity scattering is clearly seen as an inflection at 60 K. The reason why the mobility continues to rise at lower temperatures lies in the fact that the Ga acceptors freeze out, i.e.,

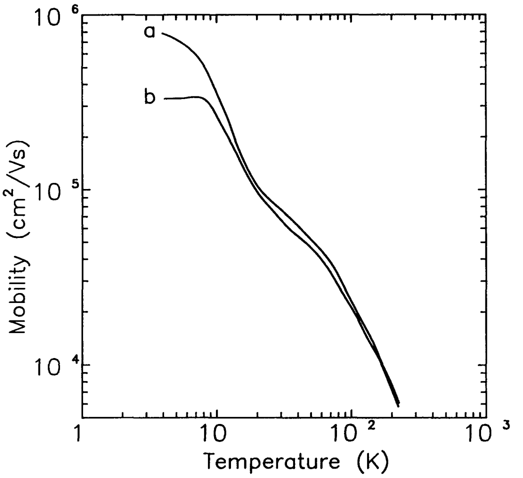

FIG. 8. Hall mobility in two moderately doped Ge:Ga crystals.

they become neutral when they bind a hole at temperatures <20 K. Below ~7 K the mobility becomes constant and is dominated by neutral impurity scattering. In moderately doped crystals that are highly compensated, a large fraction of the acceptors and donors remain ionized, and the mobility does not rise because of freezeout. In such material one observes the lattice-scattering regime at high temperatures and the ionized-impurity scattering regime at low temperatures.

At large impurity concentrations ($>10^{15}$ cm^{-3}) the conductivity is dominated by carrier hopping at low temperatures and at high doping ($>2\times10^{17}$ cm^{-3}), an impurity band forms, and the germanium exhibits metallic conduction (i.e., conduction persists down to $T=0$ K). These various conduction regimes are illustrated by experimental data in Fig. 9 for 16 compensated Ge samples with varying acceptor concentrations. In the most lightly doped sample (No. 1, $N_A=1.7\times10^{14}$ cm^{-3}) hopping conduction is observed below 5 K, and it is rather weak ($\rho\simeq10^9$ Ω cm). In the extreme of high doping concentration (Nos. 15, 16) the resistivity stays practically constant at $\sim1.3\times10^{-2}$ Ω cm over the full temperature range. These samples conduct like a metal. The effect of impurity concentration on minority electron mobility in *p*-type Ge at 300 K is shown in Fig. 10.

The discussion of electrical transport has so far been limited to low electric fields that do not heat up the free carriers to energies larger than kT. At high electric fields the carriers become hot and give up their kinetic energy by generating optical phonons. The carrier drift velocity is observed to saturate at

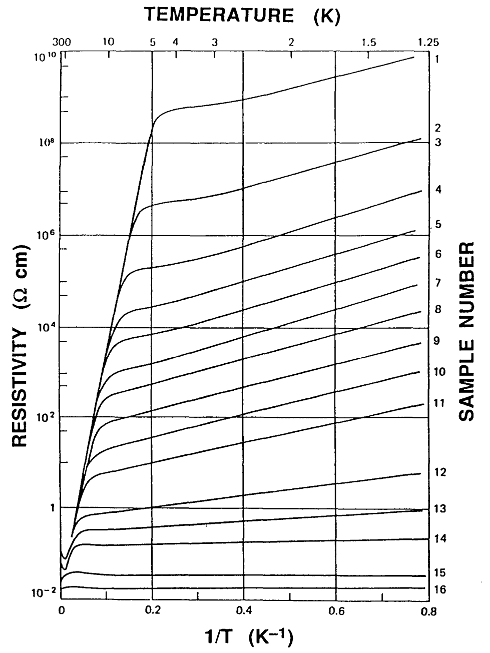

FIG. 9. Resistivity of *p*-type germanium with compensation K ($=N_D/N_A$)$=0.4$ (after Fritzsche and Cuevas, 1960). The concentrations (in cm^{-3}) of acceptors for the various curves are as follows: 1, 7.5×10^{14}; 2, 1.4×10^{15}; 3, 1.5×10^{15}; 4, 2.7×10^{15}; 5, 3.6×10^{15}; 6, 4.9×10^{15}; 7, 7.2×10^{15}; 8, 9.0×10^{15}; 9, 1.4×10^{16}; 10, 2.4×10^{16}; 11, 3.5×10^{16}; 12, 7.3×10^{16}; 13, 1.0×10^{17}; 14, 1.5×10^{17}; 15, 8.8×10^{17}; 16, 1.35×10^{18}.

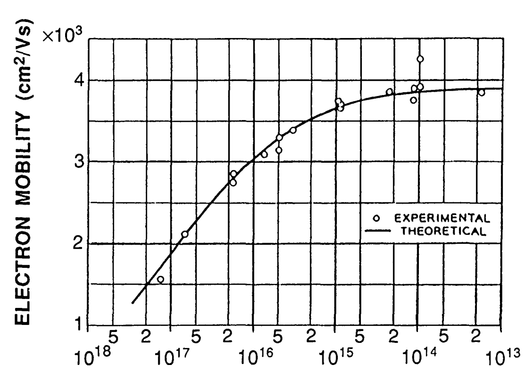

FIG. 10. Drift mobility of minority electrons in *p*-type Ge at 300 K as a function of acceptor concentration. The solid line is calculated (after Prince, 1953).

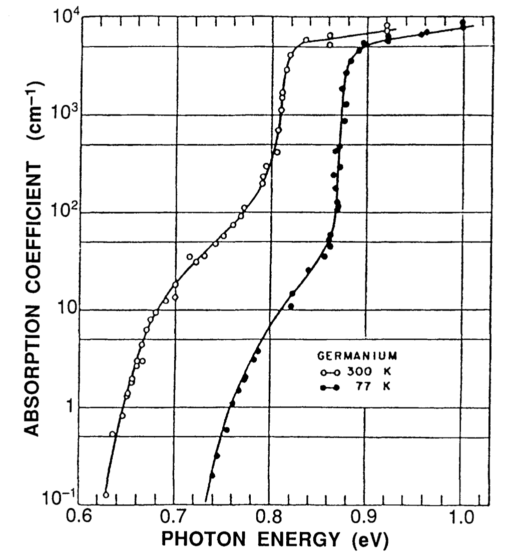

FIG. 11. Linear absorption coefficient of Ge near the fundamental absorption edge vs photon energy at 77 and 300 K.

values close to 10^7 cm s^{-1} for electric fields larger than 10^4 V cm^{-1}.

Transport phenomena become very complicated when electric and magnetic fields are present. It has been demonstrated that under appropriate conditions a population inversion of free holes between the light- and the heavy-hole bands can be achieved with crossed electric and magnetic fields at low temperatures. Such Ge crystals can be induced to lase in the far-infrared range of the electromagnetic spectrum (Gornik, 1991).

3. OPTICAL PROPERTIES

3.1 Linear Absorption Coefficient and Refractive Index

All semiconductors exhibit a very rich variety of optical properties, and Ge is no exception. Pure crystals cooled to low temperatures contain such small concentrations of free carriers that their effects can be ignored. The most striking feature for these conditions is the fundamental absorption edge, the most important feature in a plot of the linear absorption coefficient as a function of photon energy. The absorption edge occurs at an energy corresponding to the minimum band gap (Fig. 11). Because Ge has an indirect band structure, optical transitions of electrons from the top of the valence band at the Γ point of the first Brillouin zone to one of the four conduction-band minima at the *L* points require assistance of a phonon. This three-particle process is clearly less probable than a direct band-gap transition. At photon energies > 0.8 eV, direct transitions can occur, and the linear absorption coefficient rapidly rises to large values.

The linear absorption coefficient is defined by the equation

$$I = I_0 \exp(-\alpha x); \qquad (7)$$

I_0 and I are the photon beam intensities before and after passage of the beam through a semiconductor slab of thickness x. The linear absorption coefficient is typically given in units of cm^{-1}. This simple equation does not take into account external or internal reflections caused by a refractive index different from unity.

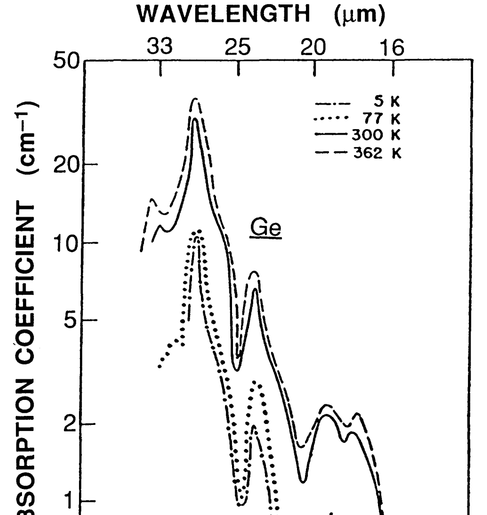

FIG. 12. Optical absorption coefficient α in the far infrared as a function of photon wave number (after Collins and Fan, 1954).

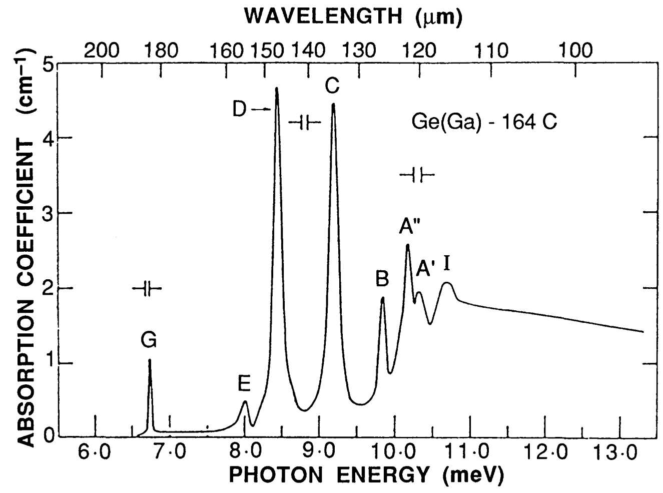

FIG. 13. The absorption spectrum of Ge doped with 2×10^{14} cm^{-3} Ga (after Jones and Fisher, 1965).

Below the fundamental absorption edge pure Ge is transparent and is used for a large number of infrared optical components. As a covalently bonded material, Ge is not infrared active, though at low photon energies lattice (multiphonon) absorption gives rise to a broad absorption feature reaching from approximately 25 to 90 meV (wave number $\tilde{\nu}=200$ to 700 cm^{-1}, $\lambda=50$ to 14 μm), with α reaching a peak value of 10 cm^{-1} at $h\nu=44$ meV ($\tilde{\nu}=350$ cm^{-1}, $\lambda=28.6$ μm) at 77 K (Fig. 12).

At even lower photon energies one encounters effects of shallow dopants. The absorption spectrum of a Ge crystal moderately doped with Ga acceptors is shown in Fig. 13. The narrow peaks correspond to hole transitions from acceptor ground states to hydrogenic bound excited states.

Table 2. Refractive index and extinction coefficient k as functions of photon energy E (after Potter, 1985).

E (eV)	n	k
525.3	0.99741	9.8×10^{-4}
100	—	2.57×10^{-2}
50	—	4.52×10^{-2}

2	5.588	0.933
1	4.325	8.09×10^{-2}
0.8	4.275	5.67×10^{-3}
0.66	—	6.73×10^{-5}
0.60	—	6.58×10^{-7}
0.59	4.104	—
0.20	4.011	—
0.099	4.003	—
0.062	3.999	3.98×10^{-4}
0.031	3.983	8.5×10^{-4}
0.0099	4.007	—
0.0025	4.004	4.77×10^{-3}

For optical applications of Ge, it is most useful to discuss the refractive index n and the extinction coefficient k. They are related to the real (ϵ') and the imaginary (ϵ'') parts of the dielectric constant:

$$\epsilon=\epsilon'+i\epsilon'', \tag{8}$$

$$\epsilon'(\nu)=n^2(\nu)-k^2(\nu), \tag{9}$$

$$\epsilon''(\nu)=2n(\nu)k(\nu). \tag{10}$$

The linear absorption coefficient and the wavelength λ are related to k:

$$k=\alpha\lambda/4\pi. \tag{11}$$

An extensive tabulation of n and k over a very wide photon energy range can be found in the literature (Potter, 1985). A reduced set of values is reproduced in Table 2.

3.2 Photoconductivity

In a semiconductor one distinguishes between two classes of optical absorption processes, both leading to an increase in the free-carrier concentration. Intrinsic photoconductivity is due to the excitation of an electron across the band gap, while extrinsic photoconductivity is due to the ionization of a neutral donor or acceptor in a cold crystal.

Diode structures are typically used for intrinsic photocarrier generation and collec-

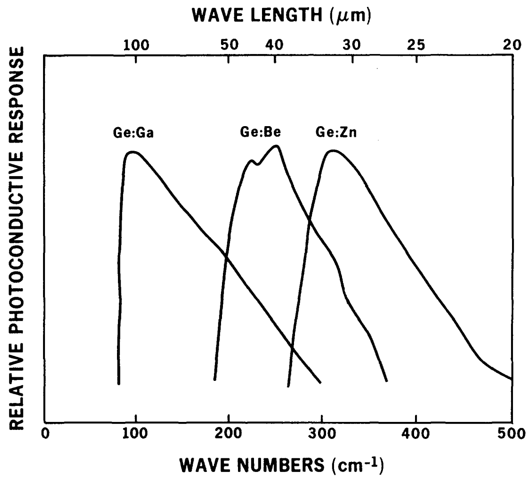

FIG. 14. Responsivity of extrinsic Ge photoconductors doped with various impurities (Haller, 1985).

tion. Ge photodiodes are widely used for infrared photoluminescence studies. They are sensitive to photons with energies larger than the indirect band gap ($E_{\mathrm{IG}}=744$ meV). Ge photodiodes are cooled, typically to liquid-nitrogen temperature (77 K), in cases where the large dark current caused by room-temperature thermal generation interferes with photodetection.

Photons with very large energies such as x rays and γ rays produce large numbers of photocarriers per photon. Through the photoeffect the energy of the incoming photons is transferred to a Ge core electron. One electron-hole pair is generated per 3 eV of the energy of the x-ray or γ quantum (Haller and Goulding, 1981).

Extrinsic photoconductivity in doped Ge has been applied to far-infrared detection. Moderately doped Ge crystals ($[\mathrm{Ga}]\sim 10^{14}$ cm^{-3}) with two Ohmic contacts are operated in the photoconductor mode. Such devices have to be cooled to liquid helium temperature in order to suppress thermal ionization of the shallow dopants. Typical dopants are Ga, Be, and Cu. Extrinsic photoconductors doped with these impurities can detect photons in an energy range from 10 meV ($\tilde{\nu}=80$ cm^{-1}, $\lambda=125$ μm) to several hundred meV ($\tilde{\nu}=1000$ cm^{-1}, $\lambda=10$ μm) (Haller, 1985; Haegel and Haller, 1986). Application of uniaxial stress along the [100] axis reduces the hole binding energy to half its unstressed value and shifts the detection limit to 5 meV (40 cm^{-1}, 250 μm) (Hall, 1962). Extrinsic Ge photoconductors are the most sensitive photon detectors beyond $\lambda=40$ μm. Figure 14 shows the individually normalized response curves of several extrinsic Ge photoconductors.

A two-step ionization process consisting of excitation of an impurity-bound carrier from the ground state to a bound excited state followed by thermal ionization from the excited state to the nearest band was discovered by Lifshits and Nad (1965). The resulting free carriers can be detected with very high sensitivity. This method has been extensively applied to the study of ultrapure Ge (Haller, 1978, 1986; Haller *et al.*, 1981). It combines high energy resolution with superb sensitivity. In ultrapure Ge, linewidths as small as 10 μeV have been obtained from hydrogenic spectra of shallow-donor complexes *D*(H,O) and *D*(Li,O) (Haller and Falicov, 1978; Haller *et al.*, 1987; Navarro *et al.*, 1988). Figure 15 displays the photothermal ionization spectroscopy results obtained with an ultrapure Ge crystal containing the shallow-acceptor complex *A*(H,C) (Kahn *et al.*, 1987). The four strongest lines are the *D* and *C* lines of the acceptors Al and $A(\mathrm{D,C})_2$. Each acceptor has a series of lines. The line spacings between

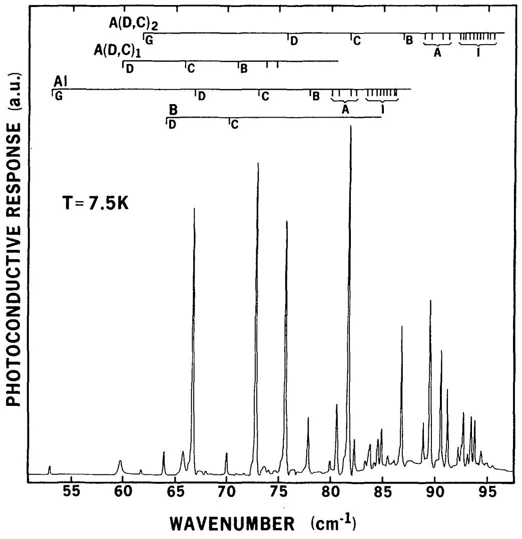

FIG. 15. Photothermal-ionization line spectrum of the shallow deuterium-carbon acceptor complex *A*(D,C), of Al, and of traces of B. The fact that two line series $A(\mathrm{D,C})_1$ and $A(\mathrm{D,C})_2$ belong to one acceptor is most unusual and is due to a splitting in the ground state of this acceptor complex. The sample contains approximately 10^9 acceptors (after Kahn *et al.*, 1987).

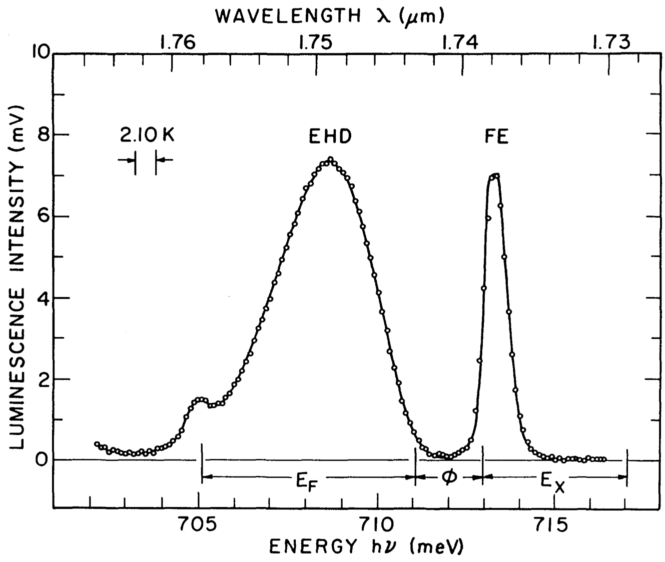

FIG. 16. Photoluminescence spectrum of optically pumped pure Ge at low temperature. The free-exciton (LA-assisted) and electron-hole-drop peaks are clearly visible (after Kelso, 1979).

specific pairs of lines are identical for all acceptors because the long-range Coulomb potential of the negatively charged acceptor core is the same for all shallow acceptors. The differences in the ground-state energies shift the individual line series to different energies. For ease of identification, the positions of the peaks in each acceptor series have been connected with a horizontal line that is labeled with the acceptor symbol.

3.3. Photoluminescence

Absorption of a photon followed by the emission of a photon is called photoluminescence (PL). The indirect-gap band structure of Ge makes PL a rare process because lattice phonons or impurities are required for momentum conservation. The PL photon originates from the decay of a free or bound exciton, an electron and a hole forming a hydrogenlike bound system. A large number of impurity-bound excitons have been studied in pure and doped Ge (Skolnick, 1989; Thewalt *et al.*, 1987).

A new state of matter, the electron-hole liquid, was predicted (Keldysh, 1968) and experimentally verified (Wolfe *et al.*, 1975; Hensel *et al.*, 1977; Jeffries and Keldysh, 1983) in pure Ge. This quantum liquid consists of condensed excitons. The electron-hole liquid is unstable because of electron-hole recombination, and it has to be regenerated continuously by a laser pumping electrons across the band gap. Figure 16 shows the PL spectrum of a pure Ge crystal at low temperature optically pumped by a laser. The free-exciton peak (FE) corresponds to the band-gap energy (744 meV) reduced by the exciton binding energy of 4 meV and the energy of the phonon (LA) assisting the transition (E_{LA}=27 meV). The electron-hole drop peak (EHD) appears at 709 meV, lower than the FE peak by the EHD binding energy.

Recently, isotopically separated Ge has become available (see Table 1). PL studies of such crystals allow the determination of the dependence of the band gap and the phonon energies on isotope mass (Fuchs *et al.*, 1991; Davis *et al.*, 1992). It can be expected that phonon transport and imaging as well as a number of special devices (see Sec. 6) will benefit from isotopically controlled crystals.

4. TECHNOLOGY

4.1 Production

Germanium concentrates are recovered as a by-product of zinc, copper, and lead refining. The concentrates are converted to oxides or germanates and treated with HCl to produce $GeCl_4$. The simple and selective chemistry involved in converting $GeCl_4$ (bp 83 °C) into high-purity germanium contributed to the early success of germanium electronics. To produce polycrystals with less than 1 ppm total impurities, the $GeCl_4$ is distilled in the

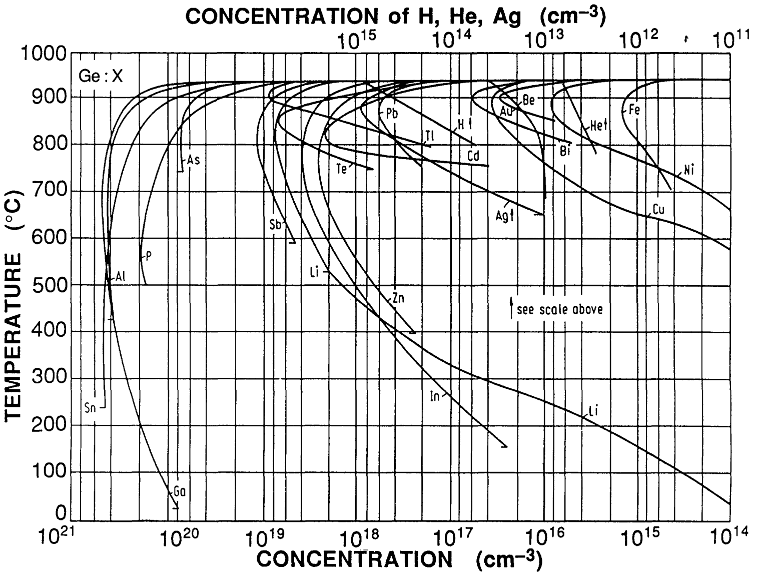

FIG. 17. Solid solubility of impurities in germanium illustrating retrograde solubility (after Trumbore, 1960).

presence of Cl_2, fractionally distilled in silica vessels, mixed with H_2O to form GeO_2, and finally reduced in H_2 and melted in graphite boats (Bridgers *et al.*, 1958). Any processing scrap, saw dust, etc. can be easily converted to $GeCl_4$ to reenter the process stream.

4.2 Crystal Growth

All electronic applications require germanium in single-crystal form and often demand ultrahigh purity. Germanium can be purified for certain impurities to better than 10^{-6} ppm by zone refining (Pfann, 1966) in silica or graphite boats, a process that was developed originally to produce high-purity germanium and now has general application in the fine chemicals industry. The zone-refined polycrystal is used as a starting charge for single-crystal growth.

Single-crystal germanium is produced by the Czochralski method (Czochralski, 1918; Teal and Little, 1950; see also CRYSTAL GROWTH), which has replaced the earlier zone-leveling process (Pfann, 1952). In the Czochralski method (CZ) an oriented seed crystal is dipped into a melt and withdrawn with temperature control to produce a cylindrical crystal of the desired diameter. This method produced the first high-quality germanium crystals (Bridgers *et al.*, 1958) and is used today for the growth of doped and ultrapure crystals. The CZ growth of dislocation-free silicon crystals has developed into the large-scale industrial production of over 10,000 tons of material per year.

4.3 Impurities and Defects

4.3.1 Solubility. The solubility is defined as the maximum concentration of an impurity in a solid phase at a given temperature that can be attained without introducing a phase

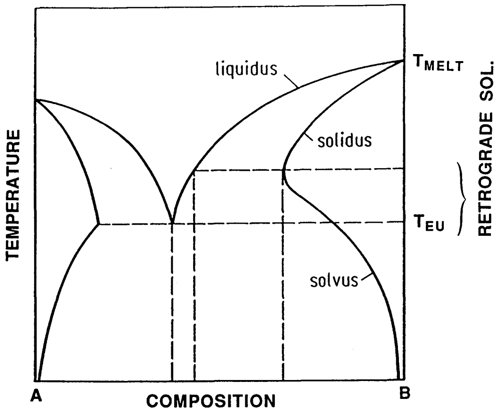

FIG. 18. Phase diagram illustrating the phenomenon of retrograde solubility (right-hand side). The left side of the figure illustrates the usual case with the maximum solubility at the eutectic temperature (after Weber, 1983).

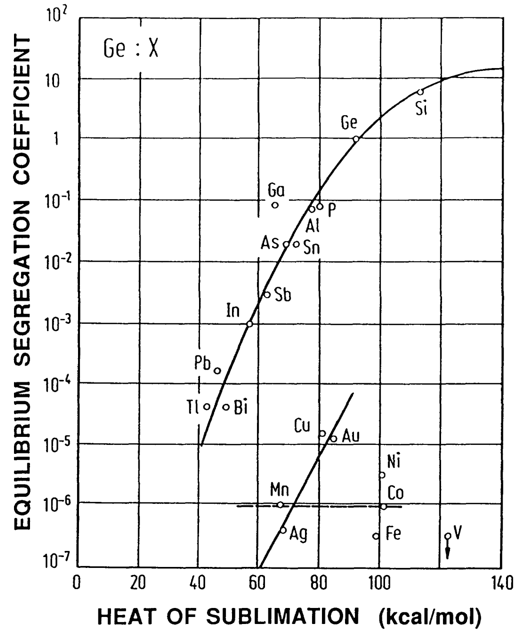

FIG. 19. Segregation coefficient of impurities vs heat of sublimation (after Trumbore, 1960).

change. Most impurities in germanium have such low solubilities that they are normally given as atoms/cm^3 instead of areas in phase diagrams (Fig. 17). As seen in the figure, most of the impurities display retrograde solubility in that the maximum solid solubility occurs below the melting temperature. This phenomenon is illustrated in Fig. 18. The left side of the figure shows the normal case where the maximum solubility occurs at the impurity(A)-germanium(B) eutectic (T_{Eu}), while the right side shows the retrograde case in which the maximum solubility is at a temperature higher than that of the eutectic.

4.3.2 Segregation Coefficient. When a solid is in contact with its liquid phase at the melting point, impurities typically will exhibit segregation effects between the two phases which at equilibrium is described by the segregation coefficient, k = (impurity concentration in solid)/(concentration in liquid). The segregation coefficient is related to several physical properties of the impurity and is shown in Fig. 19 as a function of the heat of sublimation and in Fig. 20 as a function of the maximum solubility $C^{\mathrm{eq}}_{\mathrm{max}}$. Zone purification relies on the phenomenon of impurity segregation in a narrow liquid zone that is heated by a radio-frequency heater coil. Multiple passage along a bar of germanium leads to a redistribution of the impurities along the bar. Impurities with $k < 1$ will stay preferably in the liquid and will be carried to one end of the bar, while impurities with $k > 1$ will accumulate with much less effect on the opposite side. Removal of the impure ends leads to a purified material (Pfann, 1966).

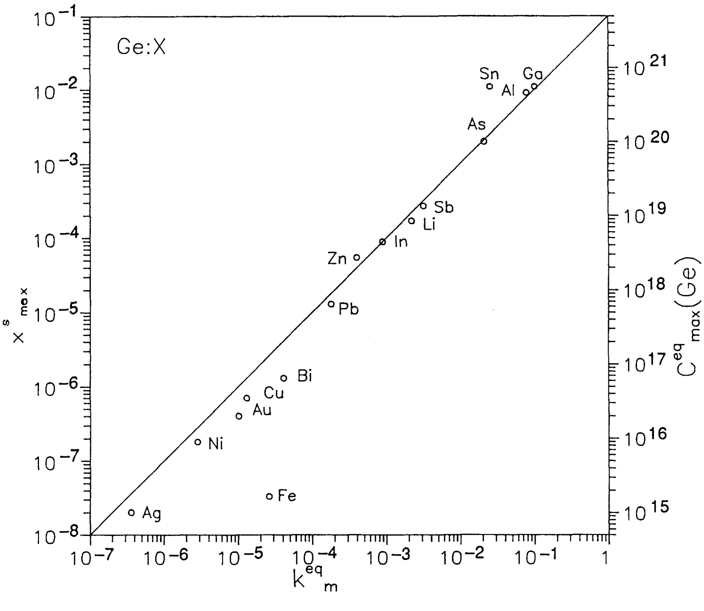

FIG. 20. Segregation coefficient $k^{\mathrm{eq}}_{\mathrm{m}}$ vs maximum solubility $C^{\mathrm{eq}}_{\mathrm{max}}$ for impurities in germanium (after Fishler, 1962).

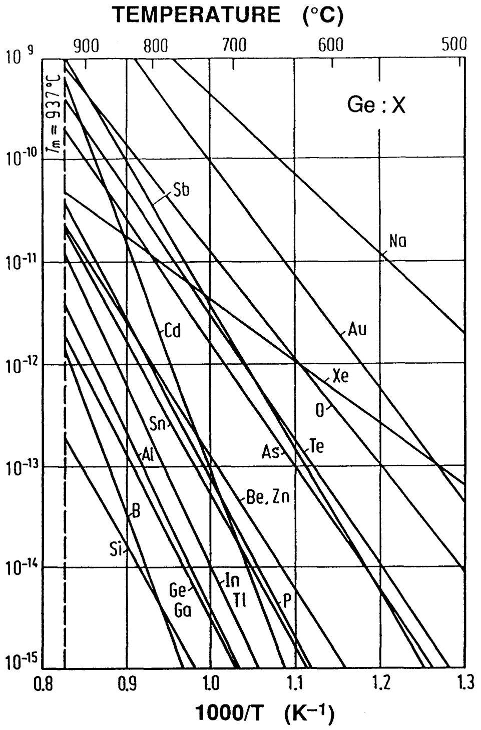

FIG. 21. Diffusion coefficient of impurities that diffuse by the vacancy mechanism. These are all slowly or moderately migrating elements (after Stolwijk, 1989).

4.3.3 Impurity Diffusion. The majority of impurities diffuse in germanium by the vacancy mechanism. This mechanism involves diffusion by impurity exchange with vacant lattice sites (vacancies). Since the concentration of vacancies is very small, the diffusion coefficients for impurities moving via vacancy assistance are small (Fig. 21) (Stolwijk, 1989). In the very open lattice structure of Ge a number of impurities can occupy interstitial spaces between the host atoms. Li, an interstitial donor, is the prototypical fast interstitial diffusor. Because Li does not form any bonds with the Ge lattice atoms, little energy (~0.4 eV) is required to jump from one tetrahedral interstitial space to the next. An Arrhenius plot of the diffusion coefficients of several interstitial impurities is given in Fig. 22.

Impurities that have both finite interstitial and substitutional solubilities usually display rapid interstitial diffusion behavior, while their electronic properties may be dominated by the substitutional component. Cu is the classical case for this dissociative diffusion mechanism (Stolwijk *et al.*, 1985). In its substitutional position it acts as a triple acceptor, as one would expect from its valence of one. In the interstitial form Cu has been characterized as a donor, though no energy level has ever been reported.

Impurities in germanium can be divided into groups that have similar properties and are studied by similar techniques. The column III and V impurities are most nearly germanium-like and thus are the slowest diffusers and have the highest solubility. The dopant atom being most like the host, the extra or missing valence electron (hole) is most weakly bound, and has a very large Bohr radius (~100 Å) and a consequent large optical cross section for ionization. These elements always diffuse by the simple vacancy method and are most accurately studied by photothermal-ionization spectroscopy.

The multivalent donor and acceptor impurities are less Ge-like, diffuse faster, and have lower solubilities than groups III-V. The multiple-charge states of these impurities have

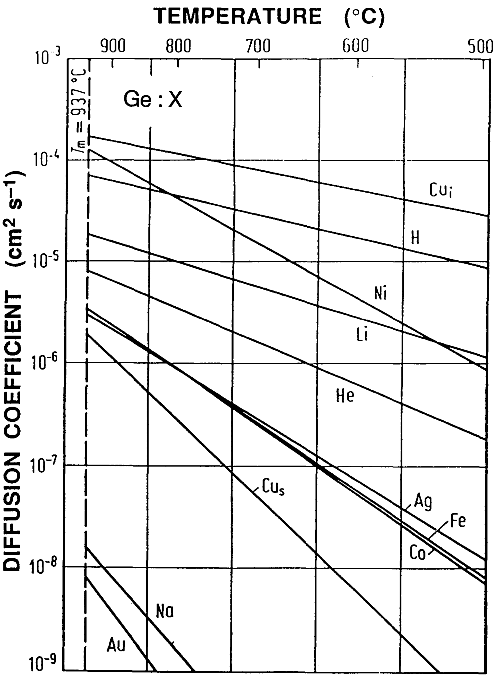

FIG. 22. Diffusion coefficient of impurities that diffuse by the interstitial mechanism. These are all fast migrating elements (after Stolwijk, 1989).

been studied by photoabsorption and photoconductivity. Diffusion is by the vacancy mechanism.

The transition metals exhibit still lower solubilities and faster diffusion. Their valence electrons are more localized, resulting in very small optical ionization cross sections. These impurities are usually studied by Hall effect or deep-level transient spectroscopy. Diffusion occurs via the vacancy mechanism.

A few impurities, e.g., H, Li, Ag, Ni, are fast-diffusing interstitial impurities that do not follow the above trends of solubility and ionization energy.

4.3.4 Defects. There exists a rich literature on point and line defects in Ge. Point defects have been generated by various kinds of energetic radiation. γ rays and electrons of ~ 1 MeV are ideally suited to form single point defects. Mashovets (1977) has reviewed the understanding of these vacancylike defects. The outstanding features of these defects are their strong localization and the resulting depth of the energy levels in the band gap. Several low-temperature annealing stages have been observed. Higher-energy radiation produces extended defects that are not understood in detail. It is known, though, that these defects act as strong trapping and recombination centers and that they compensate shallow dopants turning the crystal highly resistive.

A rich spectrum of dislocations with various Burgers vectors has been studied. The structure of these dislocations closely resembles those found in Si single crystals.

5. APPLICATIONS

The role of germanium as the dominant semiconductor material for electronic devices such as transistors ended by 1960, and its use has been relegated to those applications where some of its unique properties are of importance. Today's bulk of germanium production is consumed by detectors and optics.

5.1 Photodetectors

The long-wavelength cutoff λ_c (in μm) of a semiconductor photodetector is given by

$$\lambda_c = hc/E = (1.24\ \text{eV}\,\mu\text{m})/E, \qquad (12)$$

where E (in eV) is the energy needed to produce a free charge carrier. For a band-to-band transition in room-temperature germanium (intrinsic detector), $E=0.66$ eV, yielding $\lambda_c = 1.8\ \mu$m, which includes the technically important 1.3- and 1.5-μm low-loss windows in optical fiber communications. Intrinsic germanium photovoltaic detectors are normally reverse-biased *p-n* junctions minimizing both response time (10^{-11} s) and dark current (Sze, 1981).

Detectors can also be made using the ionization of impurities to produce charge carriers (extrinsic photodetectors). Group III and V impurities in germanium have ionization energies E_i of about 0.01 eV so that $\lambda_e = 120$ μm. Deeper-level impurities such as Be, Zn, Hg, Cu, and Au can be added to maximize the sensitivity at shorter wavelengths. Also, E_i may be reduced by uniaxial stress along [100] to extend the long-wavelength cutoff to 250 μm.

Extrinsic photodetectors must be operated at cryogenic temperatures so that the net dopants are neutral, i.e., they bind a carrier. These detectors are used as low–bias-voltage photoconductors to prevent electric field ionization of the impurities (avalanche breakdown), and, as a result of this low electric field, are much slower than intrinsic *p-n* diode detectors. For photoconductors, gain is the ratio of carrier lifetime to carrier transit time so that gain may be traded for speed. In the 30–250-μm wavelength range germanium photoconductors have the highest detectivity of any device (Haller *et al.*, 1979; Haller, 1985).

5.2 Nuclear-Radiation Detectors

The development of hyperpure germanium (Hall and Soltys, 1971; Hansen, 1971) was driven by a demand for a material to make nuclear-radiation detectors (Haller and Goulding, 1981). These detectors are giant-volume *p-i-n* diodes (up to 400 cm^3) where the *i* region forms the bulk of the device and thin ion-implanted *p* and *n* layers form blocking contacts. The *i* layer is lightly doped ($|N_A - N_D| \leqslant 2 \times 10^{10}$ cm^{-3}) and can be totally depleted at operating bias voltages of a few thousand volts. The relation between the net impurity concentration $|N_A - N_D|$, the bias voltage V, and the thickness of the region depleted of free carriers W is given by

$$W^2 = 2\epsilon\epsilon_0 V/e(N_A - N_D),$$

where ϵ is the dielectric constant, ϵ_0 is the permittivity of vacuum, and e is the charge of the electron. For example, for a depletion layer thickness of 1 cm at 1000 V bias, $|N_A - N_D|$ must be less than 2×10^{10} cm^{-3}.

These detectors are used as single-particle or photon energy spectrometers. On average, 3 eV of incident energy are required to produce one electron-hole pair. The ultimate energy resolution is dominated by the statistical nature of the charge-production processes. Because these processes are not independent, they do not follow normal statistics. The fluctuation in the number of electron-hole pairs ΔN is given by

$$\Delta N = (FN)^{1/2},$$

with $F=0.08$ (Fano factor). The full width of a 1-MeV γ-ray peak at half maximum (FWHM) can be as small as 1.2 keV, a factor of 30 smaller than a line produced by a scintillation detector. That the fluctuation in the number of electron-hole pairs is smaller than the standard statistical fluctuation is related to the fact that the ionization events are not completely random and unrelated.

5.3 Low-Temperature Ge Thermistors

Strong interest in reliable and reproducible temperature sensors by the astrophysical, radio astronomy, and "dark-matter" search communities in the subkelvin range has led to a strong development effort of neutron-transmutation doped (NTD) Ge material and devices. NTD offers the most homogeneous and controlled doping technique (Larrabee, 1984). NTD Ge is unique among semiconductors because it contains both acceptors (Ga) and donors (As) in a fixed ratio determined by the natural abundance of ^{70}Ge and ^{74}Ge and their thermal-neutron capture cross sections (Haller *et al.*, 1984). NTD Ge can be produced with resistivities ranging from 1 Ω cm to 10^9 Ω cm in a temperature range from 1 K to 15 mK. The NTD Ge thermistors are heat sensitive and do not exhibit any specific wavelength cutoff limits. The typical device has submillimeter dimensions to decrease thermal mass and is equipped with two boron-ion–implanted, degenerately doped *p* contacts (Haller, 1985).

Nonlinear conduction phenomena at very low temperature have led to interesting transport studies (Kenny *et al.*, 1989, Wang *et al.*, 1990).

5.4 Optics

The consumption of germanium for infrared optics now exceeds all other uses combined. The attraction of germanium for this application arises from its environmental inertness, good mechanical properties, moderate cost, very low dispersion, and transparency from 2 to 15 μm. Germanium's only drawback has been its high refractive index (4.0) and the difficulty of making tough antireflection coatings. This antireflection problem has now been solved by an ideal coating, diamondlike carbon, that is supertough and has a refractive index of 2.0.

Germanium exhibits significant absorption of infrared radiation in the 15- to 40-μm range due to intrinsic-crystal lattice-phonon resonances (Fig. 12). Unless specially purified, germanium will also show an absorption line at 11.7 μm because of the local vibrational mode of oxygen impurities.

5.5 Miscellaneous Uses

Graded-index optical fibers are made using a high index of refraction germanium-doped silicon core. Germanium has an almost perfect lattice match to GaAs so that high-quality epitaxial layers can be grown; these Ge-GaAs bilayers have produced the highest-efficiency solar cells. Impatt diodes, tunnel diodes (Sze, 1981), and phonon-drag detectors are made from germanium. A population inversion between the heavy-hole and light-hole bands can be induced in *p*-type germanium in crossed electric and magnetic fields at low temperature to produce a tunable, long-wavelength laser (Gornik, 1991).

A research area of great current interest is the prospect of integrating quantum-well structures on silicon using germanium. Considerable progress has been made in producing Ge-Si strained-layer superlattices for photodetectors and transistors (Bean *et al.*, 1991).

GLOSSARY

Band Structure: Electrons in solids can only assume energies in certain ranges called allowed bands. Forbidden energy ranges are called band gaps. Depending on the degree to which the highest allowed energy band is filled with electrons, and depending on the width of the band gap, a solid is an electrical conductor, an insulator, or a semiconductor.

Bound Excited State: Electrons (holes) are bound to a donor (acceptor) by the Coulomb field of the positive (negative) charge at the donor (acceptor) core. As in a hydrogen atom, there exists a ladder of discrete energy states in which the electron (hole) can exist. The lowest energy state is the ground state; all other states below the conduction-band edge (above the valence-band edge) are bound excited states. Because of the strong analogy between donors (acceptors) and the hydrogen atom, bound excited states are often called hydrogenic states or hydrogenic bound excited states.

Brillouin Zone: The regular spacing of atoms in a crystal lattice can be represented by points in an inverse or reciprocal space, also called momentum space. The Brillouin zone occupies part of this space. Every point on the Brillouin zone surface is the end point of a vector signifying a diffraction condition of the real-space crystal lattice.

Conduction Band: The first allowed energy band above the band gap in semiconductors or insulators. Electrons in this band are free to move and to conduct electricity.

Diamond Lattice: A regular array of points in space. The corners and the centers of each face of two intersecting cubes describe the basic building block of the diamond lattice. The cubes are displaced along a body diagonal by one quarter of its length. Putting real atoms on all of these lattice points leads to a crystal. These atoms form covalent bonds with each of the four nearest neighbors. Carbon, silicon, and germanium crystallize in the diamond structure.

Effective Mass: The ratio of the acceleration of an electron or hole in a crystal to the force producing the acceleration. Because of the wave nature of electrons (holes), motion in a crystal with regular atom spacings is altered and the effective mass differs from the free-electron mass. It may be different for electrons and holes, and may depend on the direction of motion. The curvatures of the conduction-band minima (valence-band maxima), i.e., the second derivatives of these curves (see Fig. 1), are inversely proportional to the effective mass.

Fano Factor: The factor by which the statistical fluctuations in the production of electrons and ions in a gas or electrons and holes in a semiconductor deviate from normal statistics.

Holes: See Valence Band.

Hydrogenic States: Bound excited states.

Interstitial: An impurity or host atom located off a lattice site. Interstitials can be very mobile in the wide-open diamond lattice and play an important role in impurity and defect motion (see Vacancy).

Neutron-Transmutation Doping (NTD): Doping resulting from transmutation of atoms of the original material that have been made radioactive by absorption (capture) of incident neutrons. Most often used for silicon, NTD produces phosphorus donors in this semiconductor. In Ge both Ga acceptors and As donors are formed through NTD.

Photothermal Ionization Spectroscopy (PTIS): Excitation of an electron (hole) at low temperatures from the ground state to one of the bound excited states in a donor (acceptor) can be followed by further excitation through thermal energy (a phonon) into the conduction (valence) band. The resulting free carrier will change the electrical conductivity of the crystal. The intense conductivity peaks at photon energies corresponding precisely to transitions from ground state to bound excited states have become the most sensitive and precise tool in the study of impurities and defect in numerous semiconductor crystals.

Vacancy: A crystal lattice site without an atom occupying it. Vacancies play a very important role in the motion of impurities and defects through a crystal.

Valence Band: The highest energy band filled with electrons. Missing electrons in the band, holes, can conduct electricity in the valence band.

INTRODUCTION

Glaciology concerns natural ice in the environment including glaciers, sea ice, seasonal snow, and frozen ground. This article discusses only glaciers. A glacier is a perennial ice body resting at least partly on land with a relatively high-altitude source area of net ice income, a relatively low-altitude sink area of net ice loss, and transfer of mass from the source to sink by flow under the action of gravity. Under the term glaciers we will include both alpine glaciers that exist on mountain slopes and the large ice sheets that completely cover the terrain (Fig. 1).

Although glaciers are restricted to high-altitude and polar environments, they form an important part of the Earth's environment. Erosion and deposition from repeated prehistoric glaciations have shaped large areas of north temperate latitudes that are now densely populated. The geomorphologic effects have therefore received considerable attention both to understand the landscape and to reconstruct the history of glacier and ice-sheet changes and the related climatological causes (Drewry, 1986). Glaciers and ice sheets store water in solid form and are fundamental to hydrology through their effects on the timing and quality of water discharges into surrounding rivers. By storing water on the land, glaciers affect global sea level (National Research Council, 1985). Changes in ice load cause time- and space- dependent depression and rebound of the Earth's surface that affect the pattern of local sea-level change and provide the principal data about the viscosity of the Earth's mantle (Peltier, 1987). Glaciers themselves are tectonic systems that experience deformation and structural changes analogous to those occurring in the solid earth. Because the physical and chemical properties of ice contain information about conditions in the atmosphere at the time of deposition, coring into ice sheets has provided a powerful tool for investigating past climate (Delmas, 1992).

The hydrological and paleoclimatological aspects of glaciers are especially important with regard to global environmental change and impacts from human activities. Two important questions may be enunciated. First, what are the potential effects of glaciers on global sea-level change? A rise in sea level would have major environmental consequences and impacts on human activities. Second, what quantitative information can glacier ice provide about climate change in the past? This is essential information for validating predictive models of climate change. In the context of these questions, our theme will be to review understanding of physical processes acting within and at the boundaries of glaciers.

1. DISTRIBUTION AND CHARACTERISTICS

At present the largest volumes of glacier ice exist in Antarctica and Greenland. These land masses are almost entirely covered by ice, and contain the only continental scale ice sheets at present. There are many much smaller glaciers in the mountain regions of the world. Table 1 summarizes geometrical characteristics of the ice sheets and glaciers.

The volume of ice can be expressed in terms of the equivalent sea-level rise that would occur if the water-equivalent volume were spread evenly over the present area of the oceans. To assess the actual sea-level change that would occur if an ice sheet were to melt, it is necessary to account for the ice volume that exists below sea level and displaces sea water [Fig 1(c)], such as in portions of ice sheets that are grounded below sea level (marine ice sheet) or are floating (ice shelf). The West Antarctic Ice Sheet is the only large marine ice sheet at present. Consequently there is a large fractional difference between its total volume in sea-level equivalent and the actual sea-level change that it could cause (Table 1). The volumes of the Antarctic and Greenland ice sheets correspond to large sea-level equivalents and their stability under changing climate is important for this reason alone.

The total volume of ice contained in other glaciers is small in comparison to the ice sheets, but is not negligible. These glaciers tend to exist in environments with relatively high precipitation and melting, so that the exchange rate of water is quite large and comparable to the exchange rate in the big ice sheets (Table 2). Glaciers experienced a period of expansion starting about 800–600 years ago called the "Little Ice Age." Since about 1890, the glaciers have retreated on average in all mountain ranges of the world (Haeberli *et al.,* 1989). Available information about the rates of volume changes suggest that the cumulative volume loss of small glaciers over the last century has made a major contribution to the rise in sea level over this time (Meier, 1984). Information about the rates of change of the ice sheets is sparse and available estimates have large uncertainties (Table 2).

Averaged over the past several million years, land ice has been much more extensive than at present (Crowley and North, 1991). Following a thermal maximum about 50 million years ago, the Earth has experienced an irregular cooling trend. Glaciation first began in Antarctica perhaps as early as 40 million years ago with extensive volumes of ice being present by 10 million years ago. About 2.4 million years ago large periodic oscillations between glacial and interglacial conditions began to appear in the northern hemisphere at mid-latitudes. These were characterized by gradual expansion of ice sheets terminated by rapid recessions that appear to be correlated with high summer insolation on the southern limits caused by cyclic changes in the Earth's orbital geometry. The most recent continental-scale glacial expansion culminated about 22–14 thousand years ago. The total ice volume at that time was more than twice the present volume, and caused a sea-level depression of about 120 m. Recession occurred rapidly and interglacial conditions similar to the present were reached by about 10 thousand years ago. The large and sometimes rapid changes of the past point to the potential importance of changes in the future.

Table 1. Characteristics of global ice. See Oerlemans (1989) and van der Veen (1991) for sources. Uncertainties are generally within 10% except as noted by * which have larger uncertainties.

	Total area (10^6 km^2)	Mean thickness (km)	Total volume (10^6 km^3)	Sea-level Equivalent (m)	Sea-level change (m)
East Antarctica	9.9	2.6	25.9	72	60*
West Antarctica	2.1	1.6	3.4	9.4	6.0*
Greenland	1.8	1.5	2.7	8.3	7.5*
Rest	0.6*	0.3*	0.2*	0.5*	0.5*

Table 2. Mass exchange of global ice. See Oerlemans (1989) and van der Veen (1991) for sources. Uncertainties are generally less than 15% except for * where uncertainties may be larger.

	Annual Accumulation		Annual Melt						Velocity Range (m a^{-1})		
	Total (10^3 km^3)	Per unit accumulation area (m)	Total (10^3 km^3)	Per unit ablation area (m)	Annual calving (10^3 km^3)	Sea-level change (mm a^{-1})	ELA (km above sea level)	Accumulation area ratio (AAR)	Normal	Ice streams, tidewater, surges	Mean residence time (10^3 a)
Antarctica	2.2		< 0.01		2*	0–1.2	Negative	1.0	10^0–10^2	~10^3	13.3
Greenland	0.5	0.35	0.3	1.2	0.2*		1.3	0.84	10^0–10^2	~10^3	5.4
Rest	0.5	~1.3	0.5	~2.4	~0.0	0.2–0.8	0–6	0.6–0.7	10^0–10^2	10^3–10^4	0.4

2. EXCHANGE WITH THE ENVIRONMENT

Glaciers exist because of accumulation of snow from the atmosphere onto the land surface. Some glaciers (tidewater glaciers) and both of the present large ice sheets reach the ocean. The exchange of mass, momentum, and energy across these boundary surfaces (land, atmosphere, and ocean) determines boundary conditions affecting the properties of the ice and the behavior of the glacier. These exchanges also determine how a glacier affects its surroundings.

2.1 Atmosphere

The upper surface of a glacier where the ice contacts the atmosphere is most importantly a surface of mass exchange. Snowfall is the primary ice mass input to a glacier. Deposition of rime (supercooled water droplets) or hoar frost (condensation of water vapor) is normally a much smaller contribution. Heat reaches the upper surface through radiative and turbulent exchanges. This heat may warm the subsurface or, if the surface is at the melting point, cause melting and mass loss. Net outward transfer of heat can cool the subsurface or freeze any water present and add mass.

In addition to the ice mass, trace amounts of impurities are added from the atmosphere. Salts of marine and terrestrial origin, dust, pollen, volcanic ash and acids, soot, and radioactive reaction products from cosmic rays occur with varying concentration and proportion depending on production processes on the ocean and land surfaces, solar activity, air mass history, and precipitation processes. Isotopic ratios (O^{18}/O^{16} and D/H) are affected by fractionation during evaporation and condensation and are related to the temperature at which the snowfall formed. As the snow is compressed to ice, some of the gas present in the pore space is trapped, thus preserving a sample of the atmosphere. In polar conditions these constituents remain locked in the ice and constitute storehouses of information about past environments that can be accessed by coring into the ice sheets. Impurities also affect the physical properties of the ice.

Exchange of momentum with the atmosphere is negligible, the upper surface being essentially stress free except for a small normal stress from atmospheric pressure.

2.2 Land Surface

The lower surface (bed) of a glacier in contact with the land supports the weight of the glacier. When the temperature of the bed is below freezing, the momentum balance can usually be adequately described by a no-slip condition. However, when the bed is at melting temperature and water is present, then the ice may move over the bed. Several theories relate the resulting basal velocity to stress parallel (shear) and normal to the bed, water pressure in the basal zone, mechanics of the ice and subglacial material, and roughness of the bed (Lliboutry, 1987). However, none of the proposed relationships have been verified by observation. The lack of proven formulations of the basal boundary mechanics is the major gap in understanding glacier motion.

A closely related problem concerns the erosion, transport, and deposition of rock debris. These processes are fundamental to glacial action on the landscape. They also determine the subglacial environment and the mechanisms that will control basal velocity. In some circumstances, a relatively clean contact between ice and solid rock exists (Kamb and LaChapelle, 1964); then roughness and the opening of cavities between the ice and rock are important. In other circumstances the ice is underlain by soft deformable debris (Blankenship *et al.*, 1987) in which shearing makes an important contribution to the basal motion. Controls on the production and export of basal debris are poorly understood, which represents one of the barriers to predicting basal velocity.

Whether the bed is hard rock or soft unlithified debris, the condition of water at the bed has a strong influence on the basal velocity. Very high basal velocities one or more orders of magnitude above typical glacier velocities occur when the water pressure approaches flotation, either by extensive separation of the ice from the bed or by pore-pressure–induced loss of strength in the subglacial material. There is a growing understanding of the drainage along glacier beds through tunnels melted in the ice, through linked cavities at the bed, and in the pore space of debris (Rothlisberger and Lang, 1987), but accurate predictions of the morphology of the drainage system and the water pressure are not yet possible.

Geothermal heat flowing upward from the Earth must either be transported up through the ice mass or, if the ice is at the melting point, cause melting. Melting from geothermal heat is usually negligible for mass balance, but the melt water may affect the subglacial hydrology and basal velocity.

2.3 Ocean

Where the ice floats as an ice shelf, stress acting on the base is essentially the hydrostatically determined ocean water pressure, which provides a simple, well-defined momentum boundary condition at the base. Water motions in the cavity between the ice and sea floor can transport large amounts of heat. The interactions with the ice are affected by the coupled diffusion of heat and salts and depression of the melting point by pressure. These thermodynamic processes can cause significant melting or freezing onto the base of an ice shelf. Water cooled by contact with ice at high pressure under thick ice shelves in Antarctica contributes to production of cold Antarctic bottom water that resides in the deep ocean basins.

The very edge of a floating ice shelf or grounded ice in contact with the ocean is susceptible to mass loss by calving. Calving refers to fracture behind the ice front that leads to formation of a free-floating iceberg.

3. GLACIERS AS FLOW SYSTEMS

Two principal mass-transfer processes interact to determine the size and shape of a glacier. They are the distribution of mass transfer across the external boundaries that determines addition and loss to the system (mass balance), and the pattern of ice transport through internal boundaries that redistributes mass inside (ice motion). These processes act in parallel to determine the ice thickness distribution and its changes with time. Both are coupled to the external environment and internally to each other in various ways that are schematically outlined in Fig. 2. The most important interactions are shown as solid arrows. Ice mass balance is affected by the meteorological environment (atmosphere) and altitude (land surface + ice thickness). Ice motion is affected by the slope of the landscape and ice thickness on it (land surface and ice thickness) and temperature of the ice (atmosphere, solid earth, and ice thickness). The ocean has direct effects on tidewater glaciers and ice sheets. Dashed arrows indicate some feedback linkages to the environment. Examples are from ice thickness to the atmosphere caused by the elevation, temperature, and reflectivity of the surface; from ice thickness to the land surface associated with isostasy; from the ice motion to the land surface through erosion and deposition; and from the ice mass balance to the land and ocean through melting and runoff.

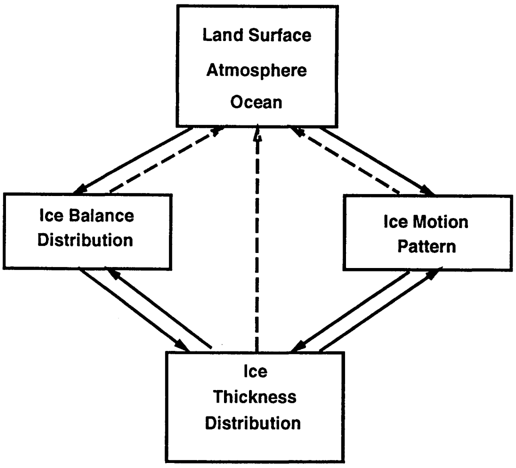

FIG. 2. Linkages between the surrounding environment (top) and the geometry of a glacier (bottom) through exchanges of ice mass across its external (left) and internal (right) surfaces.

3.1 Mass Balance

Addition (removal) of ice mass to (from) a glacier is called accumulation (ablation). The difference between the rates of accumulation and ablation on unit horizontal area is called the mass balance rate (b). It describes the spatial distribution of mass gain and loss. The integral of b over the full area of the glacier gives the total rate of mass change.

On all glaciers there is an accumulation (source) area where, averaged over time, accumulation exceeds ablation and b is positive. On glaciers terminating on land there is an ablation (sink) area where ablation exceeds accumulation and b is negative. The boundary between these zones defines the equilibrium line ($b=0$) that is described by its mean altitude (ELA). The ratio of accumulation area to total area (AAR) is commonly in the range from 0.6 to 0.7. Glaciers that calve into the ocean (or lakes) may have larger AAR values approaching 1 because mass is lost to calving at the edge as well as melting on the surface. In extreme polar conditions such as in Antarctica, there is essentially no melting on the upper surface. Then ablation is restricted to melting off the bottom of ice shelves and calving. Table 2 describes some balance-rate characteristics of glaciers and ice sheets.

Modeling of mass balance is complicated by the multiplicity of parameters that affect it. Precipitation depends on the details of microphysical processes in clouds and details of the vertical motions associated with differential heating and interaction with topography. Radiative (solar and thermal infrared) and turbulent (sensible and latent) heat fluxes depend on weather (temperature, humidity, wind, and cloud cover and type), condition of the surface (temperature, albedo, and roughness) and location (latitude, altitude, continentality, exposure angle, and horizon).

On some glaciers, the variation of altitude, exposure angle, and horizon produce a spatial pattern of b that is consistent from year to year except for nearly uniform shift Δb reflecting the conditions for a particular year. The Δb can alternatively be described in terms of the corresponding shift in ELA. This behavior provides one means for simplification.

On the basis of mass-balance observation series in several regions, it appears possible to predict ELA using winter precipitation and summer temperature. Interannual variations in several regions indicate that ELA rises about 10^2 m for each kelvin rise in summer temperature. However, on many glaciers the spatial patterns of b vary from year to year. Furthermore, in all cases it is important to recognize that phenomenological relations based on short-term records during which the atmospheric composition is nearly constant may not work for longer time scales over which concentrations of radiatively active "greenhouse" gases and volcanic aerosols could change. Such changes in the atmosphere could alter relationships between radiation and temperature (Oerlemans, 1989).

A warming climate would tend to increase accumulation at high altitudes because of availability of precipitable water vapor. It would also increase melting at low altitudes. Together these effects would increase the elevation gradient of b and alter the trends of its spatial variation. It is also important to distinguish between winter and summer temperature changes. In temperate conditions, increases in winter temperature may reduce accumulation by increasing the proportion of rain to snow with negative effect on b. In colder circumstances at high latitude or altitude, the opposite effect on b may happen because of increased total precipitation, which in any case occurs as snowfall.

A method for predicting calving is crucial for modeling the mass balance of tidewater glaciers and both of the present ice sheets. In temperate conditions floating ice shelves do not form and calving releases relatively small bergs with roughly equal vertical and horizontal dimensions. Calving rate is correlated with water depth and height of the ice cliff and is apparently related to local stress near the ice front. In polar conditions, where ice shelves form, calving occurs episodically by release of large tabular bergs with horizontal dimensions reaching tens of kilometers indicating that a large-scale stress regime is responsible. Quantitative predictive models are still not available for either case.

3.2 Glacier Motion

Glaciers, especially those flowing down valleys, are commonly described as "rivers of ice." Physically, the motion of a glacier differs from the flow of a river (a linearly viscous fluid flowing with no slip in a channel). The glacier speeds are so low (Table 2) that inertial forces are negligible. As a result the dynamic nonlinearity leading to turbulence in rivers is absent, and in this way glacier flow is simpler. Other features make it more complex. As discussed above, motion over the base introduces a relatively complex boundary condition. In addition, the fluidlike (creep) deformation of ice is described by a nonlinear relationship (flow law) between rate of deformation (ϵ) and stress (τ), which together with the basal motion introduces a rheological nonlinearity.

The foundation for modeling of glacier motion is an accurate description of a flow law for the ice. Experiments indicate that ice creep can be approximated as being like that of a "quasiviscous" fluid with an effective viscosity (η) that depends inversely on ϵ such that $\eta \propto \epsilon^{-(1-1/n)}$ with $n \cong 3$. The behavior may also be equivalently described by a power-law relationship $\epsilon \propto \tau^n$. Effective viscosity η is affected by other parameters. Most important is the thermal state. As temperature increases or as water content rises at the melting point, η decreases strongly. It is also sensitive to impurities and texture. Although many details have yet to be fully explored, a practical ice-flow law has been relatively well defined (Budd and Jacka, 1989).

The flow law of ice, field equations describing conservation of mass and momentum, and boundary conditions based on processes described in Sec. 2.2 define a fluid mechanical problem for the calculation of the instantaneous velocity field from the current geometry, thermal state of the ice, and density distribution acted on by gravity. Because of the nonlinearity and the geometrical complexity of real glaciers, this problem has been solved only with various simplified geometrical or rheological assumptions. (See Paterson, 1981; Hutter, 1983.)

The simplest model is a slab of constant thickness (h) and slope (α) with no gradients sideways across the flow or longitudinally in the down-slope flow direction. Then the stress distribution is statically determined, and the corresponding vertical variation of deformation rate is easily integrated for any specified depth profile of parameters affecting the ice-flow law (e.g., temperature). When the parameters are independent of depth one finds that speed $u \propto \alpha^n h^{n+1}$, where n is the power in the flow law.

This slab model is reasonably applicable over wide areas of the interior of ice sheets where horizontal gradients are small. These "inland" portions have smooth upper surfaces and flow lines running down slope with local and usually small perturbations from topographic features in the underlying terrain. However, the slab model is not applicable at many locations where horizontal gradients are large. This condition exists at most locations in valley glaciers as a result of drag from the sides and changes along the length in the valley profile or the basal velocity. Toward the edge of ice sheets, where mean thickness decreases, the flow commonly concentrates either into deep outlet glaciers confined between peaks reaching close to or to the surface (nunataks) or into ice streams that sometimes have no obvious relation to basal topography, but move rapidly over their bases because of special basal conditions (Bentley, 1987) [see Fig. 1(c)]. The outlet glaciers and ice streams are characterized by "fast" flow rates much higher than the more normal "slow" speeds of the surrounding ice (Table 2). The boundary zones between these fast ice currents and adjacent slowly moving ice are examples of locations where horizontal gradients are clearly important. Several analytical theories allow approximate corrections for side drag and unbalanced longitudinal forces, but numerical methods are often needed for accurate calculation.

To find the time-dependent evolution of geometry, density, and velocity, it is necessary in principle to track the parameters affecting the flow law by introducing conservation equations for energy, liquid water mass, and masses of impurities with associated boundary conditions. It is also necessary to track textural changes. While observational effects arise from all of these parameters, temperature is most important. Recent numerical models address the full coupling between the mass and heat flow caused by the strong temperature dependence in the flow law and heat advection (Huybrechts, 1990). Modeling of water, impurities, and texture is still not well developed.

For some purposes a detailed knowledge of the distribution of density (ρ) and velocity ($\mathbf{u}$) is important. One example is to determine the age, accumulated finite strain, and origin location for ice along the length of ice cores to aid in their interpretation. However, generally, to calculate the evolution of the large-scale geometry, quantities integrated over the ice thickness h can be used, and the details of the horizontal gradients are unimportant. The total mass (m) in a vertical column through the ice is given by the integral of density. The ice transport is conveniently described by the horizontal ice flux density $\mathbf{q}$ given by integrated density times horizontal velocity. The isothermal slab model gives $q \propto \alpha^n h^{n+2}$; high sensitivity of q to h and α is a feature of all theories as long as averages are taken over horizontal dimensions substantially larger than h. This approach leads to a tractable mathematical theory for advance and retreat of glaciers discussed below. The major lack is the incomplete understanding of basal motion and absence of a dependable mathematical description of the process. Predictions when basal velocity is the major contribution to the motion are especially problematical.

3.3 Advance and Retreat

Mass conservation applied to a full thickness column can be expressed as

$$dm/dt = b - \nabla \cdot \mathbf{q}. \qquad (1)$$

This equation describes quantitatively the parallel action of mass balance b and ice flow $\mathbf{q}$ on the mass distribution and corresponding thickness pattern (Fig. 2). The evolution of a glacier can be calculated from an initial condition and subsequent climate history by integration of Eq. (1) using models to predict b and $\mathbf{q}$.

When the balance-rate distribution changes on a glacier, the information about the change is spread over the full area of the glacier. The effects of the change appear at the margin spread out in time in a way that can be described by two fundamental time scales. The first is a memory length (T_m) that describes the time it takes a glacier to complete its response to the change. On this time scale or longer, the length and volume are closely related. The second is a shorter lag time (T_l) that describes the time interval between the climate change and the resulting maximum rate of change at the margin. On this time scale, the length and volume changes are not necessarily related and can even have opposite signs. Simple models of glaciers show that T_m and T_l are proportional to the length divided by velocity; see Paterson (1981) and Hutter (1983) for reviews. T_m is approximately equal to the mean residence time (Table 2) and can be expressed alternatively in terms of thickness and balance rate (Johannesson *et al.*, 1989). For typical valley glaciers with lengths in the range of a few kilometers to tens of kilometers and velocity in the range of a few tens to a few hundreds of meters per year, T_l is a few decades and T_m is decades to a few centuries. Because of the large range in lengths and velocities, there is a corresponding range in time scales that is in part responsible for diverse response histories of glaciers

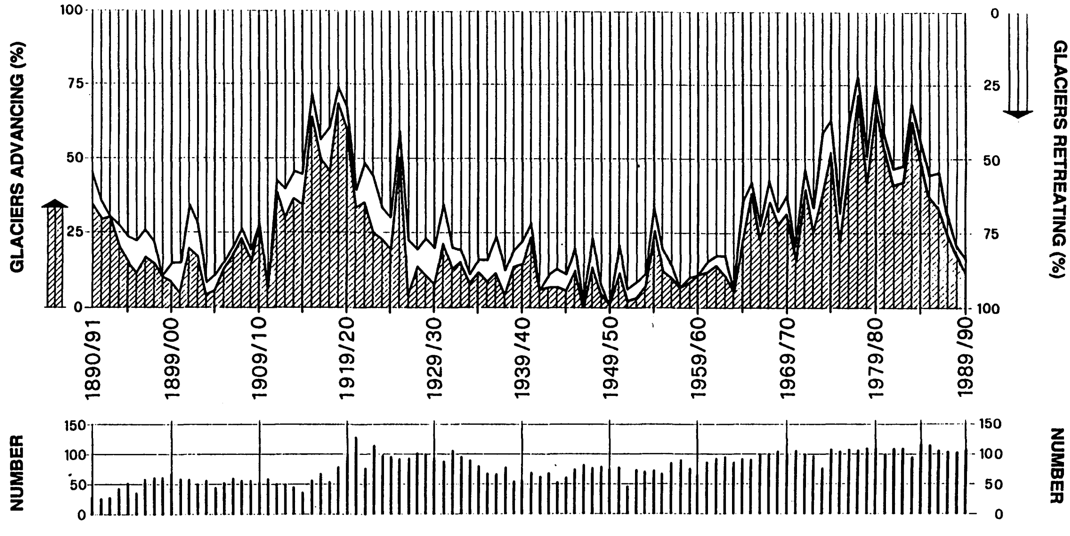

FIG. 3. Upper panel shows percentages of glaciers advancing (lower curve, scale on left), retreating (upper curve, scale on right) and stationary (space between curves) on an annual basis in the Swiss Alps over the last century. Lower panel: Number of glaciers that were observed in each year. (Adapted from Kasser *et al.*, 1983).

to climate change. As climate changes on different time scales, some glaciers may be advancing while others are retreating (Fig. 3).

As a glacier advances or retreats the elevation of its surface changes. This causes a change in balance rate on the surface in addition to those caused directly by climate. This geometry–mass-balance feedback tends to amplify changes, increase T_m, and allow nonunique steady states. For example, under the present climate a large, thick ice sheet could theoretically exist in steady state over much of northern North America. However, such an ice sheet cannot grow with the present climate because the ground surface is too low and warm to develop perennial ice.

Another example of geometry–mass-balance feedback occurs in tidewater glaciers (Meier and Post, 1987). As a tidewater glacier retreats from a moraine shoal into deeper water, the calving rate rises. This increase in loss with reduced size causes a rapid unstable retreat through deep water to a location where the bed approaches sea level. Readvance apparently occurs only very slowly because it requires the construction of a proglacial shoal by deposition in front of the glacier.

As the geometry of a glacier changes, the stress in it and the resulting velocity change. This is fundamental to the normal adjustment to climate discussed above. However, it is also possible that an incremental change in geometry can cause a dramatic shift in flow state from "slow"' to "fast" or visa versa. The primary example of this phenomenon is surge behavior. Although glaciers showing this behavior constitute only a small fraction of all glaciers, they are common in certain mountain areas and their rapid changes cause various hazards. These glaciers cannot achieve steady state in either the "slow" or "fast" states and are forced to switch between intervals of slow quiescence and fast surge (Raymond, 1987). The transitions in speed and the resulting time-dependent geometry are independent of any immediate climatological triggering. At least in some cases, the switching between quiescence and surge has to do with transformation of the drainage system along the bed that traps water and initiates the "fast" flow state as a result of very high basal velocity. Although the same hydrological processes probably do not operate beneath ice sheets and the ice streams that drain them, the possibility of dramatic auto-oscillations in these systems cannot be ruled out. Indeed, evidence has been found for changes in the speed of ice streams (Alley and Whillans, 1991), and the causes have not been identified.

4. GLACIER ICE IN A CHANGING CLIMATE

The Earth has been warming over the last century, and increasing atmospheric concentrations of radiatively active gases like carbon dioxide and methane suggest that heightened "greenhouse" warming will occur in the future. How might glaciers respond to such a scenario of "global warming"?

It is relatively certain that most glaciers in temperate latitudes would continue to experience rising ELAs, lose volume, and retreat because of increased summer melting and in some cases increased proportion of rain to snow in winter. In some exceptional cases, especially on glaciers with high-altitude accumulation areas, increased snowfall could cause growth.

In Greenland a warmer climate would cause increased melting near the margins, higher ELA, and larger ablation area. There could also be an increase in accumulation in the high interior. Although these competing effects cannot be predicted precisely, reasonable parametrizations are possible in terms of temperature change. The resulting model indicates that the Greenland Ice Sheet would retreat if the climate were to warm (Letreguilly *et al.*, 1991). The changes are predicted to be modest for temperature rises less than ~ 2 K. Temperature rise above ~ 6 K would cause disappearance of the ice sheet leaving only small ice caps and glaciers. The time scale to change the volume of the ice sheet to a new steady-state geometry is $\sim 10^4$ years.

The Antarctic Ice Sheet surface is so cold that even large warming would not produce melting with runoff from the upper surface. The principal direct meteorological effect would be increased accumulation and growth of the ice sheet. However, there are dynamic effects that could act to reduce the ice volume. Increased temperature would soften the ice, increase flow rates, and allow a thinning. This process has little effect on a short time scale when temperature changes affect only the near surface. For time scales longer than $\sim 10^4$ years thermal effects are advected and diffused to sufficient depth to speed the motion. It turns out that increased accumulation and temperature are approximately counterbalancing (Huybrechts, 1990).

The location of the ice-sheet margin is determined by calving at the coast line (except in embayments where ice shelves form). With a constant sea level and fixed land base, even large changes in accumulation rate produce only modest changes in volume. This behavior arises in part from the high sensitivity of the ice flow to changes in thickness and associated stress. Therefore, sea level fluctuations have had a dominant influence on the ice sheet dimensions in the past. During the Pleistocene ice ages, as northern hemisphere ice sheets grew and sea level dropped, the Antarctic Ice Sheet could expand on the resulting larger land base. This is one possible contribution to synchronous oscillations of northern and southern hemisphere ice sheets, even though the radiation forcing from changes in orbital parameters is quite different in the two hemispheres. Some changes could still be occurring as a result of delayed local sea level effects around the ice sheet margin because of continuing isostatic rebound arising from earlier ice volume reduction. With climate warming from present conditions, changes in the Antarctic Ice Sheet are not likely to be forced by sea-level rise from outside, although feedback from significant shrinkage of the Greenland Ice Sheet cannot be ruled out on a long time scale.

Of greater concern on the time scale of 10^2–10^3 years is the possible alteration of the drainage of the ice to the ocean through ice streams. This is of primary concern for the West Antarctic Ice Sheet because of its marine character and possible collapse by retreat of its grounding line (Mercer, 1978). Retreat could be instigated by thinning of the ice shelves through interaction with a warmer ocean, reduction of back stress on the ice streams feeding the ice shelves with a resulting increase in discharge, and thinning of inland ice. Major unknowns concern the amount of heat that could be carried by ocean currents beneath the ice shelves and lost to melting. Nor is present understanding of controls on the velocity, width, and length of ice streams sufficient to predict how the ice streams would respond to such a change in boundary conditions. The response of the West Antarctic Ice Sheet remains as one of the important unknowns of global change, especially future sea level.

GLOSSARY

Accumulation: Mass of ice added per unit area to a glacier or ice sheet.

Ablation: Mass of ice removed per unit area from a glacier or ice sheet.

Calving: Breaking off of icebergs at a glacier or ice-sheet margin with the ocean or a lake.

ELA: Elevation of the boundary between the area of accumulation and the area of ablation at the end of the summer season.

Geothermal Gradient: Temperature gradient in the Earth conducting the geothermal heat flux upward from the interior of the Earth.

Ice Shelf: Glacier ice that has flowed from the land surface onto the sea or a lake and is floating.

Ice Stream: Fast current of ice through surrounding relatively slowly moving ice.

Marine Ice Sheet: An ice sheet grounded on a bed that is below sea level even after isostatic rebound of the bed once the ice is removed.

Mass Balance Rate: The difference between the rates of accumulation and ablation.

Surge-Type Glacier: A glacier that oscillates between extended quiescent intervals of slow flow and relatively brief surge intervals of relatively very fast flow.

Tidewater Glacier: A glacier reaching sea level that calves into the ocean.

INTRODUCTION

Glass is a vital material in modern technology. In addition to the traditional uses in containers, windows, and for decorative objects, new applications in lamps, optical components, and electronics are continuously being developed. Special uses such as fiber-optic waveguides, telescope mirrors, laser optics, radioactive waste encapsulation, and biomedical implants testify to the great value and diversity of glass in contemporary society.

The emphasis in the present article is on silicate glasses because of their overwhelming commercial importance. Other glasses, such as fluorides, chalcogenides, and glassy alloys are described in appropriate sections because of recent research interest in them. This article has sections on melting and processing of glass, glass structure and microstructure, viscosity, and glass properties. A bibliography of books on glass is at the end of the article, as well as a list of highly selected review and research articles.

1. TYPES AND USES OF GLASSES

By far the greatest use of glass is of the soda-lime silicate composition, which has been known for at least ten millennia. This composition is relatively easy to melt from readily

available raw materials and is highly resistant to chemical attack, including by water. A large number of different oxides can be incorporated into a silicate glass, leading to a wide variety of commercial glasses; however, only a few glasses make up the large majority of glass production. A summary of properties and uses of important commercial glasses is in Table 1, and their compositions are in Table 2.

Glass was first used for decorative objects, and exhibits such as in the Steuben store in New York City and the Corning Museum in Corning, New York, demonstrate the recent and continuing activity in glass as an artistic medium. The second use of glass, for containers for food, perfume, and a vast number of commercial liquids continues as the largest consumer of glass, in spite of strong competition from polymers and aluminum. Flat glass, mainly for windows in buildings and vehicles, is the second largest consumer of glass. Many special applications of smaller amount but high value include lamp envelopes and seals, many optical uses, fibers in polymer matrices ("fiberglass"), and consolidation of radioactive waste. Vitreous silica, a highly pure SiO_2 composition, is especially valuable because of high optical transparency, low sensitivity to thermal shock, and high chemical durability; applications include crucibles for melting semiconductors, lamp envelopes, fiber-optic waveguides, and telescope mirrors.

Glass can be defined as an amorphous solid. A material is amorphous when it has no long-range order—that is, no regular repeating structure on the scale of many atomic distances (see AMORPHOUS MATERIALS, STRUCTURE OF). A solid is a rigid material that does not flow when subjected to moderate forces; more precisely, a solid can be defined as a material with a viscosity greater than about 10^{14} Pa s (10^{15} poises).

2. MELTING AND PROCESSING

2.1 Melting

Raw materials for making silicate glasses are quartz sand, sodium carbonate or nitrate, calcium and magnesium carbonate, and oxides such as alumina, lead oxide, sodium borate, zinc oxide, and arsenic and antimony

Table 2. Compositions (wt %) of glasses in Table 1.

Glass	SiO_2	B_2O_3	Al_2O_3	CaO	MgO	PbO	Na_2O	K_2O
Vitreous silica	100							
Soda lime	72	1	2	5	4		15	
Pyrex borosilicate	81	13	2				4	
Alkali lead	77					8	9	5
Lime-magnesia aluminosilicate	64	5	10	9	10		1	1
Sodium borosilicate	68	24	1				7	
"E" fiberglass silicate	55	7	15	21			1	1
High lead	4	11	11			74		
Barium lead	66		4	(12 BaO)		4	6	7
Barium optical	48	5	1	(29 BaO, 9 ZnO)			1	7

oxides. These materials have traditionally been mined directly, with little or no purification, and so were cheap but of variable impurity content. Some deposits of quartz crystal and quartz sand are probably the purest of naturally occurring materials, having total impurity contents of less than about 100 parts per million by weight.

Glass has traditionally been melted in a "batch" in a pot or crucible of refractory ceramic material. Raw materials are mixed to the desired composition and either heated in the crucible or added to already molten glass. The low–melting-point constituents (alkali oxides) melt and dissolve the higher–melting-point constituents such as quartz and alumina.

Quantity production of glass, especially soda-lime and borosilicate compositions, is continuous in a large "tank" or furnace made of special refractory brick; a characteristic tank is 15×25 m in size, with glass 1.5 m deep, giving a daily production of as much as 700 metric tons of glass. The tank is heated by combustion of oil or natural gas across the glass surface. Melting temperatures are about 1200–1300 °C. The furnace is separated into two positions by a refractory "wall" over which glass flows. The mixed raw materials are fed onto the top of the molten glass in the melting chamber; the molten glass flows across the wall into the refining chamber, in which the glass becomes more homogeneous and bubbles are removed.

In the refining chamber the glass is "fined" by the removal of bubbles. The bubbles contain trapped air (oxygen and nitrogen) and decomposition products of the raw materials, mainly carbon dioxide. Large bubbles rise to the top of the melt, but most bubbles are too small to be removed in this way; the gases in them must dissolve in the melt to collapse the bubbles. This dissolution is aided by fining agents added to the glass batch. Arsenic and antimony oxides are common fining agents. They have two oxidation states, and increase dissolution rates of gases by changing the oxidation state of the melt. Sulfates also are common fining agents; they also function by changing the oxidation state of the melt.

2.2 Forming

Glass containers are formed from glass that flows out of the continuous furnace. A "gob" or portion of glass is placed in a mold where a first shape is formed by pressing or blowing. This initial shape is removed from the mold, reheated, and then placed in a second mold in which the final shape is blown. The continuous machine (IS or individual section machine) on which these steps are done rapidly produces a very large number of units; a usual cycle time for one container is 10–15 s.

Lamp bulbs are made by blowing into a ribbon of glass emitting from the furnace on a "ribbon machine." Again a high rate of units is produced, up to 2000 per minute. A special nozzle blows glass in the ribbon into a mold.

Glass objects such as plates, tumblers, and vases can be made by pressing molten glass in a mold with a metallic plunger. Patterns on the mold surface are imprinted into the glass and make it look more expensive than it is.

More than 100 years ago window glass was made by hand by either the crown or cylinder process. In the crown process a gob of glass was blown into a sphere and one side flattened by pressing it against a plate. An iron rod was attached to the flat part and the blow pipe removed. The globe was then spun into a flat disk from which panes could be cut. In the cylinder process the glass was formed into a large cylinder, which was split open and flattened.

Later sheet glass was drawn directly from the melting surface, flowed through rollers, and then ground and polished. These processes are expensive. A new method of making more inexpensive flat glass of high quality was developed by Alistair Pilkington of the Pilkington Glass Company in England. In this float process, a continuous strip of glass from the melting furnace floats onto the surface of a molten metal, usually tin, at a carefully controlled temperature. The flat surface of the molten metal gives a smooth, undistorted surface to the glass as it cools. This process is continuous, and high production speeds are possible. Today most flat glass is made by this method.

2.3 Fiberglass

Glass fibers are finding increasing application in reinforcing polymer-matrix composites ("fiber glass"), which are used in automobile and boat bodies, aircraft, electronic circuit boards, and a variety of other ways. Fiberglass fabrics serve as protective apparel, industrial and decorative fabrics, and tire cord. Short fibers are used in thermal insulation. A typical fiberglass composition is given in Table 2.

In making continuous fiberglass, molten glass from a melting furnace is fed to a drawing apparatus that consists of clusters of many holes called bushings. Each bushing has hundreds of holes or nozzles through which the glass is drawn into fibers of diameter about 10–100 μm in diameter. The fibers are cooled by a water spray, and a polymeric coating or "sizing" is applied to protect and lubricate the fibers. Instead of drawing glass directly from the furnace, glass can be cast into spherical "marbles" one or a few cm in diameter, which are then fed into the heated bushings.

Short fibers can be formed either directly from glass from the melting furnace or from marbles. The molten glass is fed into a rotating cylinder through a large number of small holes in the walls of the cylinder, and inside the cylinder the glass streams are broken up by an axial high-velocity flow of gas. The short fibers formed in this way are sprayed with binder as they fall onto a collecting belt which carries them through an oven that polymerizes the binder.

2.4 Sintering and Sol-Gel Methods

Several methods of melting and forming glass have been developed for special applications or properties. Glass powder can be pressed and sintered similarly to powders of crystalline ceramics. This is expensive compared to more traditional methods of melting, but can be useful for making high–melting-point glasses and adding small amounts of desired impurities to them.

Sol-gel methods of glass making are finding increasing application in making highly pure and homogeneous glasses or special shapes such as microshells. In one method a mixture of liquid metal alkoxides is hydrolyzed, polymerized, and then dehydrated to form a homogeneous glass at temperatures much below those ordinarily used for glass melting. The hydration and polymerization are carried out in an acidic alcohol-water solution at temperatures up to 60 °C; then the mixture can be formed or made to gel in bulk by heating to somewhat higher temperatures; finally the gel is pyrolyzed and dehydrated by heating at temperatures from 500 to 1000 °C to form glass. Some superior products of this method are homogeneous multicomponent glasses, compositions hard to form into glasses by direct melting because of incomplete melting and crystallization on cooling, very pure glasses, and composites of glasses with other materials. Low forming temperatures save energy, allow less corrosion-resistant container materials, and allow formation of composites with materials not resistant to higher temperatures.

Special shapes such as fibers and thin films can be made by the sol-gel method. Glass microshells for laser targets have been made by dropping gel particles through a temperature gradient in a furnace tower; the organic compounds and water help to blow the glass into thin-walled shells.

3. STRUCTURE

The structure of amorphous materials is treated in a separate article in the Encyclopedia (AMORPHOUS MATERIALS, STRUCTURE OF), and so only a short discussion of glass structure is included here. The structure of glassy polymers is treated in articles on these materials (see POLYMERS, STRUCTURE OF).

The most useful experimental techniques for studying the structure of glasses are x-ray and neutron diffraction and infrared and Raman spectroscopy. Techniques such as nuclear magnetic resonance (NMR), x-ray photoelectron spectroscopy [XPS or electron spectroscopy for chemical analysis (ESCA)] and x-ray absorption fine structure (EXAFS) with longer-wavelength x rays are useful for special structure studies, especially to determine the coordination numbers of atoms in glasses.

The building block of all silicates, both crystalline and amorphous, is the rigid silicon-oxygen tetrahedron. In silicate glasses these tetrahedra are linked by silicon–oxygen bonds into a three-dimensional network. The network can be partially broken up by other oxides in the glass, especially alkali and alkaline-earth oxides (see the review by Wright *et al.*, 1991).

From a detailed x-ray diffraction study of pure amorphous silica, Warren and later Mozzi and Warren (1969) concluded that its structure could best be described as a random network. In this model the rigid silicon-oxygen tetrahedra are linked into a three-dimensional network; randomness results from a distribution of silicon-oxygen-silicon bond angles around an average value of 144°. The distribution of angles around the maximum is rather narrow compared to a completely random distribution of bond angles from 90° to 180°. Thus the structure of amorphous silica is quite uniform at atomic distances, although there is no order beyond several layers of tetrahedra.

In silicate glasses containing alkali and alkaline-earth oxides, these cations apparently are not randomly distributed throughout the glass; their average separation is considerably less than for a uniform distribution. It is possible that alkali ions form in sheets, as they do in certain crystalline alkali silicates. This "intermediate"-range structure has been emphasized in recent studies of multicomponent silicate glasses and other compositions such as sulfides and selenides (Gaskell *et al.*, 1991).

Metals and alloys have been made into glasses by different methods of rapid cooling (see METALLIC GLASSES). The structure of glassy metals with no more than a few percent of impurities can be described as a dense random packing of hard spheres (Bernal, 1960; Finney, 1970). The packing fraction is 0.637, compared with 0.74 for close packing of spheres of the same size in a crystalline structure, such as face-centered cubic and close-packed hexagonal. This model fits the radial distribution function derived from scattering experiments.

The structures of amorphous alloys of compounds M_4X, in which M is a transition or noble metal and X a nonmetal, have been extensively studied. The best model seems to be a slightly distorted dense random packing of hard spheres for the M atoms, with the X atoms located interstitially in polyhedra in the structure. Other structures of alloys are described by Cargil and Spaepen (1981).

The structure of zirconium fluoride glasses is of special interest because it is quite different from that of silicate glasses, especially in that the coordination number of the glass-forming zirconium atoms is high. Coordination numbers of 7 and 8 for zirconium atoms have been deduced from x-ray radial distribution functions and molecular-dynamics calculations, and several different structures have been proposed for these glasses (previous work is reviewed in Ko and Doremus, 1991). From a comparison of infrared and Raman spectra of zirconium fluoride glasses and crystals, a structure of these glasses based on eight-coordinated zirconium-fluoride units bonded into a three-dimensional network was proposed (Ko and Doremus, 1991). This structure is similar to that of β-ZrF_4, which has the Archimedean antiprism structure in which zirconium is coordinated with eight fluorines.

4. PHASE SEPARATION AND CRYSTALLIZATION

Glasses normally consist of one amorphous phase. However, in certain glass compositions, especially borosilicates, the glass can separate into two amorphous or liquid phases. Crystals also grow in glasses under different conditions, sometimes enhancing properties, as in glass ceramics, but more often causing cracking and deterioration of properties (devitrification).

4.1 Phase Separation

Binary silicate mixtures that contain alkaline-earth oxides, except for barium, and many transition-metal oxides show equilibrium phase separation at high temperatures, typically above about 1700 °C. In binary alkali silicate glasses there is no equilibrium phase separation, but these mixtures are easily cooled to glasses without crystallization, and some show liquid-liquid phase separation at temperatures below the liquidus temperature of crystallization. The maximum temperature (or "consolute" temperature) for this metastable phase separation is about 850 °C at 8% Na_2O–92% SiO_2 in sodium silicate glasses and about 1000 °C at somewhat higher Li_2O concentration in lithium silicate glasses.

The commercially important soda-lime silicate glasses can also show phase separation, which can degrade properties such as chemical durability and resistance to crystallization. Addition of a small amount of aluminum oxide to these glasses strongly reduces the tendency to phase separation.

The sodium borosilicate glasses show phase separation in a wide variety of compositions. This property is the basis for making 96% silica glass ("Vycor"). The starting material is an alkali borosilicate glass that separates into two interconnected phases. The high-silicate phase is resistant to hydrochloric acid, whereas the sodium borosilicate phase dissolves in this acid leaving a porous glass with a silica matrix. This porous glass can be consolidated at about 1000 °C into a silica-rich dense glass with properties similar to vitreous silica, which must be melted at temperatures above 1800 °C. The porous glass itself is useful for filters and absorption, and as a matrix for fillers. The pore size can be changed by changing the initial composition and by annealing at temperatures in the range 600–700 °C.

4.2 Kinetics of Phase Transitions

The usual mechanism of phase transformations is nucleation of a small region of the new phase composition followed by its growth. The rates of nucleation and of growth in a glass both reach a maximum as the temperature is decreased below the phase-boundary temperature. The driving forces for nucleation and for growth increase as the temperature decreases below the phase boundary, causing an increase in the rate of nucleation or growth. As the temperature decreases still further, transport rates (diffusion or interfacial processes) become controlling, and the rates decrease as the temperature decreases. Nucleation and growth of phases is summarized in more detail in Doremus (1985).

Another mechanism of phase transformation called spinodal decomposition can give a morphology of interconnected phases. In a nucleation and growth mechanism, small fluctuations in composition of the initial phase increase the total free energy of the system, and so only regions of the equilibrium composition of the new phase form. In spinodal decomposition small composition fluctuations reduce the total free energy, and so these fluctuations occur throughout the matrix phase with a certain extent (wavelength), and as transformation proceeds the initial concentration variations increase, and the wavelength of the spatial variations of composition remains the same. Spinodal decomposition in glasses was modeled theoretically by Cahn and Charles (1965), and agreed well with experimental results.

The experimental measurements of Hammel (1967) on nucleation rates of phase separation in a soda-lime silicate glass provide one of the very few tests of nucleation theory in condensed systems and agree well with this theory.

4.3 Crystallization

Glass is metastable with respect to crystalline phase at temperatures below its equilibrium liquidus temperature. The liquidus temperatures for commercial soda-lime glasses are usually between 900 and 1000 °C for crystallization of the compound "divitrite" or $Na_2O{\cdot}3CaO{\cdot}6SiO_2$. In a zirconium fluoride glass, the liquidus temperature can be as low as 500°. Glasses can form because the rate of crystallization is low.

Crystallization or "devitrification" of glass can lead to serious problems in glass manufacture because of the resultant changes in glass properties, such as viscosity and coefficient of thermal expansion. High stresses resulting from nonuniform contraction on cooling can cause fracture of the piece. Thus, glass technologists have always been careful to avoid crystallization by not holding their glasses at temperatures where crystals grow rapidly in them.

In surface crystallization, impurities are the most important source of nucleation. On cooling from the melting temperature, dust particles adhere to the glass surface, giving preferred nucleation. Other impurities such as alkalis can corrode the surface, leading to lower glass-air surface tension and enhanced nucleation.

Experimental nucleation rates have been measured in lithium disilicate, $BaO{\cdot}2SiO_2$, and $Na_2O{\cdot}2CaO{\cdot}3SiO_2$ glasses (James, 1985). The preexponential factor in the nucleation rate equation as calculated from these was many orders of magnitude higher than expected from the theoretical value. James showed that this discrepancy could be explained by a temperature dependence of the interfacial free energy resulting from a small negative interfacial entropy. It is also possible that the simple geometrical factors assumed for interfacial rearrangement during nucleation are not valid for this system.

Nucleation rates in sodium disilicate and anorthite ($CaO{\cdot}Al_2O_3{\cdot}2SiO_2$) showed the temperature dependence expected from the theory, and interfacial energies of 0.055 and 0.19 J/m^2 were calculated (Cranmer *et al.*, 1981). The preexponential factor was found to be close to that expected theoretically.

The kinetics of crystallization can be followed in a differential scanning calorimeter (DSC), which measures the temperature difference between a standard and a sample. Either isothermal or constant-heating-rate experiments are possible. The activation energy of crystallization and the time exponent can be found from the DSC crystallization curves (Bansal *et al.*, 1983).

4.4 Glass Ceramics

Some of the few really new materials developed recently are uniformly crystallized glass or "glass ceramics." These materials were first developed at the Corning Glass Works, and are made by special heat treatment of particular glass compositions to give a fine, uniform dispersion of crystals in the glass. These partially crystallized glasses can have many superior properties, such as high strength and impact resistance, low bulk and surface electrical conductivity, low dielectric loss, low chemical reactivity, low coefficient of thermal expansion, and a range of optical properties from clear to completely opaque or white resulting from light scattering from the crystals. Important uses of glass ceramics are radomes, cookware, insulators, telescope mirrors, bearings, heat exchangers, reactor control rods, sealing, vacuum tube envelopes, substrates for electronic circuits, and capacitors. Some examples of crystalline phases in glass ceramics are β-spodumene ($Li_2O{\cdot}Al_2O_3{\cdot}4SiO_2$) and cordierite ($2MgO{\cdot}2Al_2O_3{\cdot}5SiO_2$).

To make a glass ceramic a nucleating agent is usually added to the glass composition to insure uniform crystallization. Typical nucleation agents are titanium dioxide, phosphorous pentoxide, zirconium dioxide, fluorides, and noble and platinum metals.

5. VISCOSITY AND THE GLASS TRANSITION

5.1 Viscosity

The viscosity of a glass is one of its most important technological properties. It determines the melting conditions, the temperatures of working and annealing, fining behavior (removal of bubbles from the melt), upper temperatures of use, and devitrification rate. The viscosities of different glasses vary enormously with composition and are strong functions of temperature. The most common viscosity unit is the poise (P), which is a dyne-second per square centimeter or a gram per centimeter per second. In most literature viscosity is reported in poises. The SI unit of viscosity is the pascal-second or Pa s; one of these units is equal to 10 P. The viscosity of most common fluids such as water and organic liquids is about 0.01 P at room temperature.

The working point of a glass is defined as the temperature at which it has a viscosity of 10^4 P. At this temperature the glass can be readily formed or sealed. The softening point of a glass is the temperature at which it has a viscosity of $10^{7.6}$ P. At this viscosity a rod about 24 cm long and 0.7 mm in diameter elongates 1 mm/min under its own weight. The annealing point is the temperature at which the viscosity is $10^{13.4}$ P, and the strain point, the temperature at which the viscosity of $10^{14.6}$ P. The thermal expansion curve of an annealed glass begins to deviate considerably from linearity at a viscosity of about 10^{14} or 10^{15} P. At the annealing temperature a rapidly cooled silicate glass becomes reasonably strain-free in about 15 min.

The viscosities of several commercially important silicate glasses are compared in Fig. 1, as functions of temperature. The working, softening, and annealing points are marked on the plot.

As with many transport properties the viscosity η fits an Arrhenius-type equation over some ranges of temperature:

$$\eta=\eta_0 \exp[(Q)/(RT)], \qquad (1)$$

where Q and η_0 are temperature-induced coefficients called the activation energy and the preexponential factor, respectively.

The activation energies for viscous flow of various simple glass-forming oxides are given in Table 3. Vitreous germania shows a constant activation energy over a factor of 10^{10} change in viscosity. However, vitreous silica definitely shows a change in activation energy with temperature, and B_2O_3 shows a large change in activation energy with temperature. Also, multicomponent silicate glasses for which viscosity data are plotted in Fig. 1, and most organic glasses, have changing activation energies for viscous flow as functions of temperature. From calorimetric measurements of the glass transition temperature of P_2O_5, Martin and Angell (1986) concluded that the activation energy for its viscous flow, at least from 317 to 636 °C, was constant.

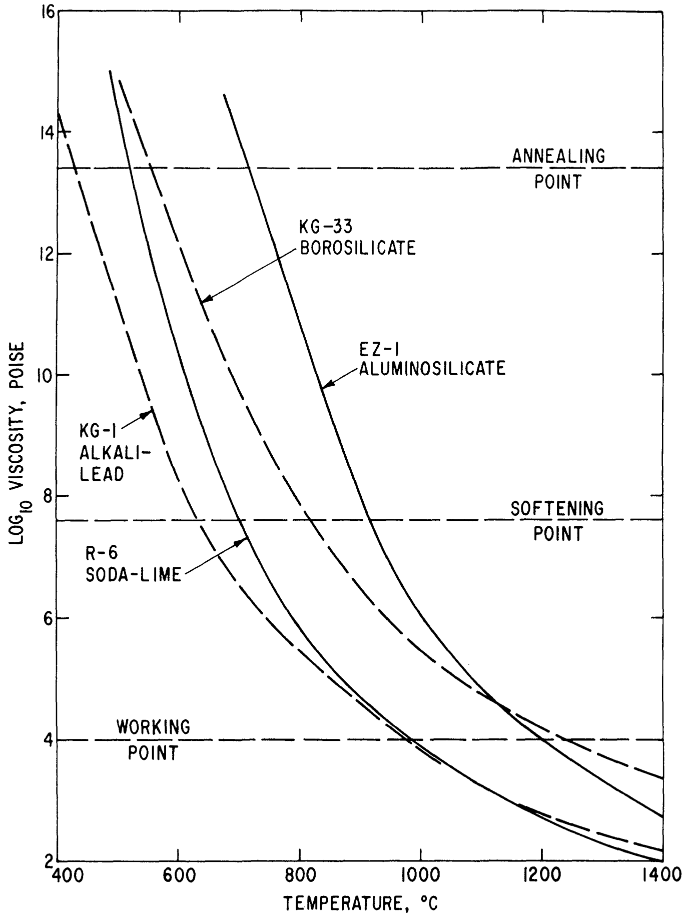

FIG. 1. Viscosities and special temperatures for some commercial silicate glasses.

Table 3. Activation energies for viscous flow of simple oxide glasses.

Glass	Activation energy (kJ/mole)	Temperature range (°C)
SiO_2	710	1100–1400
	515	1600–2500
GeO_2	310	540–1500
P_2O_5	174	545–655
B_2O_3	347–50	26–1300

The strengths of oxygen–central-atom bonds in the simple oxides such as SiO_2, GeO_2, P_2O_5, and B_2O_3 are about 100 kcal/mole. The very great difference in viscosity of these oxides is, therefore, quite surprising, since the mechanism of flow undoubtedly involves breaking of oxide bonds. The melting points of the crystalline oxides parallel the variations in viscosity: SiO_2 (cristobalite), 1710 °C; GeO_2 (hexagonal), 1116 °C; P_2O_5, 580 °C; B_2O_3, 450 °C. The differences indicate that the detailed structure of the oxide network is also important in determining the ease of viscous flow and bond breaking.

The viscosities of the simple oxides decrease sharply with the addition of most impurity ions. Such impurities as water, in the form of —OH groups, and alkali oxides are particularly effective in lowering the viscosities. Zinc and boric oxides among the multivalent oxides are particularly effective in lowering the viscosity of silicates.

The activation energy for viscous flow in multicomponent silicate glasses decreases as the temperature is increased. At low temperatures where the viscosity is about 10^{12} P the activation energy for flow of sodium silicate glasses is about 100 kcal/mole, and it decreases to 50 kcal/mol or less at high temperatures where the viscosity is about 100 P.

The viscosities of a number of non-oxide glasses drop very sharply at temperatures above the glass transition temperature; examples are zirconium fluorides and nitrates, and many molecular organic glasses, such as butyl benzene. These materials have bonds that are easily exchanged between the first and second coordination shell, as compared with the network glasses such as silicates, perhaps explaining this rapid decrease of viscosity with increasing temperature.

The empirical equation

$$\eta=\eta_0\exp[B/(T-T_0)], \qquad (2)$$

where η_0 and B are temperature independent, has been found to fit viscosity data for glasses over certain temperature ranges. This equation is the basis for two theories of viscosity: one based on "free volume" and the other on entropy. However, Eq. (2) is inconsistent with experimental data on glass-forming liquids at high viscosities. In a variety of different glasses the activation energy for viscous flow becomes temperature independent at high viscosities just where Eq. (2) would predict it should vary most sharply. In at least two glasses, P_2O_5 and GeO_2, T_0 is zero, since Eq. (2) is valid over the whole viscosity range in which measurements were made.

Two more recent theories emphasize the importance of defects in the melt structure as they affect viscosity. Mott (1987) suggested that the concentration of broken Si—O bonds in vitreous silica increases as the temperature increases, and provides for easier flow. Brawer (1985) has proposed a change in coordination number of a glass constituent as the defect likely to result in flow, or at least in structural relaxation.

5.2 Glass Transition

As a glass-forming liquid is cooled, certain of its properties such as specific volume, enthalpy, heat capacity, and electrical conductivity change abruptly in a narrow temperature range. This temperature is called the glass transition or transformation temperature.

It is significant that the viscosity does not show an abrupt change at the glass transition temperature. This result suggests that the viscosity determines the rate at which properties relax, but may not be related to the magnitude of property changes under different conditions.

The glass transition temperature can be associated with the slowing down of rearrangements in the glass structure. The rate of these molecular rearrangements is closely associated with viscous flow, and indeed the glass transition temperature occurs at a viscosity of about 10^{13} P.

5.3 Stress Relaxation

When a glass is cooled rapidly from a temperature above the transition region into this region, it retains some properties of the higher temperature, and these properties "relax" to those characteristic of the lower temperature as a function of time. To study stress relaxation, Kurkjian (1963) rapidly twisted an annealed soda-lime glass silicate rod a certain amount with a known stress. The stress in the rod at this fixed twist and at a constant temperature was then measured as a function of time. The "instantaneous" initial stress S_0 was used to normalize the stresses at different temperatures. When this was done, the stress relaxation at different temperatures in the transition range fitted on the same master curve. Kurkjian fitted his stress S as a function of time by a sum of six exponential terms; the spectrum of relaxation times was the same for the different temperatures of the experiment. An empirical equation that is often used to describe relaxation processes in glass is

$$S=S_0 \exp[(-t/\tau)^b]. \tag{3}$$

In this equation there are only two independent parameters, the relaxation time τ and the exponent b. However, the data of Kurkjian cannot be described by a single value of b.

Two recent books by Scherer (1986) and Brawer (1985) give much detailed information on relaxation processes in glass.

6. STRENGTH OF GLASS: FRACTURE, FATIGUE, AND STRENGTHENING

6.1 Strength Distributions and Surface Treatments

When the failure stress of a number of glass samples is measured under identical conditions of sample preparation and loading, the failure stresses vary over a wide range of a factor of 2 or more. The strengths are often distributed symmetrically, and so they can be described by a normal (Gaussian) distribution,

$$P=(1/d\sqrt{2\pi})\exp[-(S-S_m)^2/2d^2]. \tag{4}$$

P is the probability of finding a sample of strength (failure stress) S, S_m is the strength of greatest probability, and d is a measure of the spread of the distribution, called the standard deviation, and is equal to the root mean square of deviations from the mean strength. The integral of Eq. (4) gives the fraction F of samples that break below the stress S. Another distribution function called the Weibull distribution has become quite popular in describing strength distributions:

$$F=1-\exp[-(S/S_0)^m], \tag{5}$$

where S_0 is a scaling factor and m is a measure of the spread of the distribution—the smaller m, the broader the distribution. For m larger than about 3 the Weibull distribution is nearly symmetrical and closely resembles the normal distribution.

When a glass surface is abraded or bombarded with particles, the strength of the glass is reduced. Alternatively, if glass samples are carefully prepared and kept "pristine," they have very high strengths. Many results up to 10^{10} Pa have been reported, and Hillig (1962) measured strengths of up to 1.5×10^{10} Pa at -196 °C for fused-silica rods 1 mm in diameter. These samples were flame-drawn from larger rods and carefully protected from contact with solids. It is spectacular to bend a 1-mm rod of glass into a closed loop. If one so much as touches the fiber lightly with a finger tip, it breaks at much lower stress.

The strength of ordinary or abraded glass can be substantially increased by etching with hydrofluoric acid. Etching leads to some samples with very high strengths, because flaws in their surfaces have been removed. However, samples etched in HF are highly sensitive to damage by handling, so that many etched samples have strengths lower than before etching because new and larger flaws have been introduced into their surfaces.

6.2 Observations of Fracture Surfaces

A fracture surface on glass shows several characteristic regions—an origin usually on the glass surface, as shown in Fig. 2, a smooth surface called the mirror, a misty region outside the mirror, and finally a region of coarse surface roughness, called hackle. The distance R from the fracture origin to the mirror-mist boundary (or the distance to the mist-hackle boundary) is related to the fracture strength S by the empirical equation

$$S\sqrt{R}=A, \tag{6}$$

where A is a constant for a particular brittle material and temperature. Values of about 2×10^6 N/m$^{3/2}$ were found for A for glass at

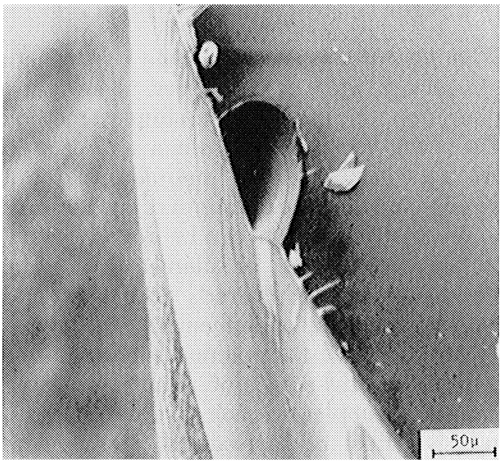

FIG. 2. Micrograph of a fracture origin in a soda-lime silicate glass. Region on the left is the glass surface; region on the right is the fracture surface.

room temperature. Apparently, A is not significantly dependent on temperature or glass composition.

Equation (6) is of considerable practical value because it allows one to make an accurate estimate of fracture stress without having to measure it directly. Thus for pieces with complex shapes where a stress analysis is difficult, or where load measurements are not possible, Eq. (6) is invaluable.

If a hard sphere is pressed against a glass surface, a crack around the contact region first develops and then grows into the glass in a conical shape. These cracks are called Hertzian cracks because the elastic stress distribution for contact of a hard sphere on a plate was calculated by Hertz.

If the indenter is sharp rather than spherical, the crack pattern is entirely different. A "median vent" crack propagates into the glass directly under the indenter during loading. When the load is released, winglike cracks called "lateral vents" propagate radially from the contact region. A region of the glass directly under the indenter is deformed in a particular way that is discussed in more detail in the section on plastic deformation in glass.

The impact of a hard spherical projectile gives damage with features of both spherical and sharp indenters. At low impact velocities Hertzian cone cracks are formed, but at higher velocities the cone cracks turn up at their ends and finally resemble the radial winglike cracks; at high velocities median cracks also propagate down into the glass.

When a hard object such as a diamond indenter is dragged across a glass surface, median and lateral cracks form along its track much as under an indenter. Abrasion of a hard surface against the glass also gives this kind of linear damage.

6.3 Fracture Criteria

The experimental results described above provide strong evidence that the surface condition of a glass determines its strength, and that flaws in the surface reduce the strength. These results therefore led to a model of surface cracks as the origin of brittle fracture. It is difficult to observe these cracks directly, and there still is uncertainty about their size, depth, and shape. Inglis (1913) solved the elastic problem of an elliptical crack subjected to a tensile strength S. He showed that the stress σ along the inside crack surface right at the tip is

$$\sigma/S = 1 + 2(c/\rho)^{1/2} \approx 2(c/\rho)^{1/2}, \tag{7}$$

in which c is the depth of the crack (semimajor axis of the ellipse) and ρ is the radius of curvature of the crack tip. If the crack is not elliptical in shape, Eq. (7) is still the proper form. Thus, if the crack is deep and has a sharp tip, the stress at the tip can be much higher than the applied stress. Various types of surface damage on glass give rise to cracks with different depths and tip radii, resulting in the influence of surface treatment on strength found experimentally. The stress drops off very sharply away from the tip along the crack surface. The stress also drops off sharply into the glass away from the crack tip. Thus, the stress is near the maximum value given by Eq. (7) in only a very small volume of the glass.

Measured strengths of glass samples are usually in the range of about 50–200 MPa, leading to design strengths less than 30 MPa. Strengths of up to 1.5×10^{10} Pa have been measured for vitreous silica at -196 °C, and theoretical strengths for silica calculated from various models are about 2.4×10^{10} Pa. The ultimate strength for soda-lime glass is about 1.6×10^{10} Pa, reflecting the lower Si—O bond density in this glass.

Another fracture criterion is based on the strain energy change in a stressed material caused by a crack. Griffith (1920) derived the equation

$$S_f^2 = 2E\gamma/\pi c \qquad (8)$$

for the fracture stress S_f in a material with a crack depth c, fracture surface energy γ, and Young's modulus E. This criterion is different from that of Inglis. In a treatment of crack energies and fracture criteria in terms of thermodynamic laws, it is shown that the Griffith equation provides a necessary but not sufficient condition for fracture, and that the Inglis equations provide the correct criterion for fracture (Doremus, 1976). The second law of thermodynamics shows that the fracture stress cannot be less than that given by Eq. (8), but can be greater.

6.4 Faulting

In contrast to tensile and bend tests of glasses, indentation of glass with a sharp point leads to some regions of deformation under the indenter that do not recover when the load is removed. This deformation in fused silica is apparently a "densification" that recovers completely on heating. In glasses with modifiers (alkali and alkaline earth oxides) this deformation can be partly a densification, but only a small part of the deformation recovers upon heating. More detailed examination of this deformed region under a sharp indenter shows that is made up of flow or fault lines between which there are only elastic strains (Hagan, 1979, 1980). This shear deformation under a concentrated compressive load is distinguished from other types of deformation and is called faulting, in analogy to geological faulting. The fault lines resemble geological faults and are quite different from slip in plastic deformation of crystals. Therefore, it seems important to distinguish this faulting deformation from plastic deformation in ductile crystals.

Viscous flow is much too slow in glass to cause appreciable deformation at ambient temperatures. The viscosity of commercial soda-lime glass at 490 °C is about 10^{15} P, with an effective activation energy of greater than 400 kJ/mole; the activation energy increases with decreasing temperature. Thus, the viscosity at room temperature is greater than 10^{59} P.

6.5 Fatigue

Fatigue in glass results when its strength deteriorates while it is stressed in an atmosphere containing water. The simplest method of studying fatigue in glass is a static test in which a constant load is imposed on a set of samples and the time of failure of each sample is recorded. Such tests can be done in bending, simple tension, or diametral loading; bending is easiest for rods and tubes and requires simple test equipment. Although static tests are the closest to practical situations they have the disadvantages of requiring a large number of samples for each of several stresses, and also must be carried out over a large spread of times, leading to long delays in obtaining results.

Fatigue can also be measured with samples tested at different loading rates; the dependence of fracture strength on loading rate is related to the stress-failure time relation in static loading. This method requires fewer samples and less time, but a testing machine with a linear load application is needed.

Failure times of Pyrex borosilicate glass rods in bending are shown in Fig. 3. Each point represents the mean of many measurements, usually forty or more. The results are plotted as reduced stress S/S_N against logarithm of fracture time, where S is the maximum stress in four-point bending and S_N is the mean fracture stress in the same test at -196 °C, where there is no fatigue. Humidity strongly influences the failure time. Rods of soda-lime glass all treated in the same way and all having a mean S_N of 86 MPa had mean failure times of 8.7, 200, and 3470 s in water, 43% r.h. (relative humidity), and 5% r.h. respectively, all at a stress $S/S_N=0.5$. Log$t_{1/2}$ is about linear with relative humidity over this range of humidities.

Surface treatment and sample history strongly influence the failure times of glass tested at the same relative humidity and relative stress S/S_N. Values of $t_{1/2}$, the time of failure at $S/S_N=0.5$, for soda-lime glass after different treatments range over five orders of magnitude, and there is no simple connection with inert strength S_N.

Experimental results on strength and fatigue of very strong silica (pure SiO_2) seem to be influenced by the chemical treatment of the silica surface. Just touching lightly the surface of a pristine silica rod greatly lowers it strength.

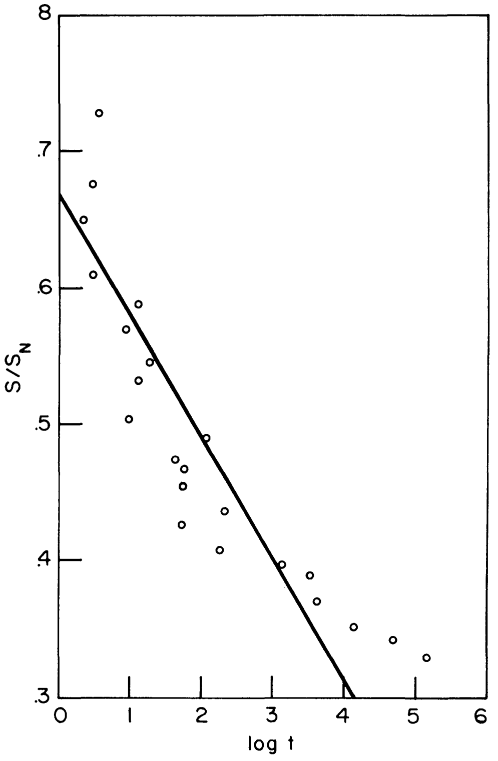

FIG. 3. Mean log(failure time) of Pyrex borosilicate glass as a function of normalized applied stress.

Silica fibers for use as waveguides are usually coated with an organic polymer to reduce their susceptibility to fatigue. These coatings reduce fatigue at short times, but at longer times, at higher temperatures, and in alkaline media the coatings are attacked, and the fatigue becomes more like that of uncoated silica.

The failure times of glass samples that are tested under identical conditions and that have identical treatments still show a large spread. This spread is related to the distribution in fracture strengths discussed above. These spreads can also be treated in statistical terms, and usually fit normal or Weibull statistical distributions.

6.6 Strengthening

Removal of surface flaws in glass by fire polishing or chemical etching leads to very strong material, but the surface can be easily damaged again, so that these methods are not practical unless the surface is immediately protected by a coating, as it is in drawing fiber glass. If the glass surface is treated to increase compressive stress in it, a higher tensile stress is required for crack propagation. Surface compressive stress can be introduced by rapid quenching, by ion exchange, and by surface crystallization. During rapid quenching, first the surface cools to a rigid state, and then the interior cools and tries to shrink, but is restrained by the already rigid surface layer. In ion exchange a large ion such as potassium is exchanged from a fused salt for sodium ions in the glass; the profile and level of stress can be controlled more easily than for quenching.

7. ELECTRICAL PROPERTIES AND IONIC TRANSPORT

7.1 Ionic Conductivity

The electrical conductivities of most oxide glasses result from the transport of monovalent cations such as sodium in them. Lithium ions are also quite mobile in glasses. Potassium and hydrogen ions sometimes carry current, but their mobilities are usually much less than those of sodium and lithium. Even in oxide glasses with no nominal addition of alkali, the conductivity results from transport of monovalent cations. In vitreous silica, electrolysis experiments show that sodium and lithium ions are the conducting species, even though they are present at concentrations of a few parts per million.

If the electrical current in a glass is carried by a single ionic species of concentration c and diffusion D, the electrical conductivity σ is given by the Einstein equation:

$$\sigma = Z^2F^2Dc/RT, \tag{9}$$

in which Z is the ionic valence, F is the Faraday, R the gas constant, and T the absolute temperature. Equation (9) agrees well with conductivity and diffusion coefficient measurements in vitreous silica, Pyrex borosilicate, and a commercial soda-lime silicate glass (see Doremus, 1973, for a review). However, many other experimental measurements have found that the conductivity must be multiplied by a factor f less than 1, often from about 0.3 to 0.7. Different workers have found different f values for the same glass. The reasons for these f values less than one are uncertain.

Below the glass transition temperature the conductivity fits an Arrhenius equation:

$$\sigma=\sigma_0 \exp(-Q/RT) \qquad (10)$$

with activation energy Q and preexponential σ_0 independent of temperature. Typical Q values for sodium and lithium transport are from 60 to 100 kJ/mole. At temperatures above the glass transition the conductivity no longer follows Eq. (10), as shown in Fig. 4. At T_g there is a discontinuous increase in activation energy, and then a continuous decrease as the temperature is increased further.

Stress or pressure influences electrical conductivity of glasses. Quenched glass has a lower density and higher conductivity than annealed glass, and compaction by hydrostatic pressure leads to lower conductivity.

At a particular temperature the electrical conductivity and alkali-ion mobility in a silicate glass increase with increasing alkali concentration. This increase corresponds with the decrease in glass viscosity as alkali is added, caused by breaking up of the silicon-oxygen network by the alkali oxide.

The addition of an oxide of a higher-valent metal ion to an alkali silicate glass tends to decrease the mobility of the alkali silicate glass and thus the electrical conductivity. For the alkaline-earth ions the decrease is related to ion size; the larger the ion, the greater its blocking action. Addition of aluminum oxide to the glass increases ionic mobility and conduction and decreases the activation energy for ionic transport.

When a second alkali oxide is added to an alkali silicate glass, the conductivity decreases sharply. This "mixed-alkali" effect is caused by a decrease in the mobility of the most mobile ion in the glass.

Anions and cations of valence greater than 1 diffuse much more slowly than monovalent cations in silicate glasses.

In zirconium fluoride glasses the conductivity is ionic, and the fluoride ion is the most mobile.

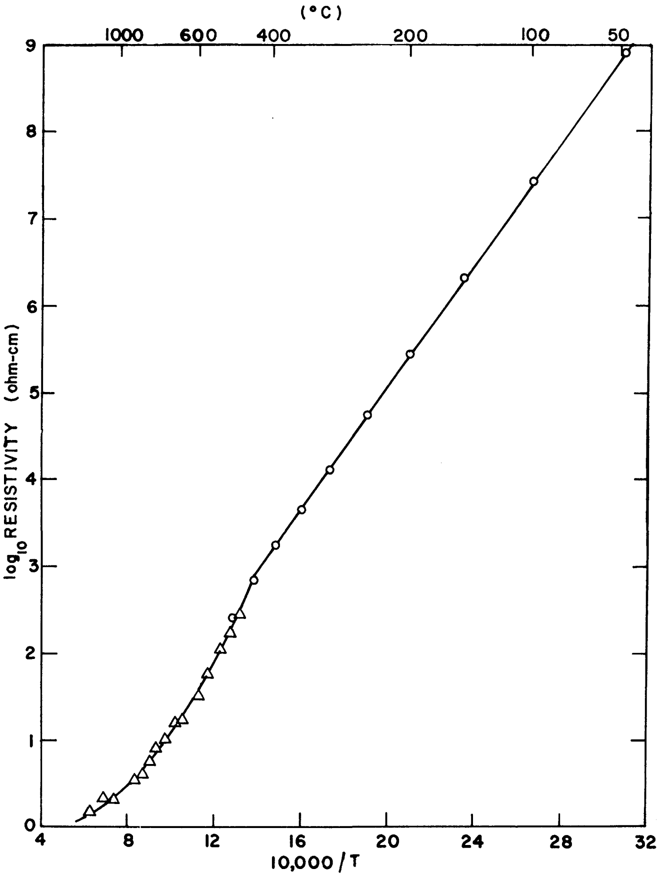

FIG. 4. Log (resistivity) of a 26.5 wt% Na_2O, 73.5% SiO_2 glass as a function of reciprocal temperature. From Doremus (1973), p. 155. T_g is 475 °C. Symbols show two different sets of measurements.

7.2 Electronic Conductivity

Certain oxide glasses containing multivalent transition metal ions are electronic conductors. Examples are barium vanadate ($BaO{\cdot}2V_2O_5$), 0.6 $V_2O_5{\cdot}0.4\ Te_2O$, and various vanadium phosphates. Also vanadium, iron, cobalt, and manganese oxides in silicate, borate, or phosphate glasses show electronic conductivity.

Chalcogenide glasses containing the Group VI elements sulfur, selenium, and tellurium alone or in combination with Group V elements phosphorus, arsenic, antimony, and bismuth, as well as other elements such as thallium and germanium, are electronic conductors. These glasses have Arrhenius temperature dependence of their conductivities, as do intrinsic semiconductors, but their conductivity is insensitive to impurities. These glasses also show a variety of switching and memory effects, as summarized in Mott and Davies (1971).

7.3 Dielectric Properties

One kind of dielectric loss in glass is closely related to electrical conductivity in the glass. The peak frequency has the same activation energy as the electrical conductivity. This loss is present in both ionic and electronic conducting glasses, and is similar to peaks found in a wide variety of dielectric materials. There are also special low-temperature loss peaks in oxide glass.

8. CHEMICAL PROPERTIES

8.1 Surfaces

Many properties of glass, such as strength, fatigue, chemical durability, and reflectivity, are strongly influenced by surface processes. The metal-oxide groups at the surface of an oxide glass are invariably hydrated, for example, to form SiOH groups. These groups can be isolated or linked with hydrogen bonds; water molecules can also absorb physically on them. Other gases such as halogens, organics, nitrogen, and even inert gases can absorb physically on glass surfaces (Dunken, 1985).

Chemical reactions with the hydroxyl groups on oxide glass surfaces can replace the hydrogen atom with a halogen or organic group. Si—O bonds in the surface can be split by reactions with water or ammonia. Silanes react with silicate surfaces to form adsorbed organic molecules, and can condense to siloxane polymers.

8.2 Diffusion and Reactions of Gases in Glasses

Gases can dissolve and diffuse molecularly in many oxide glasses because of their open structure. Table 4 gives solubilities and diffusion properties of a large range of molecular sizes and chemical types in vitreous silica. The molecular solubility is almost constant with temperature, and is reduced somewhat as the molecule becomes larger. These properties are consistent with a model of lodging of gas molecules in interstices in the glass. Diffusion is strongly influenced by molecular size. The square root of the activation energy of diffu-

Table 4. Solubility and diffusion coefficients of gases in amorphous silica.

Gas	Diameter (nm)	Solubility	Diffusion coefficient @ 1000 °C (cm^2/s)	Activation energy for diffusion (kJ/mole)
Helium	2.0	0.025	5.5×10^{-5}	20
Neon	2.4	0.020	2.5×10^{-6}	37
Hydrogen	2.5	~0.03	7.3×10^{-6}	36
Water	~3.0		$3\ \times10^{-7}$	71
Argon	3.2	0.01	1.4×10^{-9}	113
Oxygen	3.2	0.01	6.6×10^{-9}	108
Nitrogen	3.4			109
Krypton	4.2			~190
Xenon	4.9			~300

sion in vitreous silica is directly proportional to molecular size for a wide variety of gas molecules. This dependence is found in a model of jumping of molecules from one interstice to another in the glass through connecting "doorways."

Some gases can react with the silicon-oxygen network when they are dissolved in it. Examples are water, hydrogen, oxygen, and nitrogen, roughly in order of their reactivity with the Si—O bonds. Carbon dioxide and sulfur dioxide can react with constituents of the glass such as alkalis, forming, for example, sodium sulfate or sodium carbonate in the glass. Reactions of water are discussed in the next subsection. Hydrogen reacts with the silicon-oxygen network to form SiOH and SiH groups.

The concentration of dissolved molecular oxygen in a glass determines its state of oxidation. After holding for hours at glass melting temperatures the glass equilibrates with the surrounding atmosphere, and has a uniform concentration of dissolved oxygen. When the glass is cooled, the state of oxidation is determined by this oxygen concentration developed during glass melting, because the diffusion of molecular oxygen in the glass is too slow to reach equilibrium. A variety of multivalent ions change their oxidation states in response to a changing oxygen concentration in glass. A list of these ions in their oxidized state is Cr^{+6}, Mn^{+3} , Ce^{+4}, As^{+5}, Sb^{+5}, Fe^{+3}, Sn^{+4}. This list is in the order of difficulty of oxidation, chromium being the easiest to reduce and tin the easiest to oxidize. Often the ratio of amounts of ions in different oxidation states can be measured from optical absorption bands characteristic of these states, giving different colors to the glass, as described in the section on optical properties.

8.3 Reaction of Glass with Water

The surfaces of all oxides are hydrated to groups such as SiOH by reaction with water, as mentioned above. Water reacts readily with silicon-oxygen-silicon bonds to form two SiOH groups. Thus measurements of dissolved molecular water, for example by infrared absorption, give results much greater than the amount of dissolved molecular water because of this reaction.

Liquid water and water vapor exchange and interdiffuse with alkali ions in the water:

$$Na^+(\text{glass}) + H_2O = H_3O^+(\text{glass}) + NaOH. \tag{11}$$

In water vapor the sodium hydroxide deposits on the glass surface and reacts with atmospheric carbon dioxide to form sodium carbonate crystals (Husung and Doremus, 1990). The evidence for hydronium ion exchange comes from hydrogen profiles from nuclear resonant reactions on glasses rapidly chilled from the reaction temperature to prevent outgassing of water (Schnatter *et al.*, 1988). The sodium and hydronium ions interdiffuse in the glass, leading to depletion of sodium in the outer layers of the glass and its deposition on the surface. The interdiffusion can be described by the Nernst–Planck equations.

In liquid water or aqueous solutions oxide glasses also dissolve congruently—that is, the glass constituents dissolve in the solution in the same proportion as they exist in the glass. The rate of dissolution depends strongly on glass composition. A sequence of increasing dissolution rates at *p*H 7 (slowest dissolving first) is obsidian glass, crystalline quartz, and aluminosilicate minerals < vitreous silica, soda-lime glass containing alumina < soda-lime glass without alumina ≪ binary alkali silicates (Perera *et al.*, 1991). The rate of dissolution of silicate glasses increases in alkaline solution, corresponding to the increase in silica solubility as H_4SiO_4 (silicic acid) ionizes more at higher *p*H.

9. OPTICAL PROPERTIES

9.1 Vitreous Silica

Amorphous silica is highly useful as an optical material and for fiber-optic waveguides because of its high transmission of ultraviolet, visible, and near-infrared light. The transmission edge in the ultraviolet depends on the purity and oxidation state (stoichiometry) of the silica. Transition metals absorb intensely in the ultraviolet, and so they must be absent for high transmission. In silicas melted under neutral or reducing conditions, an absorption band at 0.24 μm has been associated with reduced impurities (aluminum or germanium) or an intrinsic center of a trapped electron or hole near a vacancy.

An absorption band at 11.5 eV in the ultraviolet is apparently intrinsic to the silicon-oxygen network, and therefore may be characteristic of the band gap of the vitreous silica.

In the infrared, silica has an intense absorption band at about 1100 cm^{-1} present in all silicates and assigned to the stretching vibration of the Si—O—Si bond. A band at wave number 465 cm^{-1} has been assigned to the "rocking" of the Si—O—Si bond. Lower-intensity bands at intermediate wave numbers involve various mixed vibrational modes.

9.2 Other Network-Forming Oxides

The appropriate ultraviolet absorption edges of simple oxide glasses are SiO_2, 0.16 μm; B_2O_3, 0.17 μm; P_2O_3, 0.27 μm; GeO_2, 0.22 μm.

The infrared spectrum of vitreous germania is similar to that of silica but shifted to lower frequencies, with an intense absorption band at about 880 cm^{-1} resulting from Ge—O—Ge stretching vibrations.

Boron oxide, B_2O_3, has strong infrared absorption bands at 1260 and 718 cm^{-1}, with a broad band at lower frequencies and a shoulder on the 1260-cm^{-1} band at about 1370 cm^{-1}. The Raman spectrum shows an intense band at 808 cm^{-1} and a strong band at 1260 cm^{-1}. These bands can be interpreted as resulting from a boroxyl network structure of B_2O_3. In this structure planar boroxyl (six-member B—O) rings are linked by other B—O bonds. The band at 1260 cm^{-1} is assigned to the stretching vibration of the B—O bonds linking the rings. The 808-cm^{-1} Raman band results from a "breathing" motion of the oxygen atoms in the boroxyl ring that is inactive in the infrared.

9.3 Alkali Silica Glasses

As alkali oxide is added to silica the infrared absorption band at 1100 cm^{-1} decreases and new bands at 1075 and 940 cm^{-1} develop. The band at 940 cm^{-1} has been assigned to the Si–O stretching vibration when the oxygen is not bonded to another silicon (nonbridging oxygen), and the 1075 cm^{-1} band is the 1100 cm^{-1} Si–O stretching band shifted by the presence of SiO Na^+ groups.

The optical density in the ultraviolet at wavelengths longer than the absorption edge at 0.16 μm for vitreous silica is directly proportional to the amount of alkali in the glass. This absorption is interpreted as resulting from the nonbridging oxygen ions introduced by the alkali additions.

9.4 Transition-Metal Ions and Color

Transition-metal ions color glass a variety of hues, as shown in Table 5. Thus, the green color of thick sections of most commercial glasses is caused by ferric iron ions. Other familiar colors are chromium for green, manganese for purple, and copper and cobalt for blue. The visible absorption bands listed in Table 5 result from electronic transitions of the 3*d* electrons. When the transition-metal ions are coordinated with other ions such as oxygen in the glasses, the energy levels of the *d* electrons are split by the electric field or "ligand field" of the coordinating ions, instead of being degenerate as in the free ion. The *d*-electron orbitals are strongly directional, and so the splittings are sensitive to the arrangements of the surrounding atoms.

9.5 Applications

Glass has long been an important optical material because of its transparency, stability, and chemical durability. The refractive index of glass can be varied over a wide range. A recent application of glass as a fiber-optic waveguide for communications is replacing metal cables for telephone lines. The development of very pure, strong vitreous silica fibers for this application by Bell Labs and Corning Glass was a *tour de force* of technology. The fibers, as small as 10 μm in diameter, have a different surface composition with a higher refractive index to improve the wave guiding

Table 5. Colors and absorption bands for transition-metal ions in silicate glass.

Ion	No. of *D* electrons	Absorption maxima (μm)	Color of glass
Cr^{3+}	1	0.66, 0.45	Green
Ti^{3+}	1	0.57	Purple
V^{4+}	1	1.12	Red
V^{3+}	2	0.645, 0.425	Green
Mn^{3+}	4	0.50	Purple
Mn^{2+}	5	0.435	Brown
Fe^{3+}	5	0.41	Green
Fe^{2+}	6	1.10	Blue
Co^{2+}	7	0.6	Blue
Ni^{2+}	8	0.68–0.49	Purple, grey
Cu^{2+}	9	0.79	Blue

properties of the fiber. The fibers are drawn in very long lengths (up to a kilometer) from a preform of larger diameter and controlled composition and impurity level. Intrinsic scattering and absorption are a minimum at a wavelength of about 1 μm, at which the signals are transmitted.

Zirconium fluoride and some chalcogenide glasses are much more transparent in the infrared than silicate glasses; silicates have an absorption edge at about 4 μm, whereas the fluorides are transparent to about 8 μm. This property makes the zirconium fluoride glasses attractive candidates for fiber-optic waveguides, because they have lower minimum absorption. This potential is difficult to realize because the glasses must be highly pure and contain no scattering centers such as crystallites or pores.

Glass can be used in many applications related to lasers: as a host for laser ions that lead to active devices such as oscillators, amplifiers, and Faraday rotators, and as an optical material for fibers, lenses, windows, and thin-film waveguides. Glass can dissolve a wide variety of laser ions, and is useful for high energy storage and high peak power. The spectral distribution of laser light from a glass is usually broader than from a crystal, because of the disordered glass structure. The low thermal conductivity of glass limits its use to pulsed operation with average power.

9.6 Nonlinear Optical Properties

Glasses with certain optically absorbing compounds show nonlinear optical properties at high light intensities. An example is glasses containing cadmium sulfide or selenide; apparently small (~few nm) crystals of these compounds impart nonlinear properties to the glass.

GLOSSARY

Annealing: Removal of stress in a glass by heating it at a temperature just above the glass transition temperature.

Chalcogenide: Compound of sulfur, selenium, or tellurium.

Devitrification: Nonuniform crystallization of a glass.

Faulting: Shear deformation in which planes of broken bonds form along particular directions.

Fiber-Optic Waveguide: Fine fiber of glass for conducting optical signals.

Fining: Removal of bubbles in a glass melt.

Float Glass: Flat glass made by floating a sheet of molten glass onto a bath of molten metal, usually tin.

Glass Ceramics: Uniformly crystallized glasses; can be partially glassy; crystal grains usually small (microns).

Glass Transition Temperature: Temperature at which glass properties change discontinuously. Can be taken as the temperature at which the viscosity is 10^{12} Pa s.

Hertzian Cracks: Cone cracks made by pressing a spherical indenter against a brittle solid.

Liquidus: The temperature above which a mixture consists of a single liquid phase. In a phase diagram, the temperature-composition line above which temperature there is a single phase, and below which crystallization starts.

Nonbridging Oxygen: An oxygen atom bonded to only one silicon atom.

Random Network: The amorphous structure of atoms bonded into a network that shows no order beyond a few atomic dimensions.

Soda-Lime Glass: A glass made from silica sand, sodium oxide, and calcium oxide, with other oxides possible.

Sol-Gel Fabrication: Making a glass from organic compounds that form a gel from a liquid solution.

Spinodal Decomposition: A phase transition in which a single multicomponent phase forms two interconnected phases. The spatial extension of the phases is constant with time, but their compositions change.

Tank: A large container for melting glass continuously.

INTRODUCTION

Grain boundaries are interfaces between identical crystals (or grains) that have different orientations. An example is shown in Fig. 1. They are a subset of solid-solid interfaces and share many features (most notably in terms of geometry) with phase boundaries, which are interfaces between unlike crystals. All such interfaces are commonly regarded as defects in crystals, reflecting a tradition of referring all structures to some ideal case or "reference structure," which is usually that of the perfect crystal. There is an important thermodynamic distinction between grain boundaries and phase boundaries, their geometric similarity notwithstanding: phase boundaries may exist in thermodynamic equilibrium, where a crystalline solid has two coexisting phases, but grain boundaries never exist in a single-phase solid in its thermodynamic ground state. In this sense, at least, grain boundaries truly are defects in crystalline solids. Grain boundaries usually exist in crystalline solids for kinetic reasons, and it is only through the application of elaborate precautions that single-crystal materials can be produced. Likewise, phase boundaries may never be able to reach a stable state and their structures are likely to be controlled by the kinetics of the phase transformation that creates them.

Although commonly regarded as planar or two-dimensional defects, grain boundaries are often not flat but may be curved or faceted, so that they frequently do not lie in a mathematical plane. They also may have finite width ranging between a few atom diameters and several hundred nanometers, depending upon

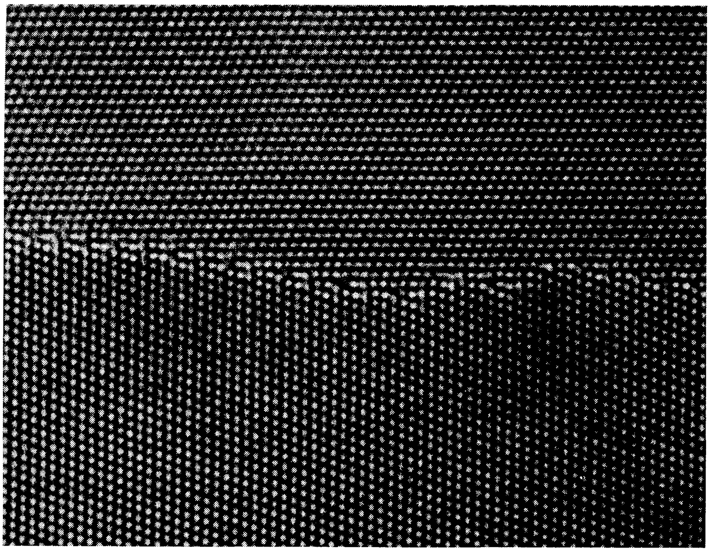

FIG. 1. Atomic-resolution electron micrograph of a tilt grain boundary in aluminum. Each white dot is a column of aluminum atoms, and the crystals are viewed along a common ⟨110⟩ direction, which is also the rotation axis. The rotation angle in this case is 90°. (Micrograph courtesy of Dr. Ulrich Dahmen of the National Center for Electron Microscopy at the Lawrence Berkeley Laboratory.)

the definition of "width" and measuring technique. These quibbles aside, however, the terms "planar" or "two-dimensional" do broadly describe the morphology of these defects. Grain boundaries form three-dimensional networks in polycrystalline materials, very much akin to the networks of liquid films that constitute foams.

The importance of grain boundaries lies in their effect upon a variety of material properties including strength, diffusion, and electrical conductivity. The net impact of these effects is great, because of the natural abundance of grain boundaries, and it was such effects that were first studied by Rosenhain, nearly a century ago (see, e.g., Ewing and Rosenhain, 1901). A typical engineering metal or ceramic is polycrystalline with a mean grain diameter of a few tens of microns. (The grain size is usually controlled in processing to optimize at least one property of the material.) At a grain size of 20 μm, a wedding ring of half a cubic centimeter contains approximately 500 cm^2, or about half a square foot, of grain boundary. As grain size is reduced, the area of grain boundary contained in any piece of solid crystalline material increases, and a subject of current importance is the preparation and properties of "nanocrystalline" materials with grain sizes in the range of nanometers and grain-boundary contents of the order of thousands of square meters per cubic centimeter.

In this brief review we will concentrate upon the structure and properties of grain boundaries rather than their control for engineering purposes. The latter subject remains at a very rudimentary stage of development, though with a great deal of potential at the time of writing (in the early 1990s).

1. GRAIN-BOUNDARY PARAMETERS

1.1 Crystal Misorientation

Grain boundaries are characterized in terms of the relative orientations of the crystals that they separate and the orientation of the grain-boundary plane. In most cases only bicrystals are addressed in present-day studies; one of the two crystals is designated as "crystal 1," while the other is "crystal 2." The default choice of reference frame for geometrical purposes is usually the natural axis system of crystal 1. It is always possible to find a simple rotation operation that would give the orientation of crystal 2 from the starting point of crystal 1 in the case of grain boundaries. Such rotation operations describe the misorientation of crystal 2 with respect to crystal 1, and may be described either as an axis-angle pair (where the axis is defined as a crystallographic direction in crystal 1, and the angle is the right-handed rotation about that axis that would bring crystal 1 into the orientation of crystal 2) or equivalently as a rotation matrix

R. Thus, for example, two equivalent descriptions of the same misorientation in cubic crystals might be

$$70.53°;[110]\equiv R=\begin{bmatrix} 0.67 & 0.33 & 0.67 \\ 0.33 & 0.67 & -0.67 \\ -0.67 & 0.67 & 0.33 \end{bmatrix} \tag{1}$$

The matrix product of any vector in crystal 1 with *R* gives the equivalent vector in crystal 2, but still referred to the axis system of crystal 1:

$$RX(1)=X(2). \tag{2}$$

Because of crystal symmetry, there may be more than one description of the misorientation of any grain boundary. For example, in the case of cubic crystals there may be 24 equivalent choices of axis systems in each crystal, meaning that there are as many as 1152 ($=2\times24^2$) possible descriptions of the misorientation between two cubic crystals. It is convenient to choose one particular description of the misorientation between two crystals, and this description has been dubbed the "disorientation." The disorientation is that description of the misorientation that embodies the smallest angle of rotation of all 1152 choices, and has the axis of rotation described as [*uvw*], where $u \geqslant v \geqslant w \geqslant 0$. The disorientation corresponding to the example given above is 60°; [111]. A distinction is often drawn between small-angle grain boundaries and large-angle grain boundaries, the latter having disorientation angles larger than approximately 15°.

1.2 Grain-Boundary Plane

Once the misorientation of two crystals is fixed, the orientation of the grain-boundary plane must be determined. The boundary plane is conventionally expressed as a crystallographic plane, relative to crystal 1. Grain-boundary planes are described as symmetrical or asymmetrical, depending on whether they have the same crystallographic form $\{hkl\}$ in both crystals. "Symmetrical" boundary planes need not contain crystal symmetry elements, and "asymmetrical" boundary planes need not be entirely devoid of them. Grain boundaries are commonly described as "tilt boundaries" when the boundary plane contains the axis of misorientation, and "twist boundaries" when the misorientation axis is perpendicular to the boundary plane, as illustrated in Fig. 2. Boundaries fitting neither description are sometimes described as having mixed character. While the distinction between tilt and twist grain boundaries is frequently useful, it must be remembered that such a description refers only to one particular description of the misorientation: a boundary that can be described as "twist" with respect to the disorientation can also have a "tilt" description with respect to another fully equivalent misorientation and a "mixed" description with respect to a third.

It is often convenient to define the grain-boundary plane normal **n**, which is a unit vector perpendicular to the boundary plane, pointing in the direction from crystal 1 into crystal 2.

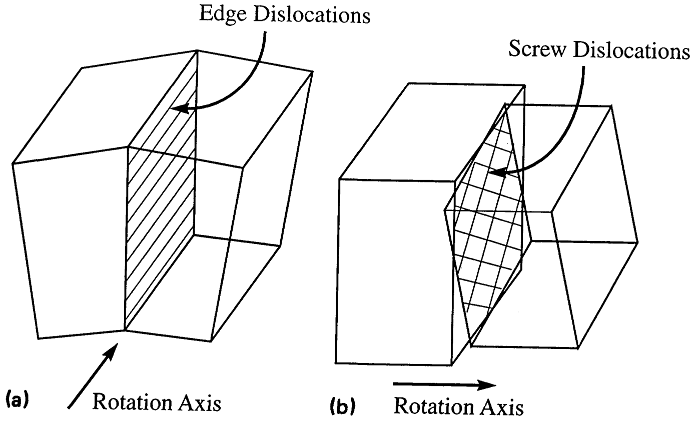

FIG. 2. Schematic diagrams showing (a) a symmetrical tilt grain boundary and (b) a twist grain boundary, and the dislocation arrays that they are normally expected to contain.

1.3 Macroscopic Degrees of Freedom

A grain boundary has five degrees of freedom with respect to crystallographic orientations, and these are now referred to as the macroscopic degrees of freedom, in contrast with the four additional microscopic degrees of freedom described below. Three of the macroscopic degrees of freedom relate to the relative orientation of the two crystals: two for the axis and one for the angle. The remaining two degrees of freedom relate to the orientation of the grain-boundary plane, which can be described by a single unit vector. It is possible through a variety of means to grow bicrystals in which all of the five macroscopic degrees of freedom of the grain are controlled.

2. GRAIN-BOUNDARY PROPERTIES AND BEHAVIOR

Grain boundaries have profound effects upon many aspects of material behavior and performance. In certain circumstances it is desirable to increase the density of boundaries in a material, while in others the opposite is true. We consider first the intrinsic properties of grain boundaries and then their effects upon material properties.

2.1 Energy

There is a free energy per unit area associated with every grain boundary, and it is usually denoted as γ. The grain-boundary energy varies with material, purity, grain-boundary parameters, and temperature, but for most metals it typically takes values in the range of about 0.5 $\mathrm{J\,m^{-2}}$. This energy is somewhat akin to a surface tension in that it always tends to minimize the grain-boundary area. Where three grain boundaries meet (a "triple line") the angles formed by the three boundary planes are determined by the relative energies of the grain boundaries. The variation of γ with misorientation is sufficient to cause the rotation of small single-crystal balls welded to single-crystal substrates as the energy of the intervening grain boundary is minimized (Herrmann *et al.*, 1975).

Because grain-boundary energy is a function of purity, it may be reduced through the segregation of impurity elements to the grain boundary. It is commonly the case that the composition of an alloy varies between the grain boundaries and the grain centers, and in many cases an impurity may be located exclusively in the grain boundaries of a specimen.

2.2 Mobility

Grain boundaries are able to move in response to various driving forces that might be applied to them. Atoms jump across the boundary from the shrinking crystal to the growing one, moving the boundary in the opposite direction. This is a thermally activated process and is typically observed at temperatures greater than half of the absolute melting temperature of the material. The mobility of grain boundaries depends upon the boundary parameters and on the purity of the material. Grain-boundary mobility is particularly sensitive to small amounts of impurity, which give rise to the "solute drag effect."

Mobility enables grain boundaries to move through a deformed material in response to the driving force provided by the strain energy stored in the crystals during the deformation process. This is called recrystallization. Grain-boundary migration leaves in its wake relatively defect-free crystals, which therefore contain lower strain energy, and the difference in energy between the deformed and recrystallized materials provides the driving force for grain-boundary migration. In contrast, the driving force for the process known as grain growth derives from the grain-boundary energy itself. As the grain size increases, the grain-boundary area and hence the total grain boundary energy are reduced. As with recrystallization, though, grain growth is effected by grain-boundary migration.

2.3 Diffusion

The transport of solute through a solid solvent, or the transport of atoms of the solid itself, occurs through the process of diffusion. At high temperatures, above two-thirds of the absolute melting temperature of the solvent, diffusion occurs predominantly through the crystal lattice, but below approximately half of the melting temperature, atom transport via the grain boundaries predominates, and the process is sometimes referred to as "short-circuit" diffusion.

Grain-boundary diffusion follows a modified form of Fick's law:

$$J = -D_{gb}\delta \frac{\partial C}{\partial x}, \tag{3}$$

where J is the diffusive flux, D_{gb} is the grain-boundary diffusivity, δ is a term with units of length, C is the solute concentration, and x is a distance measure. The value of δ is often identified with a "grain-boundary width" but in fact it is simply a term included in the equation to maintain dimensional consistency. It is usually only possible to determine the value of the product $D_{gb}\delta$ from an experiment, and the two terms cannot be disaggregated. Grain-boundary diffusion predominates at low temperature because of the small activation energy relative to that of bulk diffusion. It is mechanistically related to grain-boundary migration, although atomic jumps take place predominantly across the boundary in the case of the latter but along the boundary in the former. $D_{gb}\delta$ is found to depend upon the grain-boundary parameters, in some cases quite sensitively (Herbeuval *et al.*, 1973).

In a curious phenomenon known as diffusion-induced grain-boundary migration (or DIGM), grain-boundary diffusion is found to produce grain-boundary migration as a by-product (King, 1987). This results in the solute borne by the boundary being deposited in its wake, creating locally alloyed (or de-alloyed) regions.

Grain-boundary diffusion is capable of transporting atoms through significant distances at moderate temperatures, and it is a matter of some concern in the design of integrated circuits, where length scales are very small. In certain cases grain-boundary diffusion is important in the formation of circuit components, while in others it can be a mechanism for their failure. With ever-shrinking device dimensions, current densities in integrated circuits have increased markedly, and heat production is significant. This results in the devices running at temperatures in the range where grain-boundary diffusion occurs in certain of the component materials. A particular manifestation of grain-boundary diffusion in these devices is the phenomenon of electromigration, in which atoms drift in response to the electron "wind" in a conductor line. This drift is particularly problematical in aluminum interconnections, where the atom flux is carried along the grain boundaries and results in significant stress buildup in the material. A variety of different types of failure ensue from this phenomenon.

In addition to facilitating the buildup of stress in materials, grain-boundary diffusion can be an important mechanism by which a material responds to stress, as we shall see in the next section.

2.4 Strength of Materials

At low temperatures and high loading, grain boundaries act as barriers to crystal deformation, by impeding dislocation motion. As grain size decreases, the yield strength of a crystalline solid increases according to the Hall-Petch relationship (Hall, 1951; Petch, 1953):

$$\sigma_y = \sigma_i + k_y\, d^{-0.5}, \tag{4}$$

where σ_i is the lattice friction stress, d is the mean grain diameter, and k_y is a constant. Under these conditions, then, grain boundaries are desirable features in a material.

Grain boundaries promote brittle fracture, however, by providing an easy path for the propagation of cracks. The excess energy of fracture that is required to form two new surfaces is reduced by the grain-boundary energy that is released in fracturing the specimen. Grain-boundary fracture is especially promoted by segregating elements such as phosphorus and sulfur in iron. In the case of boron in the ordered alloy Ni_3Al, however, the impurity seems to have the opposite effect, removing the intrinsic propensity of the material to grain-boundary brittleness (Aoki and Izumi, 1979).

At high temperatures and low stresses grain boundaries become undesirable with respect to material strength. First, they become a locus of deformation because they allow the viscous sliding of one grain over another. This is a significant mode of failure in hot wires and filaments, which can develop a "bamboo" structure in which grain boundaries extend across the whole width of the material. Sliding on these boundaries causes a reduction of load- and current-bearing area as illustrated in Fig. 3. This increases the stress at the boundary (and also increases the temperature if the material is heated by the Coulomb effect), which eventually causes the separa-

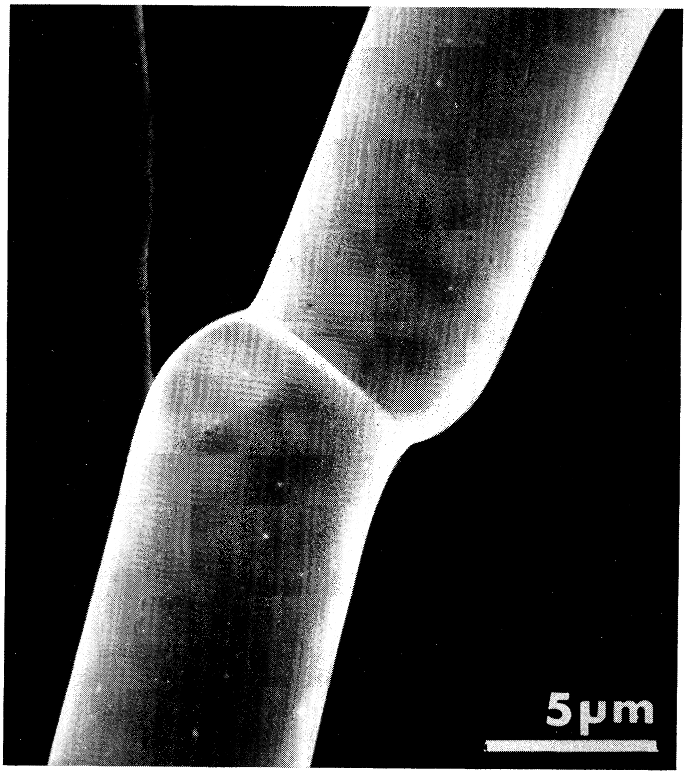

FIG. 3. Illustration of grain-boundary sliding in a thin gold wire. The grain boundaries in this "bamboo structured" specimen extended all the way across the wire and allowed for unconstrained sliding upon the application of stress at a temperature close to the melting point.

tion of the material. Filaments for incandescent lights are made from tungsten doped with impurities such as potassium that help to prevent grain growth and preserve a structure of long thin grains extending along the wire axis, which helps to prevent sliding of the type seen in Fig. 3. It is found that grain-boundary migration often accompanies sliding.

The second contribution of grain boundaries to creep deformation arises from their acting as sources and sinks for point defects, which makes possible diffusive deformation in which material is transferred from the sides of grains to their ends, making them longer and thinner in response to applied stress. When the mass transfer occurs through the grain interiors, Herring-Nabarro creep results at a strain rate that is proportional to the stress and d^{-2} (Herring, 1950; Nabarro, 1948). Coble creep is similar but occurs at lower temperatures by means of grain-boundary diffusion and has a strain rate proportional to d^{-3} (Coble, 1963). For these modes of deformation, then, large grain size is desirable for the resistance to deformation. This materials design paradigm is taken to the logical limit for gas-turbine blades as all grain boundaries are eliminated and the blades are cast as single crystals of high-performance superalloys.

There is a "threshold stress" of the order of 1 MPa below which no deformation occurs in diffusive creep. This is too small to be of any engineering significance in conventional materials. However, the threshold stress varies as $1/d$, and so there may be a regime of creep resistance at the extremely small grain sizes of nanocrystalline materials, provided that the problem of grain growth at high temperature can be solved.

Grain boundaries promote creep failure by acting as the sites of creep cavitation. At grain-boundary junctions, sliding allows one grain to act as a wedge forcing apart two others, giving rise to W-type, or wedge, cavities. At boundaries normal to an applied tensile stress, R-type or rounded cavities grow by accumulating vacancies emitted from the grain boundary. When creep cavities grow sufficiently large, they cause the failure of the material through the reduction of the cross-sectional area to the point where it can no longer bear the applied load.

Superplasticity is a phenomenon in which very large strains can be achieved at low strain rates, without fracture. This can be useful in forming complex shapes from sheet material, although the fabrication speed is typically slower than is usually associated with a manufacturing operation. Most applications of the phenomenon are found in the aerospace industry. Superplasticity requires fine grain sizes, and although the detailed mechanism by which it occurs is still not clear, it is certain that grain-boundary sliding plays a very important part.

2.5 Electronic Properties of Materials

Relatively little work has been done upon the effects of grain boundaries on electronic properties, especially in metals, where they add but a small contribution to the electrical resistivity. There is a greater wealth of information in the case of ceramic materials, some of which have rather more interesting electronic properties. For example, zinc oxide is used widely for its varistor properties, which make it very useful in the construction of electrical surge protection devices. Measurements made on a microscopic scale on this material reveal that the varistor effect only arises for current transport across grain boundaries, and within individual grains, there is no variation of resistance with current density. Thus the useful property of ZnO in this regard is effectively only a property of the grain boundaries themselves (Levinson, 1986).

In the high-temperature superconducting ceramics such as yttrium barium copper oxide, a major barrier to commercial device development is the small critical current density beyond which superconductivity breaks down. It has been found that the current-carrying capability of these materials is relatively good within single crystals but that the grain boundaries form weak links across which superconductivity is much less reliable. The weak-link behavior of the grain boundaries is strongly dependent upon the grain-boundary parameters, with a marked decrease in current-carrying ability being found as the misorientation angle increases (Dimos *et al.*, 1988).

3. SMALL-ANGLE GRAIN-BOUNDARY STRUCTURE

The structure of any grain boundary can be described formally in terms of arrays of dislocations lying in the boundary plane. This is perhaps most clearly seen in the cases of small-angle tilt and twist grain boundaries, which contain edge and screw dislocations, respectively, as shown in Fig. 2. For these simple cases, the dislocation spacing in the boundary plane is given by

$$S=\frac{b/2}{\sin(\theta/2)}, \tag{5}$$

where b is the Burgers-vector magnitude (i.e., the magnitude of the lattice displacement associated with each dislocation) and θ is the misorientation angle. This simplifies to $S\sim b/\theta$ in the small-angle approximation. For more general grain boundaries, it is necessary to adopt more complicated techniques that provide the overall dislocation content of the interface. Frank's formula is one such approach, which gives the total Burgers vector crossed by a "probe vector" lying in the grain-boundary plane (Frank, 1950):

$$\mathbf{B}=2\sin(\theta/2)(\mathbf{V}\times\mathbf{a}), \tag{6}$$

where $\mathbf{B}$ is the total Burgers vector crossed by the probe vector $\mathbf{V}$, and $\mathbf{a}$ is a unit vector parallel to the axis of rotation. Unfortunately, Frank's formula does not give unique results, because of the availability of different descriptions of the misorientation, which correspond to different choices of θ and $\mathbf{a}$. This ambiguity persists through all methods for determining the dislocation content of interfaces and gives rise to the concept of the "most physically meaningful" description of the grain boundary, which is the one that most closely describes the structure that nature selects. It is commonly held that the dislocation content that has the lowest elastic energy provides the most physically meaningful description of the grain boundary, and certainly where there is a "small-angle" description of a grain boundary, the disorientation is usually associated with the most meaningful description. In any case, it can be seen from Eq. (5) or (6) that as the misorientation angle increases, the dislocation content also increases or, equivalently, individual dislocation lines in the grain boundary get closer together. The conventional wisdom holds that for disorientations larger than about 15°, the dislocations that make up the grain boundary are so close together as to be physically indistinguishable from each other. It is this loss of individual dislocation character that marks the limit of small-angle grain-boundary behavior and the point beyond which dislocation descriptions of the grain-boundary structure are usually seen as having purely formal significance.

3.1 The O-Lattice

An important development in the geometrical theory of grain-boundary structure has been Bollmann's O-lattice approach (Bollman, 1970). The basis of the approach is the identification of locations of minimum strain between the two crystals, which are identified as those points of identical structure that occupy coincident positions. These "minimum strain sites" form a lattice known as the O-lattice, which extends throughout the bicrystal. The minimum strain sites are the O-lattice elements. The method is perhaps best developed rather abstractly by considering both crystals to extend to infinity, interpenetrating each other everywhere. This amounts to treating the crystals by considering their lattices only. The structures that are derived can be related to real grain boundaries by the formal artifice of selecting a grain-boundary plane and clothing the sites of lattice 1 with atoms or molecules on one side of the plane to create the crystal 1, and likewise clothing the sites of lattice 2 on the other side of the boundary plane.

With a lattice site chosen as an origin for the rotation that creates lattice 2 from lattice 1, the origin is by definition a point of good registry between the two crystals and thus a point of minimum strain. It is found that other "minimum strain points" exist at positions defined by the vectors $\mathbf{X}(\mathrm{O})$ that are solutions of the equation

$$(I-R^{-1})\mathbf{X}(\mathrm{O})=\mathbf{b}, \tag{7}$$

where $\mathbf{b}$ is a vector of crystal lattice 1. This equation also applies when the transformation between one crystal and the other is not a simple rotation, if R is replaced by a general transformation matrix. In the case of grain boundaries, where the transformation is most frequently a rotation, the O-elements take the form of infinite lines parallel to the rotation axis. Shear transformations give rise to O-lattices in the form of infinite planes parallel to the shear direction, and dilations and other general transformations (combinations of the three types listed here) create O-lattices made up of points.

The O-lattice elements, in fact, mark the possible origins for the transformation R, since they are positions at which the two crystal lattices are in perfect registry. It is this property of the O-elements that gave rise to the name of this formalism. The points of maximum disregistry between the two lattices are found on the planes that are perpendicular bisectors of the lines joining adjacent O-elements, as shown schematically in Fig. 4. Each O-element thus sits in a cell, surrounded by walls of maximum disregistry. In order to determine the structure of a grain boundary from the O-lattice, the boundary plane is drawn through the O-lattice construction, and lattice dislocations are placed at each intersection of the boundary plane with an O-cell wall, according to the "duality rules" given by Bollmann. This method for finding the dislocation structure of a grain boundary is essentially equivalent to Frank's formula, but instead of giving the average dislocation content, it allows us to determine individual dislocation positions at least on a purely geometrical basis.

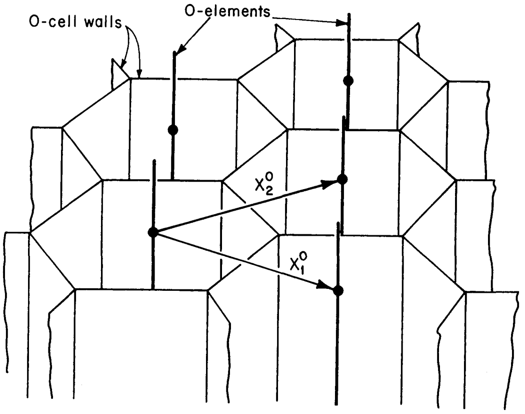

FIG. 4. Schematic illustration of the O-lattice construction. The O-elements are infinite lines parallel to the rotation axis for a grain boundary, and the O-cell walls situated between them are the positions of maximum disregistry between the two crystal lattices that make up the grain boundary. When a grain-boundary plane is chosen, the intersections of the boundary plane with the O-cell walls mark the positions of the dislocations in the boundary plane.

Energetic considerations can alter certain details of the predicted arrays, but cannot change the overall Burgers-vector content. This approach can also be extended to certain problems of large-angle grain-boundary structure, as we shall see below.

3.2 Grain-Boundary Energy

Once the dislocation structure of a grain boundary is known, the energy of the interface can be found, in principle, as the elastic strain energy of the array of dislocations that comprise the boundary. This was first done by Read and Shockley (1950), who obtained the result that the strain energy per unit area of interface, γ, for a symmetrical tilt boundary is

$$\gamma = A\theta(B - \ln\theta), \tag{8}$$

where A is a term proportional to the shear modulus and the Burgers vector, and B is a term that depends upon the exact geometry of the interface. This formula has been experimentally confirmed in numerous studies, and it applies well up to a misorientation of about 15°, especially in metal specimens. Beyond this angle, the formula predicts decreasing energy with increasing misorientation, but its basis is dubious because of the closeness of the lattice dislocations that make up the boundary. Grain boundaries in ceramic materials are amenable to this dislocation-based analysis, but only to the extent that they have crystalline grain boundaries. In many cases, particularly where the material is impure, the grain boundaries in ceramics are covered with a thin film of an amorphous (or glass-like) second phase, and the properties of the boundary then become simply the properties of this second phase.

An important finding of this theory is that the displacements due to the interfacial dislocations make up a strain-free rotation at distances from the boundary greater than about S, where S is the separation of the dislocations in the boundary plane. Within this distance from the boundary, there are strains and therefore stresses associated with the dislocations, but essentially all of energy of the interface is contained within a region with width of the order of S, surrounding the boundary.

4. LARGE-ANGLE GRAIN-BOUNDARY STRUCTURE

The structures of large-angle grain boundaries are more complicated than those of small-angle ones, and as yet there is no theory that allows for the analytical prediction of the structure of any randomly chosen boundary. However, observations of the properties of large-angle boundaries have yielded nearly constant results with respect to misorientation or boundary-plane inclination, except for a few "special" boundaries with particular misorientations. The structures of these special boundaries have been investigated with considerable vigor, both experimentally and theoretically.

4.1 Geometrical Characteristics of Special Large-Angle Grain Boundaries

The best known special interface is perhaps the twin boundary created by inversion of the stacking sequence of close-packed planes from ...*ABCABC*... to ...*CBACBA*... in face-centered-cubic metals. The boundary may also be described by the disorientation 60°;[111]. This boundary exhibits, *inter alia*, low interfacial energy, a high degree of sensitivity of interfacial energy to boundary orientation, low diffusivity, and limited effect upon various forms of deformation. Other special grain boundaries are found to be associated with other disorientations, such as 36.9°;[100] and 50.5°;[110] in cubic materials.

In each case of special boundary behavior, it is found that the misorientation of the boundary is at or close to a misorientation that creates a coincidence-site lattice, or CSL, which is a special form of coincidence between the two crystal lattices. In Sec. 3.1, we introduced the idea of lattice coincidence in a rather general form, in which a coincidence between any point of lattice 1 and a corresponding point of lattice 2 was considered as a point of minimum disregistry between the lattices. Such O-points can occur anywhere in the lattice, and they always form a lattice. The CSL, by contrast, considers only coincidences between lattice 1 and lattice 2 that occur at lattice points.

For simple crystal structures, the lattice points may also be taken to be atom sites. While the O-lattice exists at all misorientations and changes its unit-cell size, shape, and orientation continuously with crystal misorientation, coincidence-site lattices exist only at certain discrete misorientations. Obviously, where a CSL exists, at least some of the O-elements must also pass through coincident lattice sites. Figure 5 shows an example of a CSL in a simple-cubic material and a corresponding grain-boundary geometry (which we will shortly distinguish from grain-boundary structure) for a symmetrical tilt grain boundary. It can be seen that the grain-boundary geometry is periodic and highly ordered. The period of the grain-boundary geometry is related to the size of the CSL, and it is generally regarded as desirable to have an index of the size of the CSL unit cell. It is common to use the parameter Σ, which is defined as the ratio of the CSL unit-cell volume to the crystal unit-cell volume. For the example in Fig. 5, $\Sigma=5$, and greater values of Σ correspond to lower densities of coincident sites.

The misorientations giving rise to CSLs in cubic crystals are predicted by the generating function

$$\theta=2\arctan(pN^{1/2}/q), \tag{9}$$

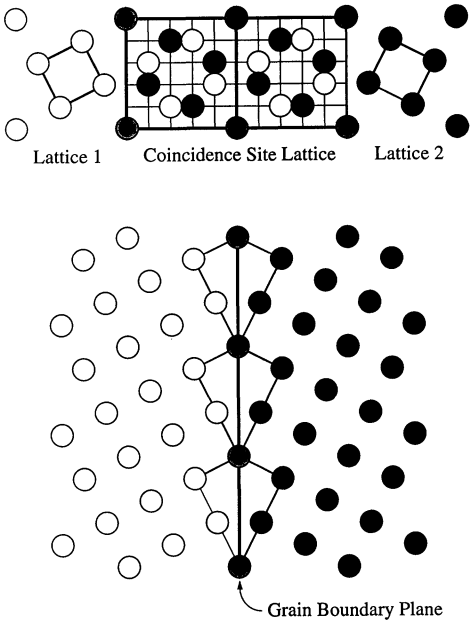

FIG. 5. A coincident-site lattice made up by the intersection of two crystal lattices, and a grain-boundary geometry based upon the CSL. Two unit cells of the CSL are shown, and the fine mesh within each CSL unit cell represents the DSC lattice.

where p and q are integers, and N is $h^2+k^2+l^2$ if $[hkl]$ is the rotation axis. The value of Σ is then given by

$$\Sigma=(p^2N+q^2)/2^n, \tag{10}$$

where n is chosen to make Σ an odd integer. A rotation matrix R that produces a CSL can be written in the form

$$R=(1/\Sigma)R', \tag{11}$$

where R' is a 3×3 matrix all of whose elements are integers.

Special grain-boundary properties are generally associated with small values of Σ (for example, the common twin in fcc crystals is a $\Sigma=3$ coincidence boundary, commonly denoted as $\Sigma3$) but not all small values of Σ necessarily predict special properties. Table 1 gives the disorientations leading to CSLs with Σ up to 25 for cubic crystals, and most of these correspond to large angles of misorientation between the two crystals. Even so, every boundary could, formally at least, be described in terms of lattice dislocations exactly as for small-angle grain boundaries. A special feature of boundaries that have CSL geometry is that the lattice dislocations they contain are always separated by integer numbers of exact climb distances (for the case of edge disloca-

Table 1. Disorientations corresponding to short-period CSLs in cubic crystals. Where more than a single, physically distinct rotation gives rise to the same value of Σ, the Σ value is conventionally postfixed with a lowercase letter, chosen in order of disorientation angle.

Σ	Axis	Angle (deg)

13a	[100]	22.62
13b	[111]	27.80
15	[210]	48.19
17a	[100]	28.07
17b	[221]	61.93
19a	[110]	26.53
19b	[111]	46.83
21a	[111]	21.79
21b	[211]	44.40
23	[311]	40.45
25a	[100]	16.25
25b	[331]	51.68

tions in tilt boundaries) or by integer multiples of the distance between Peierls valleys (for the case of screw dislocations in twist boundaries). Climb distances and the distances between Peierls valleys are the minimum separations between locally stable dislocation positions in the crystal lattice.

Alternatively stated,

$$S = MS^0, \tag{12}$$

where M is an integer and S^0 is the smallest distance between stable dislocation positions imposed by the crystal lattice. Thus for the case of coincidence boundaries, and only for that case, the lattice dislocations making up the boundary can simultaneously exist at uniform separation and at locally stable positions relative to the crystal lattice. For all other cases, one of those two conditions for a low-energy structure cannot be fulfilled: in small-angle grain boundaries, where the dislocations are relatively well separated, it appears that the perturbation of a uniform spacing, say S, into individual spacings of MS^0 and $(M \pm 1)S^0$ has relatively little effect upon the grain-boundary energy because the interactions between adjacent dislocations are relatively weak. For large-angle grain boundaries, though, the energy associated with such a perturbation can be large.

4.2 Structure of Coincidence-Related Boundaries

Although the periodic geometry of a grain boundary may be well described by a CSL, the actual structure of the boundary may not contain any atoms shared between the two crystals. This is because of possible local reconstruction of the boundary to minimize its energy. One form of reconstruction that is particularly important in the metals removes a certain amount of the free volume associated with a structure that contains atoms in coincident sites. Consider, for example, the geometry shown in Fig. 5. If we draw circles on each lattice site to indicate the ionic radii, we find gaps and overlaps in the structure as shown in Fig. 6(a). The overlaps in particular can be relieved if crystal 2 is translated with respect to crystal 1, as shown in Fig. 6(b), and computer simulation studies have consistently found that structures of lower symmetry but better space-filling properties, as in Fig. 6(b), have lower energy. This gives rise to the addition of three additional degrees of freedom for grain boundaries, corresponding to the magnitudes of the rigid translations of one crystal with respect to the other, in three orthogonal directions. These three degrees of freedom are often referred to as "microscopic" because they relate to translations that must be smaller than the unit cell of the crystal. A fourth microscopic degree of freedom exists when the crystal structure has more than one atom per lattice site in the unit cell: when this condition exists, as, for example, in ionic compounds, then there is also a nondegenerate freedom of choice of the site of the origin. This may equivalently be described as a degree of freedom related to the position of the grain boundary along its normal. A grain boundary may, then, have a total of nine degrees of freedom, five of which are considered macroscopic, and four microscopic.

The actual structure of the grain boundary will depend upon matters such as space filling in metals, bond-bending and dangling-bond avoidance in covalent solids, and Coulombic interactions in ionic materials. It is also found that energy differences between different stable structures can be small enough that the

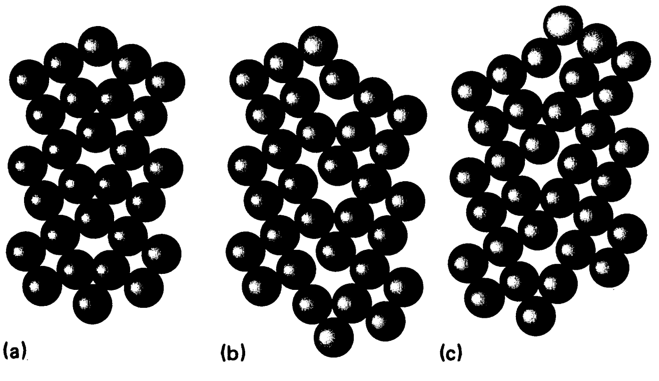

FIG. 6. Grain-boundary structures based upon the geometry illustrated in Fig. 5. (a) With the grains shown at the coincidence position (sharing atoms in the grain-boundary plane). (b) With the atomic overlaps in (a) removed by a rigid translation of the right-hand grain with respect to the left-hand grain. (c) Similar to (b) but with a different translation: this yields a structure that is symmetry related to the structure in (b) and can be transformed into (b) by a rotation of 180° about a vertical axis.

structures may coexist in a single grain boundary as adjacent patches of different structure. For certain cases, the structures may be related by symmetry and therefore embody identical energy: an example of two symmetry-related structures, based upon the Σ5 example, is given in Figs. 6(b) and 6(c).

4.3 Off-Coincidence Grain Boundaries

Although CSL-related grain boundaries occur at unique special orientations, it is found in practice that the special properties of these interfaces persist (although possibly diminished) over some range about the exact CSL-producing misorientation. For this reason, it is desirable to have a theory of the structure of "off-coincidence" or "near-coincidence" grain boundaries. As described above, CSL-related boundaries have lattice dislocations separated uniformly by distances MS^0. When the average dislocation spacing is slightly reduced or enlarged to change the angle of misorientation, a small number of spacings $(M-1)S^0$ or $(M+1)S^0$ are introduced into the lattice dislocation array, as shown in Fig. 7. These perturbations of the grain-boundary structure are defects of the defect array itself, and are sometimes referred to as "secondary defects." It can be shown that they correspond to additional dislocations superimposed upon the CSL-producing array (see, e.g., Balluffi, 1980). Their Burgers vectors can be defined, and their spacings (if uniform) are given by Eq. (4) with the simple substitution of $\Delta\theta$ for θ, where $\Delta\theta$ is the angle by which the misorientation deviates from the exact CSL misorientation.

Off-coincidence grain boundaries can therefore be described in very much the same way as small-angle grain boundaries, since the deviation from the exact coincidence misorientation is made up by superimposing a pseudo-small-angle grain boundary on the structure of the CSL interface. The energy of the grain boundary can be estimated simply by adding the energy of the superimposed small-angle interface to that of the coincidence boundary.

The O-lattice method can be applied to the so-called "secondary dislocation array" that accommodates the deviation from the ideal coincidence misorientation, by a simple modification of Eq. (7):

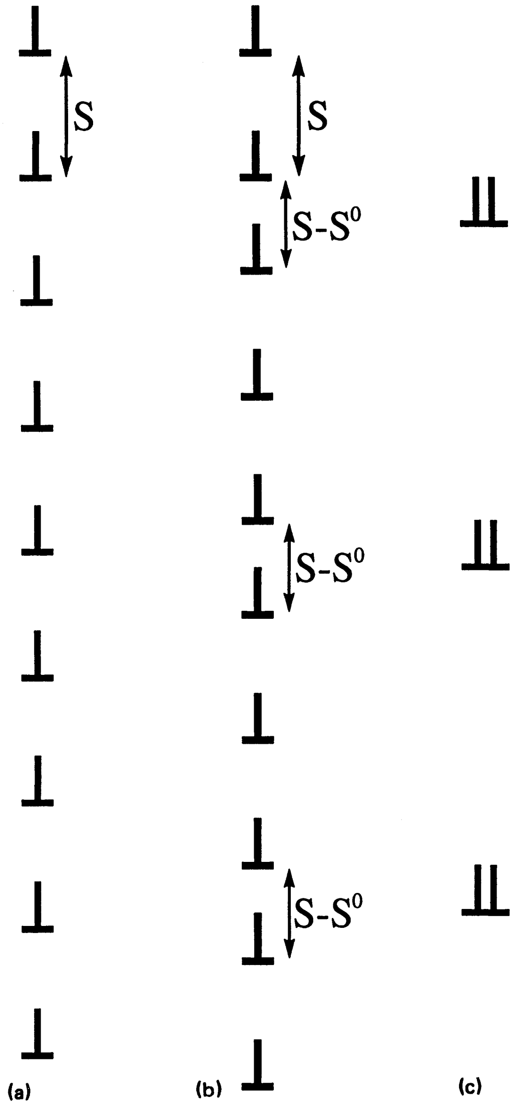

FIG. 7. (a) An equispaced array of primary edge dislocations making up a symmetrical tilt grain boundary. (b) The same array as in (a) but at a slightly greater angle of misorientation such that the dislocation array is forced to include two different spacings. (c) The array of secondary dislocations equivalent to the minority spacings in (b). The structure of the boundary can be considered as a superposition of (a) and (c), which is a particularly useful approach when (a) represents a coincidence boundary.

$$(I-R_cR^{-1})\mathbf{X}(O2)=\mathbf{d}. \qquad (13)$$

In this expression, R_c is the rotation that gives the CSL, $\mathbf{X}(O2)$ is a vector of the secondary O-lattice, and $\mathbf{d}$ is a Burgers vector appropriate to a secondary dislocation, as described below.

4.4 Topology of Secondary Dislocations

The dislocations that may exist in grain boundaries can be classified in a number of different ways. The most general of these is to consider which symmetry elements of the crystals are involved in the creation of the defect. In any crystal, the structure found on any particular plane is replicated at different locations on the same plane or parallel planes (via translational symmetry); or it may be replicated on the same plane but in a different orientation (via rotational or mirror symmetry); or it may be replicated on some nonparallel, equivalent plane (via rotational symmetry). In any case, it is possible to make a discontinuous displacement of one crystal that corresponds to one of these symmetry elements of the interfacial plane, and the line along which such a displacement is made is the core of an interfacial dislocation. The various possibilities of such defects according to Pond (1989) are illustrated schematically in Fig. 8. In each of these cases, the dislocations separate patches of identical interfacial structure and may thus be considered "perfect" dislocations within the interface. In most cases, the Burgers vectors of these dislocations are not translation vectors of the crystal lattice, and so they cannot exist in the grain interiors without the creation of high-energy stacking faults.

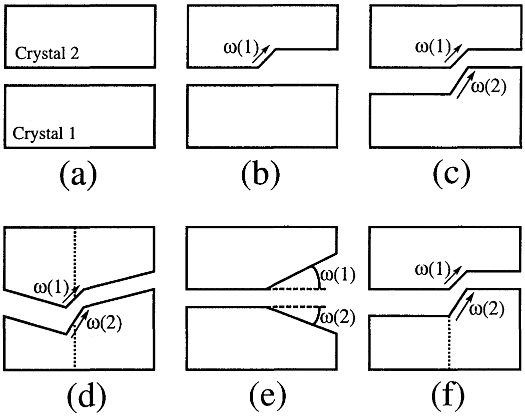

FIG. 8. Classification of line defects in interfaces according to the symmetry elements that they affect. In each case, ω is a symmetry operation in one of the crystals, and the crystals are shown as though separated along the interface. (a) The case of a perfect interface containing no defects; (b) a crystal lattice dislocation in grain 1; (c) a broken translation dislocation; (d) a "frustrated symmetry" dislocation; (e) an interfacial disclination; (f) an interfacial dislocation delineating the intersection of a domain boundary, or other stacking fault in crystal 2, with the interface [after Pond (1989)].

It is to be noted that in addition to the Burgers vector that characterizes the grain-boundary dislocations, these defects also embody a step in the interfacial plane in many cases. Motion of the step causes grain-boundary migration, and this is taken to explain the observation of grain-boundary migration in concert with sliding, when the sliding is mediated by the motion of grain-boundary dislocations. Any reaction of these dislocations must satisfy the usual node condition that $\Sigma \mathbf{b}_i = \mathbf{0}$, where $\mathbf{b}_i$ is the Burgers vector of the ith dislocation entering the node. There is, for interfacial dislocations, the additional requirement that $\Sigma h_i = 0$, where h_i is the height of the step in the boundary plane associated with the ith dislocation.

Perhaps the most widely studied class of secondary dislocations is the group defined by translational symmetries of the grain-boundary planes. This includes the so-called "displacement shift complete" (DSC) dislocations, whose Burgers vectors represent displacements of the crystals with respect to each other that shift the interfacial structure but leave it "complete." Various techniques have been developed to determine the Burgers vectors of these dislocations ("DSC vectors") and the step heights associated with them. An important result is that the DSC lattice is reciprocal to the CSL, for structures described by primitive unit cells. The structures of the DSC dislocations are specific to the CSL systems to which they relate, and their Burgers vectors are smaller than the Burgers vectors of crystal lattice dislocations. Since crystal lattice dislocations always correspond to translational symmetries of the crystal structure, they must also correspond to translational symmetries of the grain-boundary structure and may therefore be perfect dislocations within the grain boundary. In every case, the lattice Burgers vector is a sum of primitive DSC vectors so that lattice dislocations can dissociate upon entering grain-boundary planes, forming a number of DSC dislocations out of a single crystal lattice dislocation.

A special kind of defect can exist in a grain-boundary plane, and this is the "pure step," essentially a DSC dislocation with a null Burgers vector. The energies of interfacial dislocations, like ordinary crystal dislocations, have a component that is proportional to the square of the Burgers vector magnitude, but there is also a component that is proportional to the height of the step in the boundary plane. In certain cases the step energy can be of comparable magnitude to the strain energy, and so it can exert a controlling influence upon dislocation reactions (King and Smith, 1980).

4.5 Criteria of Specialness

As described above, the distinct properties of "special" grain boundaries extend over some range of misorientation close to certain exact coincidence values. Our understanding of this phenomenon is based upon the analogy with small-angle grain boundaries. Just as the dislocation description for a small-angle boundary loses utility when the constituent dislocations are too close together to be considered separately, the description of an "off-coincidence" large-angle boundary also breaks down, too. The point at which the secondary dislocations lose their individual physical identities is often considered to be the point at which the special properties of the boundary are lost. A variety of approximate formulas have been proposed to provide rules of thumb for the misorientation range over which special properties are retained.

The most commonly used of these criteria of specialness is the Brandon criterion (Brandon, 1966):

$$\Delta\theta_{\max}=15^\circ/\sqrt{\Sigma}. \tag{14}$$

This is the maximum rotational deviation from the coincidence misorientation for which a grain boundary is considered to be "coincidence related." It is based upon an approximate measure of dislocation spacing in the grain boundary and presumes that the secondary dislocation array comprises only primitive DSC dislocations. Like most rules of thumb, this provides a reasonable guideline but is by no means exception-free. The most significant problem with using the Brandon criterion, or any other developed from a consideration of dislocation spacing alone, is that all coincidence-related boundaries up to some arbitrarily chosen value of Σ are considered to embody special properties, and although a small value of Σ seems to be a prerequisite for a boundary to have special properties, not all low-Σ boundaries do in fact exhibit them. What is needed, but is still unavailable, is some rule of thumb to determine which interfaces are fundamentally "special."

4.6 Beyond CSL Geometry: Structural Unit Models

Computer simulation studies of grain-boundary structure (see Sec. 5) have shown that low-energy periodic boundaries are made up of recognizably shaped clusters containing between four and approximately ten atoms (Sutton and Vitek, 1983). The lower-energy boundaries tend to have structures that are characterized as being completely made up of a single type of cluster (say *P*) arranged periodically so as to occupy the whole interfacial area. The structure of this boundary might then be described as ...*PPPPP*..., and it would also be a coincidence grain boundary. At a different misorientation about the same rotation axis another low-energy boundary might be found with a structure made up entirely of a different structural unit, for example, ...*QQQQQ*... . This would also be a coincidence boundary. At misorientations between those of the *P* and *Q* boundaries, the structure is made up of simple "lever-rule" mixtures of the two types of structural unit. Close to the *P* misorientation, then, the structure would take the form ...*PPPPPQPPPPPQPPPPP*... . It is also found that the *Q* units in this interface correspond to the cores of DSC dislocations appropriate to the *P* CSL boundary, and thus the structural unit model and the CSL model for large-angle boundary structure are different descriptions of essentially the same thing.

Interestingly, at a misorientation halfway between the *P* and *Q* misorientations, the boundary structure is ...*PQPQPQP*..., which is also a coincidence boundary. It is found, however, that this boundary is one of those which does not embody special properties. Boundaries made up purely of a single structural unit are termed "favored" boundaries, and these have special properties as described above. The structures of other boundaries are essentially mixtures of the structures of favored boundaries. This provides some insight into the question of which values of Σ are significant, but still calls for computer simulation studies to determine which boundaries are likely to be special.

4.7 Noncubic Materials

It is not generally possible to form three-dimensional CSLs in noncubic crystal structures. It is required that there exist special relationships between the lengths of the unit-cell edges and the angles between them in order for CSL formation to be possible. In most cases, however, the crystal structure is quite close to such a special relationship, and then CSLs can be formed if there is a slight deformation or "constraint" of the crystal lattice. The boundary structure can then include an additional dislocation content that exists to accommodate the constraint of the crystal lattice. Constrained-CSL (CCSL) models have been successfully applied to explain observed grain-boundary structures in hexagonal, tetragonal, and orthorhombic crystals.

5. TECHNIQUES FOR THE STUDY OF GRAIN BOUNDARIES

A very wide range of techniques has been applied to the study of grain boundaries, and it would be impossible to list all of the types of experiments that have been performed. In many cases direct measurements of properties of interest are made either using bicrystals prepared with known boundary parameters or using polycrystalline specimens and accepting whatever boundaries are present in the material. Most studies of grain boundaries *per se* concentrate upon the structure or chemistry of the boundary in order to draw inferences about the ways in which structure and chemistry affect properties of interest. Three techniques stand out from the many that are applied.

5.1 Electron Microscopy

This accounts for the largest number of reported studies of grain boundaries and provides a wealth of different types of information. High-resolution transmission electron microscopy (TEM) can allow the determination of atomic-level structure of the grain boundary, provided that low-index crystallographic directions in each grain lie parallel to each other. Figure 1 is an example of an atomic-resolution transmission electron micrograph.

Conventional TEM, using diffraction imaging, can provide information about the primary and secondary dislocation structure of grain boundaries. When TEM is coupled with either an x-ray spectrometer or an electron energy-loss spectrometer, elemental analysis can be performed with spatial resolution depending upon the size of the electron probe—typically several nanometers. Analytical electron microscopy of this kind has provided much information about the segregation of solutes to grain boundaries.

5.2 Field-Ion Microscopy (FIM)

Although used much less than TEM, FIM provides atomic-level imaging of solid material without any constraints upon the boundary parameters and can be coupled with mass spectrometry to provide chemical analysis on an atom-by-atom basis. It has been applied to a number of grain-boundary segregation problems, but has provided structural information of lower content than TEM investigations. This is largely because it is not possible to create FIM specimens containing grain boundaries of known parameters with the ease that is available to the electron microscopist.

5.3 Computer Simulation

Modern computers have facilitated the construction of atomic models in which each atom is represented by a point and the interatomic forces are modeled with varying sophistication. The earliest models used pairwise central force approximations such as the Lennard-Jones potential, or more realistic pseudopotentials designed to model the properties of actual elements. More recently, certain many-body potentials have been developed that are still determined only by the atomic positions and apply very well to the metals. Potentials have been developed to include bond-bending effects applicable to covalently bonded solids such as silicon, and finally, complete quantum-mechanical solutions have also been used. In every case, the model consists of a finite block of atoms containing a section of grain boundary. Periodic boundary conditions are typically applied, which means that atoms close to one edge of the model are used, as though translated by the model dimension, to determine forces acting upon atoms close to the opposite edge of the model. The model thus becomes infinite and periodic. In principle, any grain boundary can be constructed as a computer model of this type, although available memory limits the size of the model and thus imposes a requirement that the boundary have a certain periodicity in its structure. Models can be "dynamic," allowing atomic vibration subject to a chosen total kinetic energy (equivalent to a chosen temperature), or they may be "static," effectively becoming models appropriate to absolute zero temperature. In either case, the models can be used to find lowest-energy structures and to measure internal stresses around the interface. In the case of dynamic models, the behavior of the boundary can also be investigated with respect to phenomena such as sliding, migration, and diffusion.

6. SUMMARY

Grain boundaries have been studied now for a century and their properties and behavior are quite familiar, although with as many as nine degrees of freedom, they are more different from each other than are snowflakes. Most research in the last two decades has centered on understanding grain-boundary structure and how it affects properties and behavior, but general rules are hard to find for such richly varied defects.

As individual grain boundaries become better understood, it becomes possible to consider how the network of boundaries that extends throughout a polycrystal controls the properties of the specimen. Important considerations then become the distribution of grain-boundary characters in the specimen and the behavior of "triple lines," where three grain boundaries meet. Much present research focuses on the possibility of controlling the distribution of grain-boundary parameters in polycrystalline specimens in order to optimize the properties of the material. This represents a significant refinement of traditional microstructure control, which typically concerns itself only with average grain size for single-phase materials. The payoff from such research is potentially very great, particularly with regard to electrical properties. For example, the critical current density in many ceramic superconductors can be radically increased by replacing "bad" grain boundaries with "good" ones. Techniques for controlling the grain-boundary character distribution include traditional thermal processing, which has been shown to have significant effects on the percentage of special boundaries. Other approaches include directional solidification from the melt and the sintering of prealigned powders into polycrystalline compacts. In the realm of thin-film technology, crystal orientation can often be controlled by suitable choice of substrate material, and where more than one crystal orientation is formed on a particular substrate, the result is a network of highly selected grain boundaries. As the ability to control the formation of various grain boundaries is perfected, it will be possible to build into materials the desirable properties of specific interfaces while avoiding the undesirable properties of others. This may result in the creation of usable electronic devices such as tunneling junctions out of individual grain boundaries, or may allow the creation of alloys with tailored grain boundaries that have enhanced resistance to embrittlement or other forms of metallurgical failure.

GLOSSARY

CCSL: Constrained coincidence-site lattice.

CSL: Coincidence-site lattice.

DIGM: Diffusion-induced grain-boundary migration.

Disorientation: The choice of misorientation (*q.v.*) embodying the smallest rotation angle and having a rotation axis described as [*uvw*], where $u \geqslant v \geqslant w \geqslant 0$.

DSC Dislocation: A dislocation whose Burgers vector is a vector of the DSC lattice.

DSC Lattice: "Displacement shift complete" lattice; lattice made up of vectors that can be Burgers vectors for perfect dislocations in grain-boundary planes.

Facet: Flat section of interface with well-defined extent and plane.

GBD: Grain-boundary dislocation.

General Boundary (Sometimes "Random Boundary"): Large-angle boundary embodying no special properties.

Large-Angle Boundary (Sometimes "High-Angle Boundary"): Grain boundary with a disorientation angle greater than approximately 15°.

Ledge: Linear discontinuity in a grain-boundary plane with either dislocation character, step character, or both.

Misorientation: Any description of the relative orientations of two crystals separated by a grain boundary.

O-Lattice: Lattice made up of possible origins for the mathematical transformation of one crystal into the other.

Secondary Dislocation: A DSC dislocation (*q.v.*) where the Burgers vector is not a lattice vector of either crystal.

Small-Angle Boundary (Sometimes "Low-Angle Boundary"): Grain boundary with a disorientation angle less than approximately 15°.

Special Boundary: A large-angle boundary with properties significantly different from general boundaries; usually corresponds to a CSL in cubic materials.

Triple Line: The intersection of three grain boundaries; topologically the only way a grain boundary can terminate other than at a free surface.

Twin Boundary: Any boundary with a 180° misorientation. Frequently applied to mean the $\Sigma3$ boundary, which is observed profusely in many cubic materials.

INTRODUCTION

Carbon materials are unique in many ways. One distinction is related to the various allotropic forms that carbon materials can assume. Under ambient conditions, the graphite phase with strong in-plane trigonal bonding is the stable phase, as indicated by the phase diagram of Fig. 1 (Bundy, 1985). Under the application of high pressure and high temperature, transformation to the tetrahedrally bonded cubic diamond structure takes place. Once the pressure is released, diamond remains essentially stable under ambient conditions although, in principle, it will very slowly transform to graphite. Figure 1 shows that for the direct transformations from graphite to diamond, high temperatures and pressures are required, but these high temperature and pressure requirements can be somewhat reduced by the use of catalytic particles, e.g., of iron. Another crystalline phase found at high temperatures and pressures is hexagonal diamond. The phase diagram further indicates that other carbon forms are obtained by exposure to shock waves and rapid solidification, though these carbon forms have not been studied in much detail. Although considerable attention has been given to study of the phase diagram of carbon, many unanswered questions remain concerning the high-temperature, high-pressure phases on the one hand, and the relation to the phase diagram of the recently discovered C_{60} and higher-mass fullerenes, on the other hand.

Graphite tends to be a material of extremes. The structure and properties of graphite are highly anisotropic, exhibiting, for example, strongly metallic behavior in the basal (*ab*) plane and poor electrical conductivity along the *c* axis (Kelly, 1981). In terms of mechanical properties, graphite is the stiffest material in nature and has the highest in-plane elastic modulus. Of all materials, graphite (in-plane) along with diamond exhibits the highest thermal conductivity (Kelly, 1981). Graphite is the highest–melting-point elemental material (Dresselhaus and Steinbeck, 1988).

Atomic carbon has an atomic number of 6 and is in the $1s^2 2s^2 2p^2$ electronic ground-state configuration, indicating that two of the six electrons are very tightly bound core electrons, and four are valence electrons. In the graphite structure, strong in-plane trigonal bonds are formed between a carbon atom and its three nearest neighbors from $2s$, $2p_x$, and $2p_y$ electronic orbitals and are called σ bonds; this bonding arrangement utilizes three of the four valence electrons and is denoted by sp^2. The remaining valence electron with a p_z orbital, called the π bond, provides only weak interplanar van der Waals bonding, but is responsible for the semimetallic electronic behavior in graphite. In contrast, the carbon

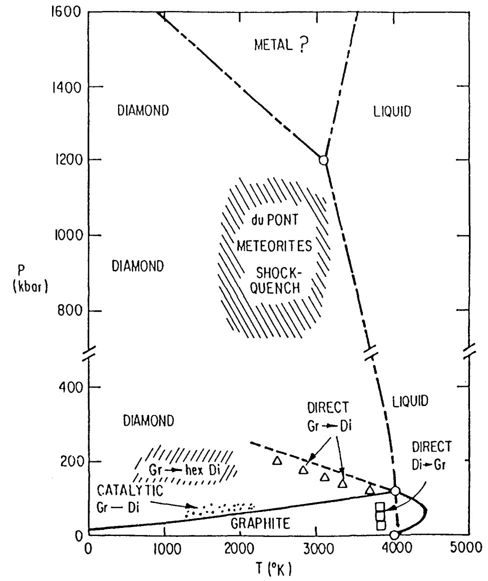

FIG. 1. The phase diagram of carbon suggested by Bundy. Under ambient conditions, graphite is the stable phase (Bundy, 1985).

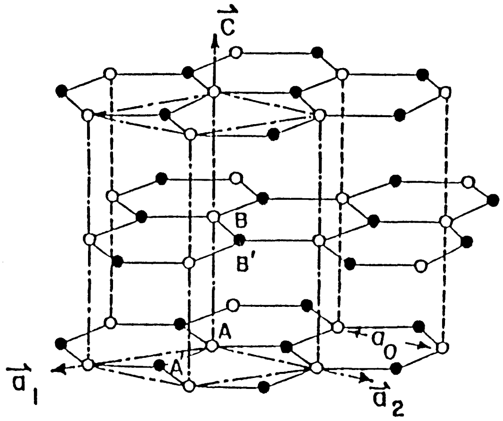

FIG. 2. The crystal structure of hexagonal single-crystal graphite. Planes of carbon hexagons are stacked in an ...*ABAB*... sequence (Wyckoff, 1964). The *A* and *B* carbon sites are denoted by open circles and the *A'* and *B'* sites by black circles, so that the *A* and *B* atoms are directly above one another, but the *A'* and *B'* atoms are not, as shown in the diagram. The in-plane lattice constant is denoted by a_0, and the vectors of the unit cell in the directions $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{c}$ are indicated (Wyckoff, 1964).

atoms in the diamond structure are tetrahedrally bonded to their four nearest neighbors using all four valence electrons in $2s$, $2p_x$, $2p_y$, and $2p_z$ orbitals in an electronic configuration denoted by sp^3. The difference in the structural arrangement of these allotropic forms gives rise to wide differences in their physical properties.

1. STRUCTURE

The ideal crystal structure of graphite (Fig. 2) consists of layers in which the carbon atoms are arranged in an open hexagonal network. Figure 2 shows two inequivalent layers with *A* and *A'* atoms on one of these layers and *B* and *B'* atoms on the other layer such that the *A* and *B* atoms are on top of one another, but the *A'* atom in one plane is over the unoccupied center of the adjacent layers, and similarly for the *B'* atoms (Wyckoff, 1964). This gives rise to an *ABAB* stacking arrangement of the layer planes as shown in Fig. 2, with an in-plane nearest-neighbor distance of 1.421 Å, an in-plane lattice constant of 2.462 Å, a *c*-axis lattice constant of 6.708 Å, and an interplanar distance of 3.3539 Å (Table 1). This structure is described by the D_{6h}^4 ($P6_3/mmc$) space group, which has four atoms per unit cell (see Fig. 2).

When graphite is deformed, a second layer stacking sequence, the *ABCABC* rhombohedral sequence, is introduced (Kelly, 1981). Graphite crystals extracted from mineral deposits or grown synthetically exhibit predominantly *ABAB* stacking shown in Fig. 2 with some *ABC* stacking faults. Such stacking faults tend to have little effect on the in-plane lattice constant, largely because the in-plane C—C bond is very strong and the nearest-neighbor C—C spacing is very small; stacking faults do, however, have a significant effect on the interplanar spacing because of the weak interplanar bonding. One consequence of this is that impurity species are unlikely to enter the in-plane lattice sites substitutionally, but rather will occupy some interstitial position between the layer planes.

Structural defects in the graphite lattice give rise to an increase in the interlayer distance, but essentially no change to the in-plane lattice structure. As the interlayer distance increases, the stacking order of the layers decreases until a value of about 3.44 Å is reached, at which distance the stacking of the individual carbon layers (called graphene layers) becomes uncorrelated; the resulting

Table 1. Properties of graphite.

Properties	Values[a]
Lattice structure	Hexagonal
Space group	$P6_3/mmc\text{–}D_{6h}^4$
Atom locations in unit cell	(000), $(00\frac{1}{2})$, $(\frac{1}{3}\frac{2}{3}0)$, $(\frac{1}{2}\frac{2}{3}\frac{1}{2})$
Lattice constant (RT) (Å)	2.462, 6.708
Atomic density (cm^{-3})	1.14×10^{23}
Specific gravity (g/cm^3)	2.26

Electron mobility (RT) [$cm^2/(V\ s)$]	20 000, 100
Hole mobility (RT) [$cm^2/(V\ s)$]	15 000, 90
Carrier density (cm^{-3})	6×10^{18}
Electrical resistivity (RT) (Ω cm)	4.0×10^{-5}, 0.12
Dielectric constant (RT, low frequency)	3.0, 5.0
Melting point (K)	4200
Thermal conductivity (RT) (W/cm K)	30, 0.06
Debye temperature (K)	2500, 950
Thermal expansion coefficient at RT (K^{-1})	-1×10^{-6}, $+29\times10^{6}$
Velocity of sound (cm/s)	$\sim2.63\times10^5$, $\sim1\times10^5$
Raman shift (cm^{-1})	42, 1582

[a] Anisotropic quantities are given first as the in-plane (*a*-axis) value, then the *c*-axis value, where the *a*-axis value refers to the value in the *ab* plane. Room-temperature values of the parameters are denoted by RT.

two-dimensional (2D) structure of uncorrelated graphene layers is called turbostratic graphite (Dresselhaus *et al.*, 1988). As is discussed below, the electronic structure of 2D turbostratic graphite is that of a zero-gap semiconductor, and is qualitatively different from that of ideal 3D graphite, a semimetal with a small band overlap of 0.04 eV between the lowest-energy occupied conduction-band states and the highest energy of the unoccupied valence-band states. From a structural standpoint, a graphite sample is characterized by the magnitudes of its interlayer separation and by the interlayer and intralayer crystallite lengths L_c and L_a, all of which can be obtained from the x-ray diffraction line positions and linewidths. The microstructure of graphite is typically determined by polarized-light microscopy, SEM micrographs, and high-resolution TEM lattice fringe patterns.

Graphite single crystals tend to be very small in size (on a millimeter scale) and very thin (on a 0.1-mm scale), and for this reason are not useful for many scientific studies and practical applications which require larger samples. For this reason a variety of graphite-related materials are used for both scientific studies and practical applications. A very brief review of these materials is given below.

2. GRAPHITE-RELATED MATERIALS

The comparison material in all graphite studies and applications is the natural single-crystal graphite flakes that are found in several locations around the world, especially in Madagascar, the former USSR, and the Ticonderoga area of New York State in the United States. The natural crystal flakes can sometimes be as large as several mm in the basal plane, and are typically much less than 0.1 mm in thickness. Natural graphite flakes usually contain several twinning planes, so that careful selection of the flakes is necessary for detailed structural studies. The natural flakes also contain impurities which are chemically removed in a purification step by boiling the flakes in concentrated HF and/or heating the flakes (to ~2000 °C) in flowing fluorine gas. Even after such chemical purification, metallic impurities (especially transition metals such as Fe) remain in the material at the ppm level (Spain, 1981).

2.1 Kish Graphite

A synthetic single-crystal graphite called kish graphite is commonly used in scientific investigations. Kish-graphite crystals form on the surface of high–carbon-content iron melts, and are harvested as crystals from such solutions (Austerman, 1968). The as-grown kish-graphite flakes are subsequently purified in much the same way as natural-graphite flakes (Spain, 1981). There are several reasons for using kish graphite in scientific studies. First, some kish-graphite flakes can be found with relatively large sizes in the basal plane, relative to natural-graphite flakes. Second, very small kish-graphite flakes ($\leqslant 1$ mm in size) without twin boundaries and with a relatively low density of defects can be found. Thus kish graphite is often used as a material of choice for sophisticated detailed structural studies. Third, the structural perfection of selected kish-graphite flakes can be very high relative to selected natural single-crystal graphite flakes.

2.2 Highly Oriented Pyrolytic Graphite

Many important experimental studies of graphite requiring larger size crystals have been carried out on highly oriented pyrolytic graphite (HOPG), which is prepared by the pyrolysis of hydrocarbons at temperatures above 2000 °C and is subsequently heat treated to higher temperatures (Übbelohde and Lewis, 1960; Moore, 1973; Moore, 1981). When stress annealed above 3300 °C, the HOPG exhibits electronic, transport, thermal, and mechanical properties close to those of single-crystal graphite. For the high-temperature, stress-annealed HOPG, the crystalline order extends to about 1 μm within the basal plane, and to about 0.1 μm along the *c* direction. HOPG has short-range in-plane order, with an in-plane crystallite size L_a up to ~ 1 μm depending on the heat-treatment temperature. HOPG, however, has no long-range in-plane *a*-axis alignment, and the *a* axes of adjacent crystallites are randomly arranged (Moore, 1973, 1981). In contrast, HOPG shows a high degree of *c*-axis alignment, with misalignment angles of a few tenths of a degree between adjacent crystallites.

The degree of in-plane structural order (usually expressed in terms of the magnitude of L_a) and *c*-axis alignment (expressed in terms of the magnitude of L_c and the half-width of the *c*-axis misalignment distribution) can be varied by control of the major processing parameters: heat-treatment temperature T_{HT}, residence time at T_{HT}, and applied stress during heat treatment. Turbostratic pyrolytic graphites are obtained for $T_{\mathrm{HT}} < 2300$ °C, and yet higher T_{HT} values are needed to establish 3D ordering. HOPG has been the material of choice for many of the fundamental studies of the structure and properties of graphite, as well as for industrial applications in x-ray monochromators and widespread use in neutron monochromators (Moore, 1973, 1981).

2.3 Graphitic Films

Recently, new precursor materials, such as polyimide (PI) and polyoxydiazole (POD) resins, have been used for the synthesis of graphite films. When heat treated to $T_{\mathrm{HT}} > 2800$ °C (Hishiyama *et al.*, 1991), these films show a high degree of 3D structural ordering. The structural perfection of these films, especially those based on the Kapton and Novax (polyimide) precursors, is rapidly improving and these films may soon become materials of choice for selected scientific studies or practical applications where high-quality thin films are needed. One potential application of these graphite films may be as a high–thermal-conductivity substrate which is electrically conducting, in contrast to diamond which has an equally high thermal conductivity but is electrically insulating.

2.4 Carbon Fibers

Carbon fibers represent another important class of graphite-related materials. Despite the many precursors that can be used to synthesize carbon fibers, each having different cross-sectional morphologies (Fig. 3), the preferred orientation of the fiber axes for all carbon fibers is close to an *a* axis in a graphene layer, thereby accounting for the high mechanical strength and stiffness of carbon fibers (Dresselhaus *et al.*, 1988). Referring to the various morphologies shown in Fig. 3 for carbon fibers, the as-prepared vapor-grown carbon fibers have an onion-skin morphology [Fig. 3(a)], which after heat treatment to about 3000 °C forms facets [Fig. 3(b)]; of all carbon fibers, these faceted fibers are closest to crystalline graphite in both crystal structure and physical properties. The commercially available mesophase pitch fibers with either the radial morphology [Fig. 3(c)] or the "Pan-Am" morphology [Fig. 3(d)] are exploited for their extremely high bulk modulus, while the com-

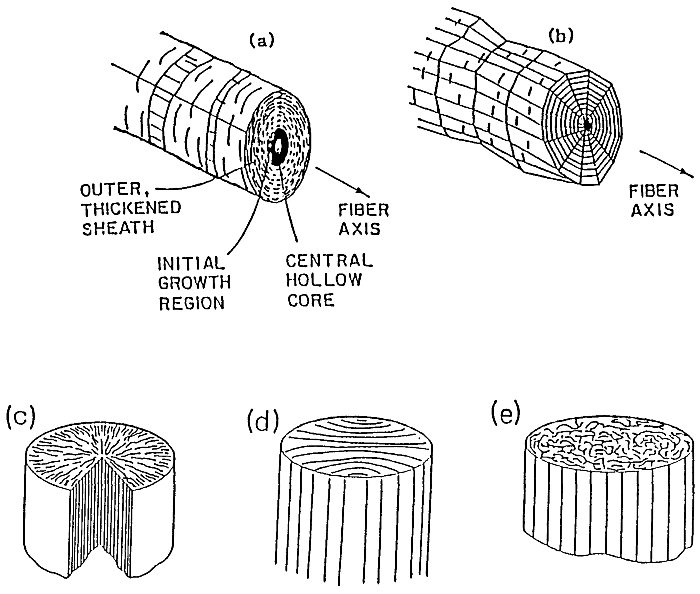

FIG. 3. Sketch illustrating the morphology of vapor-grown carbon fibers (VGCF): (a) as-deposited at 1100 °C, (b) after heat treatment to 3000 °C. The morphologies for commercial mesophase-pitch fibers are shown (c) for a "PAC-man" section with a radial arrangement of the straight graphene ribbons, (d) for a "Pan-Am" section showing a transverse alignment with nearly parallel graphene planes, and (e) for a PAN fiber, with a preferential circumferential arrangement of graphene ribbons in the sheath region and a random arrangement of ribbons in the core (Dresselhaus *et al.*, 1988).

mercial PAN (polyacrylonitrile) fibers [Fig. 3(e)] with circumferential texture are widely used for their high strength (Dresselhaus *et al.*, 1988). The high bulk modulus of carbon fibers is associated with the high degree of stiffness of graphite, and is an intrinsic property of crystalline graphite. The high tensile strength of carbon fibers is associated with the special defects in the microstructure which inhibit crack propagation. Typical fiber diameters are ~10 μm. The various morphologies shown in Fig. 3 exploit the highly anisotropic layered structure that is characteristic of graphite.

Scientific applications of carbon fibers for electromagnetic studies and electrical transport measurements typically exploit the large length-to-diameter ratio of carbon fibers. Practical applications of carbon fibers generally depend on their exceptional mechanical stiffness and strength. Large-scale applications of high-performance fibers are made in aircraft and spacecraft structures, and smaller-scale applications are made in sporting good equipment such as tennis racquets, racing bicycles, and pole vaulting poles. Many of the applications of carbon fibers exploit their high tensile strength, stiffness, and large strength-to-weight ratio. In many of these applications the fibers are assembled along with other materials to form composites. For high-temperature applications carbon fibers are often assembled with carbon-based host materials in so-called carbon-carbon composites. Lower-performance, lower-cost carbon fibers have been successfully used as reinforcement for concrete in building construction.

When activated at elevated temperatures (800–900 °C) in the presence of water vapor, the resulting activated carbon fiber can have enormous specific surface areas (SSA). Values of SSA up to 3000 m^2/g have been reported. Such fibers are used both for gas adsorption applications and for electrical applications as double-layer capacitors (Dresselhaus *et al.*, 1992).

2.5 Glassy Carbon

Glassy carbon (GC), another graphite-related carbon material, is manufactured as a commercial product by slow, controlled degradation of certain polymers at temperatures typically on the order of 900–1000 °C (Jenkins and Kawamura, 1976). This material is glass-like, granular, and moderately hard, can be easily polished, and is thermally conducting, impermeable, biocompatible, and stable at high temperatures (see CARBON MATERIALS; DIAMOND AND DIAMONDLIKE CARBON). The apparent density of GC is in the range 1.46–1.50 g/cm^3 irrespective of heat-treatment temperature, implying the existence of pores in the matrix. According to the Jenkins–Kawamura model, the microstructure of GC consists of a tangle of graphitelike ribbons or microfibrils, about 100 Å long and 30 Å in cross section, and resembles the polymer chain configuration from which the GC was derived. Because of the tangled ribbon microstructure, Jenkins and Kawamura have argued that glassy carbon does not fully crystallize into a three-dimensional graphite structure, even when heat treated above 3000 °C. For this reason glassy carbon has been used as a prototype hard (nongraphitizable) carbon for scientific investigations. X-ray diffraction studies of the radial distribution function show that the carbon atoms are well ordered in the honeycomb in-plane structure of the graphene layers, but that the 3D registry between the graphene layers is poor, so that the graphene ribbons form a turbostratic structure, typical of hard carbons (Oberlin, 1989). Recent structural studies have shown that the pores in glassy carbon form closed structures (Fig. 4) rather than an open interconnected network of ribbons (Yoshida *et al.*, 1991).

2.6 Graphite Intercalation Compounds

Graphite intercalation compounds (GICs) are formed by the insertion of layers of guest species between the layers of the graphite host material (Ubbelohde and Lewis, 1960; Dresselhaus and Dresselhaus, 1981; Zabel and Solin, 1990) (see INTERCALATION COMPOUNDS). The guest species between the graphite layers may be either atomic or molecular, and may act as either a donor or an acceptor of electrons to the surrounding graphite layers. Because of the weak interlayer forces associated with the sp^2 bonding in graphite, the intercalated species can easily be inserted between the graphite layers to form highly anisotropic layered graphite-based GICs. In diamond, on the other hand, the strong sp^3 bonding does not permit insertion of layers of guest species, and does not support intercalation. One practical application of graphite intercalation compounds is in the preparation of exfoliated graphite or Grafoil. This high–surface-area material is produced by heating selected acceptor GICs to introduce tiny gas bubbles between the layers, which, upon heating, expand rapidly, separating many of the graphite layers and greatly increasing the volume occupied by the material. Exfoliated graphite is used as an adsorption agent and as a packing material for valves.

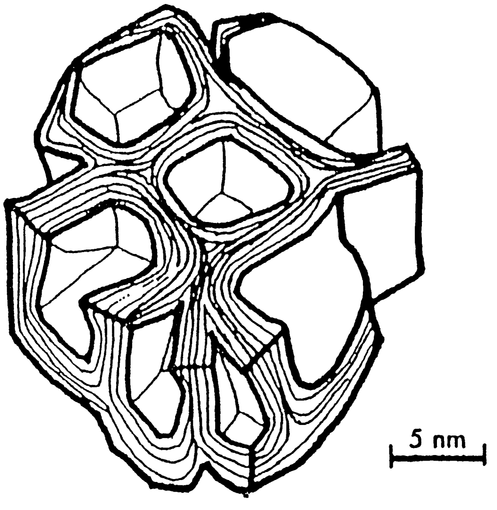

FIG. 4. Schematic diagram for the microstructure of the closed pore structure model for glassy carbon and other hard carbons (Yoshida *et al.*, 1991).

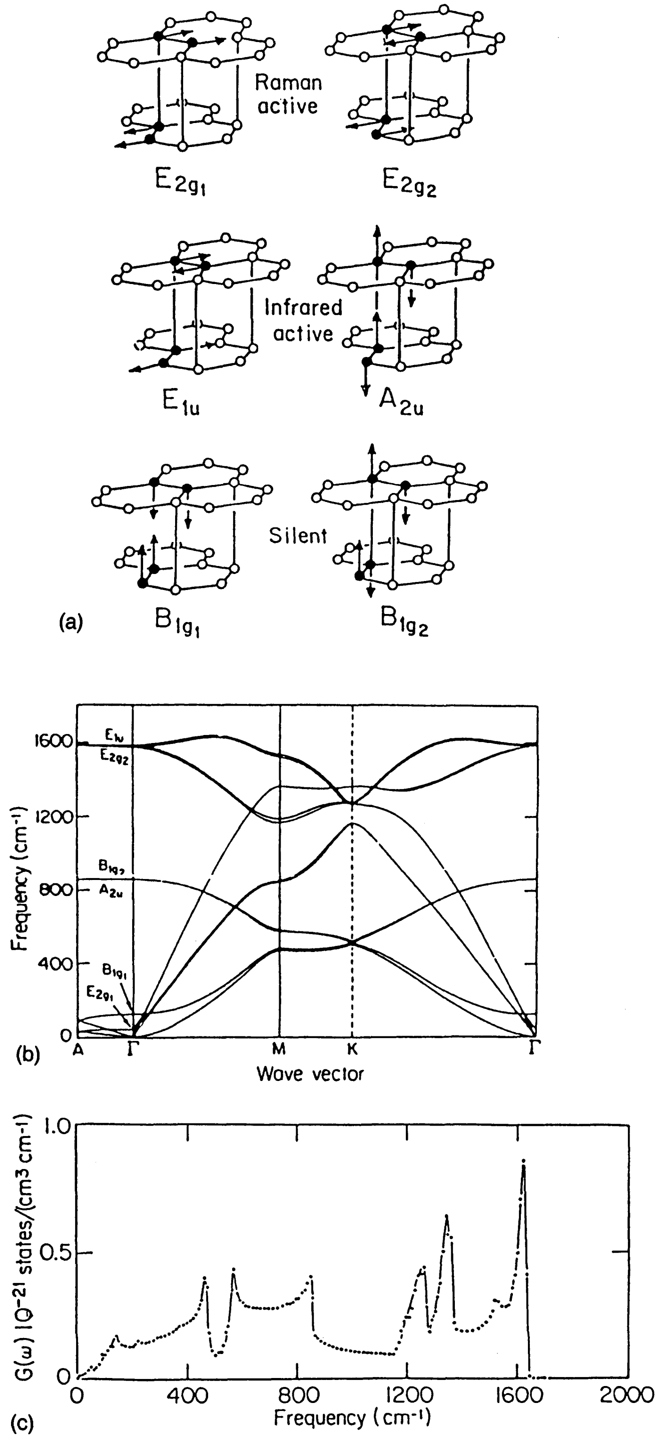
3. PROPERTIES OF GRAPHITE

The highly anisotropic structure of graphite gives rise to lattice, transport, optical, thermal, and mechanical properties that are likewise highly anisotropic. These are briefly reviewed below.

3.1 Lattice Properties

Because of the strong in-plane and weak interplanar bonding in graphite, the force constants controlling the atomic vibrations, the dispersion relations for the lattice vibrations, and the velocity of sound are all highly anisotropic (Table 1). Since there are four atoms/unit cell, there are $4 \times 3 = 12$ degrees of freedom giving rise to nine optical and three acoustic branches for the lattice vibrations (phonons). Of these, there are two infrared-active zone-center phonons with E_{1u} (1588 cm^{-1}) and A_{2u} (868 cm^{-1}) symmetries for the in-plane and out-of-plane vibrational modes, and two Raman-active in-plane vibrational modes denoted by E_{2g_1} (45 cm^{-1}) and E_{2g_2} (1582 cm^{-1}) (Dresselhaus and Dresselhaus, 1982). The atomic displacements associated with these normal-mode vibrations in graphite are shown in Fig. 5(a). Of particular importance to the characterization of graphite materials is the E_{2g_2} vibrational mode. In the case of 2D turbostratic graphite, the Raman-active vibrational mode at 1582 cm^{-1} persists.



45p

FIG. 5. (a) Zone-center optical vibrational modes for carbon atoms in the graphite structure. For the in-plane vibrational modes (E_{1u}, E_{2g_1}, and E_{2g_2}), only one of the degenerate pairs of modes is shown. The *c*-axis modes (A_{2u}, B_{1g_1}, and B_{1g_2}) are nondegenerate. The zero-frequency acoustic modes (E_{1u} and A_{2u}) correspond to pure translations and are not shown. (b) Phonon dispersion curves for the lattice vibrations in graphite along certain high-symmetry axes in the hexagonal Brillouin zone. (c) Phonon density of states corresponding to the phonon dispersion curves for graphite. The phonon frequencies are expressed in cm^{-1} (Dresselhaus and Dresselhaus, 1982).

In addition, strong features in the Raman spectra are observed in disordered graphites at the maximum frequency in the graphite phonon dispersion relations at 1630 cm^{-1} [Fig. 5(b)] and the maximum in the phonon density of states near 1360 cm^{-1} [Fig. 5(c)] (Dresselhaus and Dresselhaus, 1982). Crystalline disorder breaks down the selection rules for Raman scattering, allowing contributions to the scattering intensity from non-zone-center phonons. Thus the integrated intensity of the disorder-induced lines at $\sim$1360 cm^{-1} and $\sim$1630 cm^{-1} relative to that for the Raman-allowed 1582-cm^{-1} line allows for characterization of disordered graphites in terms of their average in-plane crystalline size (L_a) (Knight and White, 1989). Information on the phonon dispersion relations $\omega(q)$ has been provided by inelastic neutron scattering measurements and a variety of other techniques, and this information has been used to obtain $\omega(q)$ for the 12 phonon branches and the phonon density of states shown in Fig. 5.

3.2 Electronic and Transport Properties

The electronic and transport properties of graphite have been extensively studied and reviewed (McClure, 1971; Spain, 1973; Spain, 1981). These properties are dominated by the strong in-plane sp^2 or σ bonding and by the large anisotropy of the graphite crystal structure. Corresponding to the strong sp^2 in-plane bonding of a single graphene sheet, three σ bonds are formed far below ($\sim$10 eV) the Fermi level E_F, and three antibonding σ bonds far above E_F. Thus the transport properties of 2D graphite are largely determined by the two π bands (one bonding and one antibonding) which lie close to E_F. By symmetry, the two π bands formed by the p_z orbitals are degenerate at the 2D hexagonal Brillouin zone corners, and the Fermi level E_F passes through this degenerate point in reciprocal space, giving rise to a zero-band-gap semiconductor. This zero-band-gap semiconductor model is appropriate for the description of turbostratic graphite, which has a well-developed crystalline structure within the layer planes but no correlation between the atomic positions of atoms on adjacent layer planes.

In contrast, perfectly ordered crystalline graphite has a weak interlayer interaction giving rise to semimetallic behavior with a band overlap between the conduction-band minimum energy and the valence-band maximum energy of about 40 meV. The band structure near the Fermi level is described by the Slonczewski–Weiss–McClure energy-band model for the four π bands in the 3D Brillouin zone in reciprocal space in terms of seven band parameters (McClure, 1971). These band parameters are identified with overlap integrals and transfer integrals arising from the tight-binding Fourier expansion of the electronic energy bands along k_z and a $\mathbf{k}\cdot\mathbf{p}$ treatment of the energy bands in the k_x, k_y directions away from the Brillouin-zone edges. Figure 6 shows the 3D hexagonal Brillouin zone and the location of the various high-symmetry points. The band-structure model near E_F focuses on the electronic dispersion relations in the vicinity of the *HKH* and *H′K′H′* edges of the Brillouin zone. In two-dimensional or turbostratic graphite the Brillouin zone of Fig. 6 collapses into a single hexagonal sheet and the *HKH* axis collapses into a single point at each corner of the hexagon where the π bands are degenerate as discussed above.

The Fermi surface for semimetallic 3D graphite consists of both holes and electrons, and these carriers are located in carrier pockets along the Brillouin zone edges as shown schematically in Fig. 6. Because the carrier pockets occupy only a small volume of the Brillouin zone, as indicated in the figure, graphite has a low concentration of holes (p) and electrons (n), with $n=p=3\times10^{18}$ cm^{-3} in the low-temperature limit of an ideal graphite crystal (McClure, 1971). The highly anisotropic Fermi surfaces (see Fig. 6) give rise to small effective masses for both electron and hole motion in the basal plane, but to very large effective masses for motion along the c axis. The high in-plane mobility of the elec-

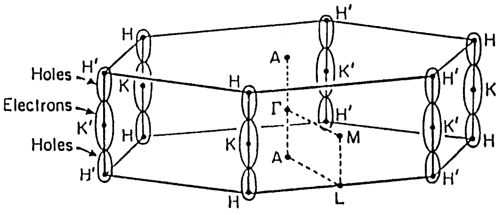


FIG. 6. Brillouin zone for three-dimensional graphite showing several high-symmetry points and a schematic version of the graphite electron and hole Fermi surfaces located along the *HKH* and *H′K′H′* axes of the Brillouin zone (Dresselhaus and Dresselhaus, 1981).

trons and holes in graphite allow accurate measurements of the Fermi surface, using the de Haas–van Alphen, Shubnikov–de Haas, and other magneto-oscillatory Fermi surface measurements (McClure, 1971).

The anisotropic Fermi surface is responsible for the high-mobility carriers [$\sim 1.3\times 10^4$ $cm^2/(V\,s)$] that dominate the in-plane transport properties and for the low-mobility carriers that dominate the electronic transport along the *c* axis. Anisotropy ratios of the in-plane to *c*-axis conductivity $\sigma_a/\sigma_c \sim 10^5$ are characteristic of low-temperature electronic transport in graphite (Spain, 1973). Since the Fermi level is only 24 meV above the *K*-point band extremum for electrons (see Fig. 6), there is significant thermal excitation of carriers at room temperature. Thus the temperature dependence of the in-plane electrical conductivity [$\sigma_a(T)$] for graphite is anomalous in comparison to that for conventional metallic conductors and is quite different from that along the *c* axis [$\sigma_c(T)$] (Spain, 1973). The temperature dependence of the electrical conductivity of single-crystal graphite in comparison with that for vapor-grown carbon fibers heat treated at various temperatures is shown in Fig. 7. At temperatures above $\sim$100 K lattice vibrations are the dominant scattering mechanism for electronic transport, while at low temperatures, scattering of electrons by crystalline defects is dominant. Thus the residual resistivity ratio (RRR), defined as the ratio between the room-temperature (T=300 K) and low-temperature (T =4.2 K) electrical resistivities ($\mathrm{RRR}=\rho_{300\,\mathrm{K}}/\rho_{4.2\,\mathrm{K}}$), is often used to characterize a conducting material for its crystalline defects. In Fig. 7 we see that single-crystal graphite can have residual resistivity ratios RRR of as

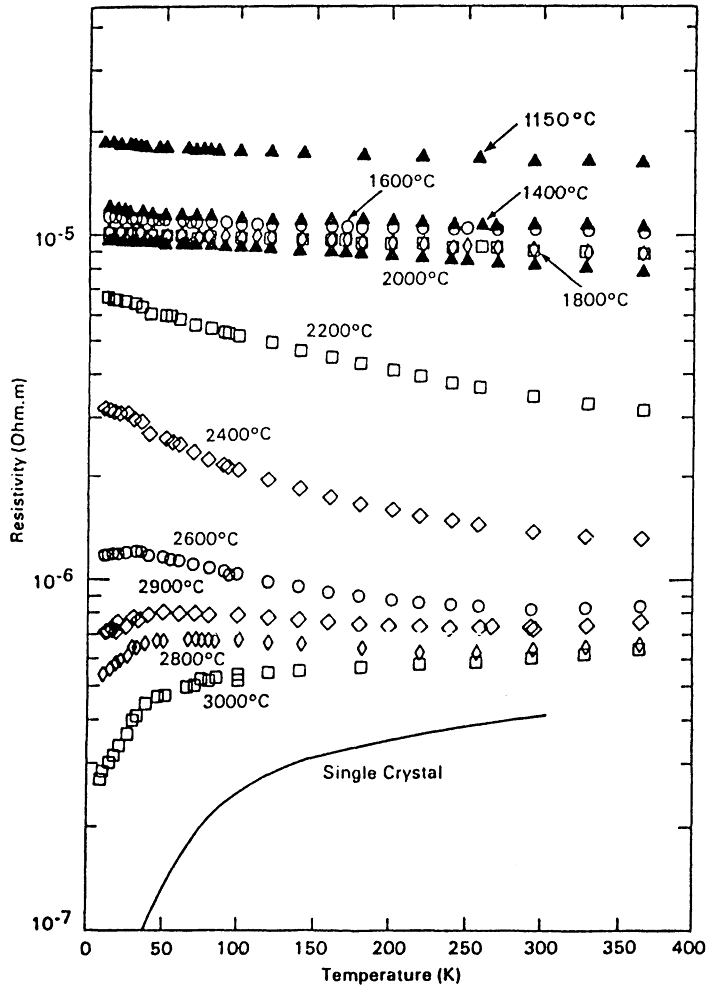

FIG. 7. The temperature dependence of the resistivity of single-crystal graphite and for benzene-derived vapor-grown graphite fibers heat treated to the various indicated temperatures (Dresselhaus *et al.*, 1988).

much as 10^2. Disordered carbons typically show RRR values approaching unity (see Fig. 7) and reduced anisotropy in $\sigma(T)$ as well. The special geometry of carbon fibers makes them attractive materials for transport studies. Vapor-grown carbon fibers when heat treated to high temperatures (e.g., 3000 °C) exhibit transport properties quite similar to graphite (see Fig. 7). However, in their as-prepared state ($T_{HT} \simeq 1150$ °C), their room-temperature resistivity is about 40 times higher and the resistivity is nearly temperature independent, since for these fibers the defect scattering of the electronic carriers is much larger than for crystalline graphite and dominates over the scattering by lattice vibrations over the entire temperature range of measurement in Fig. 7.

The introduction of crystalline defects tends to reduce the effective band overlap (thereby reducing the carrier density). Crystalline defects also reduce the carrier mobility, leading to a significant increase in resistivity ρ_a relative to its value ($\rho_a = 41\ \mu\Omega$ cm) in crystalline graphite (Spain, 1981). As the defect density increases, localized states are formed at the respective band edges for electrons and holes, and the conductivity drops in accordance with presently accepted models for weak localization (see ELECTRON STATES, LOCALIZED) and carrier-carrier interaction effects. Eventually, when a high degree of crystal disorder is reached, the Fermi level drops below the mobility edge (for holes), giving rise to a conduction process called variable-range hopping conduction across an effective mobility gap, typical of disordered semiconductors. Glassy carbon is an example of such a disordered material where the conductivity has dropped by a few orders of magnitude relative to that of crystalline graphite. A typical range of resistivities would be 4.5×10^{-3} to 4×10^{-4} Ω cm for GC heat treated to $T_{HT} \sim 2500$ °C. The temperature dependence of the conductivity of glassy carbon, which is due to carrier hopping, exhibits an $\exp[-(T_0/T)^{1/4}]$ law, characteristic of 3D variable-range hopping for $T_{HT} < 1000$ °C. As T_{HT} increases, $\sigma(T)$ increases in magnitude and becomes independent of temperature.

The magnetic susceptibility χ for crystalline 3D graphite has a large diamagnetic contribution arising from strong interband coupling terms (McClure, 1971), and this diamagnetic contribution can be used to provide an accurate determination of the nearest-neighbor π-orbital overlap integral γ_0. The introduction of disorder reduces the magnitude of the diamagnetic contribution, and in the 2D limit where adjacent graphene layers become decoupled (i.e., for turbostratic graphite), the diamagnetic contribution provides a measure of the interplanar coupling in graphite.

Electron-spin-resonance (ESR) measurements provide another common characterization tool for graphite and disordered graphite. For highly ordered 3D graphite, the ESR signal is typical of conduction-electron spin resonance in metallic systems with long electron mean free paths. The g factor in graphite is highly anisotropic at room temperature, where $g_\perp = 2.0026$ for $H \perp c$ axis, and $g_\parallel = 2.0495$ for $H \parallel c$ axis. The introduction of disorder reduces $g_\parallel$ sharply toward the free-electron value of 2.0023, thereby reducing the anisotropy of the g factor. For highly disordered graphite, where hopping conductivity predominates, the unpaired spins give rise to a Curie term in the low-temperature magnetic susceptibility, the ESR line becomes Lorentzian, and the g factor becomes isotropic and close to the free-electron value. Thus, ESR is also widely used for the characterization of disordered graphitic materials.

3.3 Optical Properties

Graphite is a relatively good electrical conductor; hence its optical properties are usually investigated by optical reflectivity rather than optical absorption measurements. Because of the low carrier density of graphite, the free carriers do not give rise to a clear plasma response in the reflectivity spectrum. Since the contributions to the dielectric function $\epsilon(\omega) = \epsilon_1(\omega) + i\epsilon_2(\omega)$ from the free carriers, interband transitions, and lattice vibrations all occur over the same frequency range, the frequency dependence for each of these three contributions to $\epsilon(\omega)$ must therefore be extracted from the measured reflectivity spectra through a line-shape analysis and a detailed curve-fitting procedure (Dresselhaus *et al.*, 1988).

Because of the large anisotropy of the electrical conductivity of graphite, the optical skin depth for the polarization **E** parallel to the c axis is an order of magnitude greater than for the polarization **E** perpendicular to the c axis. The resulting anisotropy of the free-carrier contribution to $\epsilon(\omega)$ together with major differences in the interband transitions for the two polarizations gives rise to highly anisotropic optical reflectivity spectra.

In a magnetic field, the optical spectra show well-defined structure associated with optical transitions between magnetic energy levels. These spectra have been extensively studied in crystalline graphite. These magnetoreflection spectra together with optical spectra in zero magnetic field and Fermi-surface measurements have all been used to determine the band parameters of the Slonczewski–Weiss–McClure model which describes the electronic structure of graphite within a few eV of the Fermi level (McClure, 1971).

3.4 Thermal Properties

The c-axis thermal conductivity is about 300 times smaller than in plane, giving rise to a material with extremely high anisotropy in the thermal conductivity; the highest thermal conductivities reported in the literature for graphite are given in Table 1. The thermal-conductivity and thermal-expansion coefficients of graphite are both highly anisotropic (Kelly, 1981; Dresselhaus *et al.*, 1988), as described below. These thermal properties of graphite (see Table 1) have been extensively studied and reviewed (Kelly, 1981). The in-plane thermal conductivity κ_a of graphite is the highest (together with that of diamond) of all materials in nature. Typically metallic materials exhibit contributions from both electrons and lattice vibrations to their thermal conductivity. Nevertheless, the thermal conductivity of graphite is dominated by lattice contributions because of the low carrier concentration of crystalline graphite. The very high in-plane thermal conductivity κ_a is reduced by defect scattering, and for this reason the best thermal conductors are highly crystalline. Likewise, the high degree of anisotropy in the thermal conductivity ($\kappa_a/\kappa_c \approx 300$) of graphite is reduced by the introduction of defects. Because of the quasi two-dimensional nature of graphite, the thermal conductivity roughly follows a temperature dependence of $T^{2.3}$ at low temperature, which is close to T^2, the temperature dependence expected for two-dimensional materials. Typically, materials in the solid state exhibit a T^3 temperature dependence of their thermal conductivity, associated with the temperature dependence of the excitation of lattice vibrations in 3D systems.

The thermal expansion coefficient α of graphite is also highly anisotropic, very large and positive along the c axis (α_c) and very small and negative in plane (α_a) at room temperature (Kelly, 1981; Dresselhaus *et al.*, 1988). As a function of temperature, α_c increases rapidly until about 400 K and much more slowly at higher temperatures. The in-plane behavior is, however, very different, with α_a first becoming more negative with increasing T until about 300 K where α_a is at its most negative value; as T is further increased, α_a becomes less negative, and finally becomes positive at about 800 K (Kelly, 1981). These unusual thermal expansion coefficients make it difficult to bond other materials to graphite over a broad temperature range.

The heat capacity of graphite is likewise dominated by the contribution from the lattice vibrations because of the low carrier density. Of particular interest is the temperature dependence of the heat capacity, which follows a T^2 dependence, indicative of the quasi-2D nature of graphite. The heat capacity C_p and the lattice thermal conductivity κ_l are related according to a kinetic model by $\kappa_l = \frac{1}{3}C_p v l$ where v is the velocity of sound and l is the mean free path for the lattice vibrations (Kelly, 1981).

The thermoelectric power for graphite is small and exhibits an unusual temperature dependence because of the importance of phonon-drag effects, which are dominant below ~100 K. These phonon-drag effects are associated with electronic motion resulting from electron carriers that are dragged along with their associated ions as the ions participate in lattice vibrations. The introduction of disorder suppresses phonon-drag effects and increases the magnitude of the thermoelectric power. For turbostratic graphite a linear temperature dependence of the thermopower can be observed (Tsuzuku and Sugihara, 1975).

3.5 Mechanical Properties

Because of its strong in-plane bonding, graphite is a very stiff material with an extremely high Young's modulus (~800 GPa)

Table 2. Elastic constants for single-crystal graphite.

Elastic moduli (GPa)		Elastic compliance (10^{-12} Pa^{-1})	
C_{11}	1060 ± 20	S_{11}	0.98 ± 0.03
C_{12}	180 ± 20	S_{12}	-0.16 ± 0.06
C_{13}	15 ± 5	S_{13}	-0.33 ± 0.08
C_{33}	36.5 ± 1	S_{33}	27.5 ± 1.0
C_{44}	4.5 ± 0.5	S_{44}	240 ± 30

and a very high in-plane tensile strength ($\sim$20 GPa) (see Table 1). These high values for Young's modulus and tensile strength were measured on carbon whiskers (Bacon, 1960) which are formed in a carbon arc discharge and consist of a highly ordered graphene sheet rolled up in the form of a scroll. This high tensile strength is exploited in most of the practical applications of carbon fibers. Because of the weak interplanar forces, graphite has a very low shear strength ($\sim 4.8\times10^5$ Pa) (Kelly, 1981); the compressional strength of graphite is also much lower than its tensile strength. Because of its hexagonal symmetry, graphite is described by stress-strain relations involving five independent elastic constants, as are listed in Table 2. In contrast, a cubic material is described by three independent elastic constants, while a completely isotropic material is described by two independent elastic constants, one relating to tension or compression, and the other relating to shear.

The mechanical properties of graphite are dominated by their high degree of anisotropy and reflect the high crystalline anisotropy. Since many of the graphite-based systems that are exploited for their mechanical properties are highly defective and are used in fibrous forms embedded in various matrix materials, the analysis of the mechanical properties of carbon fiber composites is complex.

GLOSSARY

Activated Carbon Fibers: Carbon fibers with very large surface area per unit mass.

Basal Plane: The plane normal to the main symmetry axis, usually called the *c* axis.

Carbon Fiber: Fiber morphology showing graphitic planes preferentially aligned along the fiber axis.

Carbon Whisker: A scroll made with a single graphene plane.

Exfoliated Graphite: A graphitic material in which many layer planes are widely separated, giving rise to a very large–surface-area material.

Glassy Carbon: A highly disordered, weakly conducting form of carbon containing graphitic ribbons, having high porosity and good mechanical properties.

Graphene Layer: An isolated single layer of hexagonally arranged carbon atoms such as found in graphite.

Graphite Intercalation Compound (GIC): Compound formed by the insertion of a layer of guest species between the planes of graphite.

Graphitelike Ribbon: Ribbon formed of long thin strips of graphene layers.

High-Performance Fibers: Carbon fibers specially developed for their desirable mechanical properties.

Highly Oriented Pyrolytic Graphite (HOPG): A synthetic form of graphite with a high degree of *c*-axis alignment, but having in-plane crystallites ($\sim$1 μm in size) that are randomly oriented normal to the *c* axis.

Kish Graphite: A synthetic single-crystal graphite material prepared from precipitation in high-carbon steel.

Nongraphitizable: A form of disordered carbon which is a tangled ball of ribbons that will not graphitize even at high temperature and pressure.

Pyrolytic Graphite: Graphite formed by heating organic compounds.

Rhombohedral Graphite: Graphite with *ABC* layer stacking.

sp^2 Bonding: Three planar bonds derived from one *s* and two *p* atomic carbon orbitals making angles of 120° with each other.

sp^3 Bonding: Four bonds derived from one *s* and three *p* atomic carbon orbitals making tetrahedral angles.

Vapor-Grown Carbon Fibers: Carbon fibers synthesized from hydrocarbons in the gas phase, usually involving a catalyst.

INTRODUCTION

Albert Einstein's development of general relativity in 1915 was one of the landmarks of twentieth-century theoretical physics. Einstein (1879–1955) had few experimental facts to guide him in replacing Newtonian gravity with a theory compatible with his earlier theory of special relativity (see RELATIVITY, SPECIAL). Using arguments of consistency, simplicity, and aesthetics, Einstein arrived at a theory that has subsequently passed stringent experimental tests, and that has predicted and explained a wide range of astronomical phenomena that were completely unknown at the time Einstein did his work.

Einstein's methodology had a great influence on the style of later attempts to simplify and unify theories of high-energy physics. Nevertheless, it is only since about 1970 that developments in astronomy and in experimental physics have placed general relativity into the mainstream of physics, part of the expected competence of any theoretical physicist.

General relativity is now the accepted theory of gravity. Although compatible with special relativity, it is incompatible with quantum theory. Presumably it will eventually be replaced by a quantum theory of gravity, and for this reason there is considerable interest in alternative theories of gravity and in testing gravity to find small departures from the classical theory. So far, all experiments and observations have been consistent with general relativity, many at a high level of precision.

This article discusses relativistic gravitation from a nonmathematical point of view, highlighting the underlying connections of general relativity with the rest of physics (including Newton's theory of gravity), examining the foundations of the theory (equivalence principle, geometrical approach), and emphasizing the observable and experimental consequences of the theory. These include astronomical phenomena, such as black holes, gravitational lenses, and the Big Bang; high-precision tests of the equivalence principle, of solar-system effects, and of gravitational radiation; and present efforts to make direct observations of gravitational waves from supernova explosions, colliding black holes and neutron stars, and the Big Bang itself.

Most aspects of experimental gravity push modern technology to its limits, and they are therefore fruitful areas for the application and development of new technology. Examples include the development of low-temperature superconducting quantum-interference device (SQUID) technology for space-based tests of magnetogravity and for gravitational-wave detectors; the routine employment of corrections for the gravitational redshift in the U.S. Air Force's Global Positioning System (GPS) navigation system; the application of dilution refrigeration on a large scale to cool gravitational-wave bar detectors weighing several tons to temperatures approaching 10 mK; and the use of high-power cw lasers and ultralow-loss optical components in interferometric gravitational-wave detectors. Current research into squeezed light for telecommunications (see OPTICAL COMMUNICATIONS) was stimulated in large part by theoretical work on ways of making gravitational-wave detectors more sensitive.

The field of experimental relativity is an active one; this article presents a snapshot of current developments as of the time of its completion, early in 1993.

1. GENERAL RELATIVITY AND RELATIVISTIC GRAVITY

Einstein's theory of general relativity (GR) is the accepted theory of gravity in modern physics. In the Solar System and other regions of weak gravitational fields, it differs little from Newton's theory of gravity; but when gravity is strong enough to accelerate particles to near the speed of light, its predictions are very different. General relativity describes gravity in geometrical terms; the curved geometry of space and time is an arena in which all the rest of physics takes place. The theory has become an everyday tool for astrophysicists who model the most unusual phenomena in astronomy: black holes, gravitational waves, and the theory of cosmology are all features of the theory that find application in astronomy. For textbook introductions to general relativity, see Misner *et al.* (1973) or Schutz (1985).

1.1 Gravitation Theory: An Overview

1.1.1 Relativistic Gravity in Physics

1.1.1.1 Roots in Newtonian Gravity. Newton's laws of motion and his theory of gravity had a revolutionary effect on science. They explained the motions of the planets and taught scientists that the heavenly bodies were subject to the same laws as bodies on Earth. Newton showed that masses exert forces on each other that diminish with the square of the distance between them. The success of Newtonian gravity in the Solar System, as well as in other stellar systems, is described in the article ASTRONOMY.

In Newton's theory, the gravitational forces between bodies act instantaneously across any distance. Space is flat and time is universal: once synchronized, identical clocks keep time with one another regardless of their state of motion. It was not until the nineteenth century that physicists had any experimental evidence that challenged this idea about time (the Michelson–Morley experiment). The first evidence for the *curvature* of space came from the 1919 eclipse expedition, described in Sec. 3.2.1 below.

1.1.1.2 The Impact of Special Relativity: Relativistic Gravity is Required. Einstein's development of special relativity (SR) changed notions of space and time (see RELATIVITY, SPECIAL). Space, while still flat, merged with time to form *spacetime*. Clocks in relative motion would not remain synchronized, and moving lengths would contract. Most importantly, no influences could travel faster than light.

This limiting speed undermines Newtonian gravity: gravity cannot "act at a distance" without a delay. In the solar system, where light crosses an orbit in a small fraction of the orbital period, the delay is small, and Newton's theory works well. But the theory had to be replaced.

It took Einstein another decade to find a suitable replacement: *general relativity*. It incorporates SR as the limit of vanishing gravity. It approaches Newton's theory as a limit when gravity is the dominant force but is still weak enough that the resulting motions are much slower than light. But in other regimes GR makes startlingly new predictions. Black holes, gravitational waves, the Big Bang: Einstein had no inkling of these when he devised the theory, and it is remarkable that these unforeseen consequences of the theory have been verified by astronomical observations in recent years.

It is interesting that Einstein was "beaten" to the correct form of the equations of GR by the great mathematician David Hilbert, whose paper (Hilbert, 1915) was submitted five days before Einstein presented his theory to the Prussian Academy (Einstein, 1915). Einstein is universally credited with the theory because his physical insight into its foundations, such as the equivalence principle and the geometric form of the theory, guided Hilbert as much as they guided Einstein; and it was Einstein who worked out the first physical consequences of the equations.

Despite GR's success, it is not the only possible relativistic generalization of Newtonian gravity. In many ways it is the simplest, but many others exist. Most, like the Brans–Dicke–Jordan class of theories (Sec. 1.2.5), introduce extra fields that have further gravitational effects. Others depart from GR by violating the equivalence principle (Sec. 1.2.2.2). The only way to decide which theory is right in detail is to test them experimentally. Testing relativistic gravity is one of the areas in which modern technology has made possible great advances (Sec. 3).

1.1.1.3 The Impact of Quantum Mechanics: Quantum Gravity is Required. Although GR reconciled the contradiction between SR and Newtonian gravity, it soon fell afoul of a different inconsistency. The theory of quantum mechanics matured only two decades after the birth of GR, and now almost all of physics is described by quantum theories; GR is the only major exception.

Much current research attempts to find an appropriate quantum theory of gravity. So far that effort, while producing many interesting new ideas, has not reached its goal. Because GR is a highly nonlinear theory, conventional methods of quantizing theories have so far failed to produce a consistent quantum theory of gravity. The search is made more difficult because of the paucity of experimental guidance. If there are properties of the known universe that give us decisive clues to quantum gravity, we have not yet recognized them.

Dimensional analysis is interesting in this respect. If quantum gravitational effects dominate in some situation, then the laws must involve the three fundamental constants of nature, G (Newton's constant of gravitation), h (Planck's constant), and c (the speed of light). From these constants one can construct numbers with any of the fundamental dimensions, e.g.,

$$(hc^5/G)^{1/2}=4.9\times10^9\ \mathrm{J}=3.1\times10^{28}\ \mathrm{eV}\quad \text{(Planck energy)}; \tag{1}$$

$$(hG/c^3)^{1/2}=4.1\times10^{-35}\ \mathrm{s}\quad \text{(Planck time)}; \tag{2}$$

$$(hG/c^5)^{1/2}=1.4\times10^{-43}\ \mathrm{m}\quad \text{(Planck length)}. \tag{3}$$

These are so far from accessible experimental domains that it is not surprising that we have little experimental guidance for quantum gravity.

It may well be, however, that effects related to quantum gravity are important on other scales, particularly if gravity is part of a *grand unified theory* of physical interactions. (See UNIFIED FIELD THEORIES.) There may be small corrections to Einstein's equations that are appropriate in a semiclassical limit, and these might take the form of extra gravitational fields. For this reason, there has been renewed interest of late in alternative theories of gravity and in the experimental limits that can be placed on them.

The regime of quantum gravity may be far from the experimental domain, but the theoretical motivation for finding the right theory is very strong. Besides the need simply for consistency with other theories, there is also the striking fact that GR seems to predict its own failure: many solutions, including apparently all black-hole solutions, contain *singularities*, which are places where GR fails to describe the Universe in a consistent way. (See Sec. 2.2.3.) The Big Bang begins with such a singularity. There is a strong feeling that quantum gravity will tell us what the singularities really mean.

1.1.2 Where Relativistic Gravity Is Important. Relativistic gravity is required where the speeds produced by gravitational attractions approach the speed of light. A system with mass M and overall size R will produce velocities of order

$$v_{\text{self-gravity}}=(GM/R)^{1/2}\ . \tag{4}$$

For example, the escape velocity from a spherical body is $\sqrt{2}v_{\text{self-gravity}}$, and the velocity of a planet in a circular orbit of radius R about a star of mass M is exactly $v_{\text{self-gravity}}$. A test for the importance of relativistic effects is

$$\Phi:=GM/Rc^2\ll 1 \Rightarrow \text{gravity is nonrelativistic.} \tag{5}$$

At the Sun's surface, $\Phi=2\times10^{-6}$; everywhere else in the Solar System it is smaller. This accounts for the accuracy of Newtonian gravity. One needs relativistic gravity when Φ is not small.

1.1.2.1 Compact Objects of High Density. To make Φ larger one can increase M and/or decrease R. If a body of fixed mass shrinks in size, relativistic effects become important when the radius nears the *gravitational radius* R_g:

$$R_g:=2GM/c^2\ . \tag{6}$$

The factor of 2 in this is conventional.

The gravitational radius of the Sun is about 3 km. Remarkably, stars do collapse to nearly this size: perhaps 1% of all stars are *neutron stars* (Sec. 2.4.1), with radii about 10 km. If a star actually reaches the gravitational radius, then it collapses further to a *black hole* (Sec. 2.2).

The density ρ of a neutron star is enormous. If we take $M=1M_\odot$ (astronomer's notation for the mass of the Sun) and $R=10$ km, we have $\rho_{\text{NS}}=5\times10^{17}$ kg m^{-3}. This is comparable to the density of a typical atomic nucleus.

The critical density ρ_c at which the object reaches its gravitational radius depends only on M:

$$\rho_c:=3c^6/32\pi G^3M^2\ . \tag{7}$$

For the Sun it is about 2×10^{19} kg m^{-3}, but such enormous densities are not required for bodies of larger mass. A cluster of some 10^8 stars will collapse to a black hole if it reaches the density of water. This seems to have happened in the centers of galaxies (Sec. 2.4.2.2).

1.1.2.2 Cosmology: Relativistic Gravity at Low Densities. A second interesting way of reaching a situation where relativistic gravity is required is by increasing the size of a system of fixed density. As the mass increases, the critical density drops. Eventually the critical density approaches the system's fixed density and the body becomes relativistic. For most systems, this size would be unrealistically large. But there is one system that we can make as large as we like: the Universe itself.

The average mass density of the Universe (or at least of the piece we can see) is highly uncertain, but an observational lower bound is 10^{-28} kg m^{-3}. A sphere of radius 1.3×10^{27} m, or about 10^{11} light years, would enclose enough matter to give a relativistic gravitational field. Such distances are the regime of *cosmology*, the study of the Universe as a whole (Sec. 2.4.5).

Being able to describe cosmology consistently was in fact one of the great triumphs of GR: Newtonian theory is highly ambiguous when applied to infinite systems, whereas GR provides well-defined models.

1.1.2.3 Small Relativistic Effects: Gravitational Waves and Equations of Motion. Relativistic gravity is essential for the description of compact objects and of cosmology, but it can also be important for situations where its effects make small but measurable changes to Newtonian gravity. These are easiest to measure when the new relativistic effect is absent from Newtonian gravity, so that its signature is easy to see. Some effects we will look at below include the following:

1. Gravitational radiation (Sec. 2.3) is a direct consequence of the limitation on the speed of propagation of gravitational influences: oscillating motions of stars (say, in a binary system) produce an oscillating field that moves through space, a wave in the gravitational field. These can be directly detected essentially by looking for time-dependent gravitational fields. The weakness of gravity makes this one of the greatest technical challenges in physics today (Sec. 4). Even when direct detection of the waves is impossible, the back-reaction effects of their emission can sometimes be observed. An example of great importance is the binary pulsar PSR1913+16 (Sec. 3.3).
2. Gravity deflects light and produces observable time delays, effects that can be directly observed (Sec. 3.2.1). Light deflection also leads to gravitational lensing of astronomical images (Sec. 2.4.3).
3. Relativistic gravity produces small anomalies in the motions of planets and satellites of the Earth. We will discuss these in Secs. 3.2.2 and 3.4.1.

1.2 Fundamental Ideas and New Concepts of General Relativity

1.2.1 The Incorporation of Newtonian Gravity. Any theory of gravity must address two issues: how gravity affects matter, and how matter creates gravity. We review these in the context of Newtonian gravity, and then look at what new ideas Einstein brought to the subject.

1.2.1.1 The Equivalence Principle: How Gravity Affects Matter. Gravity affects everything: unlike any other force in nature, it cannot be turned off or screened out. Galileo showed that it affects all things in the same way: all bodies fall with the same acceleration in a gravitational field. For this reason, one cannot experimentally distinguish a uniform gravitational field from a uniform acceleration of the experimenter. This equivalence between gravity and acceleration is called the *weak equivalence principle* (WEP).

1.2.1.2 Newton's Field Equation: How Matter Creates Gravity. Newton's law for the gravitational force between two bodies of masses m_1 and m_2, separated by a distance r,

$$F_{\text{grav}} = Gm_1m_2/r^2 , \tag{8}$$

incorporated the equivalence principle: the acceleration of body 1, F_{grav}/m_1, is independent of m_1. Newton arrived at the $1/r^2$ law by studying the motion of the Moon, but the resulting law turned out to describe all the known properties of the solar system. One of its great triumphs was that it predicted that planetary orbits should be ellipses with the Sun at a focus.

Later development of Newton's theory found that the simple law given by Eq. (8) was in an inconvenient form to deal with complicated bodies. The modern form introduces the *gravitational potential* created by particle 1 as the following integral over its density ρ_1:

$$\phi_1(\mathbf{r}) = -G \int \frac{\rho_1(\mathbf{r}')d^3x'}{|\mathbf{r}-\mathbf{r}'|} . \tag{9}$$

The force on particle 2 due to particle 1 is

$$\mathbf{F}_{12} = -m_2\nabla\phi_1(\mathbf{r}) . \tag{10}$$

The field ϕ solves the *Poisson equation*:

$$\nabla^2\phi = 4\pi G\rho . \tag{11}$$

This very compact form for Newton's potential is usually known as *Newton's field equation*. It is the equation that must be generalized in any new theory of gravity.

1.2.1.3 Galileo's Principle of Relativity. Galileo's other seminal contribution to modern gravitational theory is what is now called the *principle of relativity*. A simple statement of the principle is that the (uniform) speed of an experimenter does not affect the outcome of an experiment. Galileo used the example of a ship moving on a calm sea: if you stand on the deck and drop a ball, it falls straight down relative to you, not along a vertical line as judged by an observer on the shore. For modern travelers, the experience of flying in an airplane at 900 km/h is more compelling: unless one hits air turbulence or looks out the window, it is impossible to tell how fast one is going.

1.2.2 Basic Ingredients of General Relativity

1.2.2.1 Special Relativity. Newtonian gravity already incorporated the Galilean principle of relativity, that the laws of physics were independent of the state of motion of the experimenter. In SR, this becomes formalized into the idea of an *observer,* who is basically an entire reference frame with an information-gathering mechanism to determine what happens in experiments. We usually restrict ourselves to so-called Lorentz observers, who move at a uniform speed relative to one another, and who normally use a rectangular coordinate system for locating things in space. Their time coordinate consists of a set of synchronized clocks.

What Einstein added to Galileo's principle in order to get SR was the central role of the speed of light c. In SR, the speed of light has the status of a physical law: it is invariant under a change of experimenter. If two different experimenters measure the speed of the *same* beam of light, they will *each* measure $c=2.998...\times 10^8\ \mathrm{m\ s^{-1}}$, regardless of their speed relative to each other.

Special relativity made many conceptual changes in physics, which in turn carry over to any relativistic theory of gravity. Space and time are no longer distinct, but form a four-dimensional *spacetime,* whose points are called *events.* The set of all events experienced by a given particle through all its history is called its *world line.* Different observers make different measurements of simultaneity, of distance (the *Lorentz contraction*), and of time (*time dilation*), but there is still an invariant measure of distance, called the *spacetime interval* ds^2:

$$ds^2=dx^2+dy^2+dz^2-c^2dt^2\ . \qquad (12)$$

(There are many conventions for this definition. We adopt the one most commonly used in GR.)

This is a generalization of the Pythagorean theorem of Euclidean geometry. Just as in Euclidean geometry, the physical length of the hypotenuse of the right triangle is given by the square root is the sum of the squares of the sides, so also in SR is the square root of the interval a physical observable. For two events separated by a positive (*spacelike*) interval, its square root is the length of a physical ruler that would stretch between the events in a frame in which the events are simultaneous. This is called the *proper distance* between the events. For two events separated by a negative (*timelike*) interval, we define the *proper time* $d\tau$ by $d\tau^2=-ds^2/c^2$. The proper time is the time elapsed on a clock that experiences both events. Events separated by a zero (*null* or *lightlike*) interval have zero proper time between them.

Because spacetime is four dimensional, vectors have four components and are called *four-vectors.* A simple four-vector is a tangent vector to a timelike world line. All such tangent vectors at a given event are parallel to one another. A useful one, conventionally called the *four-velocity* $\boldsymbol{U}$, is defined to have components

$$(U^t,U^x,U^y,U^z)=\left(\frac{dt}{d\tau},\frac{dx}{d\tau},\frac{dy}{d\tau},\frac{dz}{d\tau}\right)\ . \qquad (13)$$

(Here we have introduced some conventions: vector indices are written as superscripts, and the time dimension is normally taken first.) Because τ is an invariant, the components of $\boldsymbol{U}$ change in the same way as the coordinates do when the observer changes. This is part of the definition of a four-vector. Note that for small velocities, the interval $d\tau$ is nearly equal to the time interval dt, and the spatial components of $\boldsymbol{U}$ are nearly equal to the ordinary velocity. At the other extreme, the four-velocity of a null world line (e.g., that of a photon) is undefined, because $d\tau=0$ along it.

Although SR is normally described in terms of Lorentz observers with rectangular coordinates, one can allow other coordinate systems for both space and time. This complicates the mathematics, such as the form of Eq. (12), but is a price worth paying in particular circumstances, such as when dealing with an accelerated particle. What distinguishes SR from GR is, fundamentally, that it is *possible* to find a single Lorentz frame that covers all of spacetime. The notion that Eq. (12) describes the way rulers and clocks behave everywhere in spacetime is very restrictive; in particular, since the interval depends only on the coordinate differences between events and not on their absolute location (no explicit dependence on x,y,z,t), it follows that SR can only hold in a spacetime that is perfectly uniform, or *homogeneous*.

Special relativity also unifies energy and momentum. Just as time is dilated under a change of observer, so is energy increased. Just as there is no invariant separation between space and time, so is there none between energy and momentum. They are parts of a single vector in spacetime, the energy–momentum four-vector, which equals the rest mass of the particle times its four-velocity. Its time component is the particle's energy, and its spatial components are the momentum. For photons, the energy–momentum vector exists, even though the four-velocity does not. Since this vector is null, photons have energy equal to c times their momentum.

The introduction of the energy–momentum vector was a great conceptual advance for physics. In Newtonian mechanics, neither energy nor momentum had any observer independence: both changed when the observer's velocity changed. In SR, there is a single energy–momentum four-vector, unique to the particle. Its time component (the energy) and spatial components (momentum) do change, but they are subsidiary to the unique four-vector.

The identification of an invariant four-vector is a way of thinking introduced by SR that has great importance for GR. It is easy to understand what it means for a scalar quantity to be invariant, such as the interval in Eq. (12): its value is the same for all observers. A four-vector is likewise an invariant under spacetime coordinate transformations, just as the electric field vector **E**, for example, is under spatial rotations; its orientation with respect to other vectors is unchanged, even though its components change. (Many authors call such a thing a *geometrical object*.)

1.2.2.2 The Einstein Equivalence Principle. Special relativity requires a new formulation of the equivalence principle. In the Galilean principle, we traded off gravity against acceleration. But what does acceleration mean for light, whose speed cannot change? Fortunately, there is a new way to state the principle that is equally at home in Galilean or Einsteinian relativity.

The key is to focus on an experimenter who falls freely in a uniform gravitational field. This experimenter could, say, be in a spaceship that is coasting through this field. Any other particle that falls freely (has no nongravitational forces on it) will keep a constant velocity with respect to the experimenter. This can then also apply to light: if a photon passes by the falling experimenter, it will maintain a constant relative velocity, maintaining not only its speed c but also its direction.

More generally, any observer who works in a *freely falling reference frame* in a uniform gravitational field will not be able to determine that there is a gravitational field at all. The results of any experimenters are just as in SR. This is the *Einstein equivalence principle* (EEP).

The EEP implies that SR can cope with *uniform* gravitational fields: just use freely falling observers and the effects of the fields go away. More importantly, it also means that SR is incompatible with nonuniform gravity, which is what one has in every real situation. Near the Earth, for example, the local acceleration of gravity changes from place to place. Since SR requires a Lorentz frame to exist and be rigid everywhere, it is not possible to identify such a frame in the presence of real gravity. Thus, SR cannot incorporate nonuniform gravity.

However, even in a nonuniform field, a *local* freely falling observer sees no gravity locally. Weightless astronauts feel no gravity, even though gravity holds them in orbit around the Earth. The EEP implies that gravity can still be removed *locally*, even if not globally. It is a powerful principle. Three of its consequences are explored in the next three sections.

1.2.2.3 Tidal Forces Are the Real Gravity. The EEP implies that all the real, irremovable effects of gravity must therefore have to do with the differences between nearby freely falling observers. Any relativistic theory of gravity must give special importance to these differences between local gravitational accelerations.

These differences are called the *tidal forces*. They get their name from the tides raised on the Earth by the Moon and Sun. The Earth's oceans bulge out on both the near side and the far side with respect to the Moon. The near side of the Earth wants to fall towards the Moon slightly faster than the average, while the far side falls slightly slower. The size of the bulge is determined by the *difference* in the acceleration of gravity due to the Moon across the Earth. This gradient is called the tidal force of the Moon. If we could not see the

Moon, we could still infer its existence from observations of the tides: tidal forces are the observer-independent gravitational forces.

1.2.2.4 Gravitational Redshift. Photons are redshifted (lose energy) as they climb out of a gravitational field. A simple thought experiment shows how this follows from the EEP. We send a photon up from the ground to the top of a tower of height h, where it is detected by equipment at rest with respect to the Earth. During the time h/c it takes the photon to reach the top of the tower, a local freely falling frame has acquired a speed $v=gh/c$ downwards, where g is the acceleration of gravity on the surface of the Earth. In this frame, the EEP tells us that the photon's frequency does not change, as measured by this observer. Since the top of the tower is *rising* at speed gh/c relative to this observer, there is a Doppler redshift that produces a lengthening of the wavelength λ by a fractional amount

$$\frac{\delta\lambda}{\lambda}=\frac{v}{c}=\frac{gh}{c^2}. \tag{14}$$

The EEP implies that an experimenter who remains at rest with respect to the Earth measures this redshift of the photon as it climbs upwards in the gravitational field. Since the product gh is the change in the Newtonian gravitational potential between the emitter and the absorber, the redshift is just a function of the potential difference.

The gravitational redshift has another important interpretation. Since the frequency of the photon is measured essentially by clocks located at the emitting and absorbing locations, it is impossible for these clocks to remain synchronized. During a given number of oscillations of the photon's electromagnetic field, the clock on the ground ticked less time than the one higher up. The clock nearer the ground runs more slowly. *The gravitational redshift implies a gravitational time dilation.* This is now routinely measured by the GPS of satellites (Sec. 3.1.3).

1.2.2.5 Gravitational Deflection of Light. Consider light passing a star. Since light must travel on a straight line with respect to a local freely falling observer, and since these observers all fall towards the center of the star, the light must continually bend its direction of travel in order to go on a straight line with respect to each observer it happens to pass. We can estimate the size of the effect roughly by the following argument, which uses Newtonian concepts.

Let us consider just one freely falling observer who is at rest with respect to a star of mass M at the point where the light beam makes its closest approach to the star as it passes it by. Let this closest distance be R. The observer's acceleration towards the star is $g=GM/R^2$. Traveling at speed c, the photon will experience most of its deflection in a time of order R/c, the time it takes for the photon to move significantly further away from the star. During this time, the observer has acquired a speed $v=gR/c=GM/Rc$ perpendicular to the motion of the photon. By the EEP, the photon must also have acquired roughly this same speed transverse to its original direction. This means it changes its direction of travel relative to the star by an angle $\alpha=v/c=GM/Rc^2$ rad.

The total deflection should be double this, since the photon will experience the same deflection in to the point of nearest approach as going out. A more careful integration of this effect along the whole of the light path gives, coincidentally, exactly the same as our rough estimate, a total Newtonian deflection of $2GM/Rc^2$. This calculation was first performed by Cavendish in 1784 and independently by von Soldner in 1801, on the assumption that light was a corpuscle moving at speed c.

In relativistic gravity, however, there is an added effect that increases the deflection. This is, as we will see later, that space is curved near the star, and so the actual natural path of light as it passes the star, even if it were to go at an infinite speed, is deflected. The result in GR is that light is deflected by a net angle of

$$\alpha=4GM/Rc^2\ , \tag{15}$$

double the Newtonian result.

For a light beam passing the Sun, just grazing its surface, the effect is small: α is less than 1.75 seconds of arc. This is measurable, as described in Sec. 3.2.1.

More dramatically, if the gravitational field is that of a faint cluster of galaxies, and the source of the light is a more distant but brighter quasar, then light from the quasar might reach the Earth by two or more different routes, giving separate images of the source separated by angles that are easy to resolve.

This is called *gravitational lensing*. By studying the distribution and relative brightness of multiple images, and the shape of distorted arclike images of a distant quasar, produced by an intervening galaxy or galactic cluster, astronomers can infer the distribution of mass in the cluster, particularly that of dark matter, which produces gravity, but not light. Indeed, one astronomer has dubbed this method *gravitational tomography*. By looking for differences in the arrival time of temporal features in the quasar signal (such as flare-ups) in the different images, a result of the light having traveled different path lengths, it may be possible to determine the distance of the lensed quasars and thereby obtain cosmological information. This is described more fully in Sec. 2.4.3.

1.2.3 General Relativity: Gravity as Geometry

1.2.3.1 Why Gravity Is Geometrical. The EEP tells us that the effect of gravity on a body does not depend on its internal properties. In a given gravitational field, a freely falling body will follow a straight line with respect to local freely falling observers. This means that its trajectory depends only on its initial position and velocity. Any body with the same initial position and velocity will follow the identical trajectory.

Einstein reasoned that the trajectories were more a property of the gravitational field itself than of its interaction with specific bodies. Gravity is not a force like electromagnetism or the strong interactions. It is a property of space and time.

It is natural to try to relate gravity to curvature. If the trajectories of freely falling bodies—bodies on which no nongravitational forces are acting—are curved lines, then maybe there is a natural way to associate these lines with the locally straight lines, called *geodesics*, of a curved space. This is exactly what Einstein did, but he had to include the curvature of space *and* time together. Consider a curved surface, such as that of an apple. By following as straight a line as possible, one traces out a curve that meanders over the surface. This curve is determined by one's initial position and direction. It is not determined, however, by the speed with which one travels along the apple. Since gravitational trajectories depend not only upon direction but also upon speed, they cannot be modeled by the curvature of space alone.

In a curved four-dimensional spacetime, the natural trajectories (the geodesics) will, by analogy, be determined by the initial position and the initial direction of the tangent vector, but not by the length of the tangent. Now, as we saw in our discussion of SR in Sec. 1.2.2.1, the four-velocity is a tangent vector to a particle's world line. Its components do contain the information about the ordinary velocity of the particle. For example, the ratio of the x component to the time component is $(dx/d\tau)/(dt/d\tau)=dx/dt=v^x$. Since any other tangent is a multiple of $\boldsymbol{U}$, this ratio will be the same for any tangent: it depends only on the direction and not the length of the tangent four-vector. Therefore, the information needed to determine a geodesic in a curved spacetime is exactly that needed to determine a gravitational trajectory: the position and ordinary velocity of the particle.

In this way, the EEP leads to the representation of gravity by the curvature of spacetime.

1.2.3.2 The Metric of Gravity. Curved spaces usually have no *natural* coordinate system. Special coordinates, such as Lorentz observers, do not exist in nonuniform gravitational fields, as we have seen. So we must admit arbitrary spacetime coordinate systems $\{x^\alpha,\ \alpha=0,1,2,3\}$ and we do not necessarily attach any physical significance to particular coordinate values or intervals. (Another convention here: we use Greek letters for spacetime indices, and the index 0 stands for the coordinate t.) Physical significance attaches only to things that can be measured. Coordinates are usually matters only of definition, not of independent measurement.

The intrinsic geometry of a curved spacetime is completely defined if one gives the distances between points (events, in our case). One only needs local distances, which may be integrated up along curves in the spacetime to give global ones. The distance information is contained in the *metric tensor* $g_{\alpha\beta}$:

$$ds^2=\sum_{\alpha=0}^{3}\ \sum_{\beta=0}^{3}\ g_{\alpha\beta}dx^\alpha dx^\beta\ . \tag{16}$$

This equation gives a prescription for calculating the invariant length ds^2 between nearby events separated by coordinate intervals dx^α in terms of the given set of functions $g_{\alpha\beta}$. The interval is an *invariant*; this property determines how the components $g_{\alpha\beta}$ change when the coordinates change. The term "tensor" refers to the fact that the 4×4 matrix of components must transform this way. (See GEOMETRICAL METHODS for more information on tensors.)

The metric tensor of SR is conventionally called $\eta_{\alpha\beta}$. By comparing Eq. (12) with Eq. (16), we find $\eta_{00}=-c^2$, $\eta_{xx}=\eta_{yy}=\eta_{zz}=+1$, and all other components of $\eta_{\alpha\beta}$ vanish. The spacetime of SR is called *Minkowski spacetime*, and the metric tensor $\eta_{\alpha\beta}$ is called the Minkowski metric.

The metric contains observable information. For example, the proper time on a clock that stays at fixed spatial coordinates ($dx=dy=dz=0$ on its world line) is related to the coordinate time interval dt by $d\tau^2=-g_{00}dt^2/c^2$. Given two clocks at different locations $\mathscr{A}$ and $\mathscr{B}$, then the ratio $g_{00}(\mathscr{A})/g_{00}(\mathscr{B})$ determines the time dilation between them.

We saw in Newtonian gravity that the gravitational time dilation depends on the difference between the potentials at the two points (Sec. 1.2.2.4). Since Newtonian theory only applies when gravity is weak and the metric is close to the Minkowski form, we have that $g_{00}=-(1+\epsilon)c^2$, where ϵ is small. Then the ratio of the two values of g_{00} depends to first order on the *difference* between the values of ϵ. Therefore, there is a close connection between ϕ and ϵ. If one follows the algebra through, one finds that, for a given Newtonian-type field, the metric needs to have $g_{00}\approx-(1+2\phi/c^2)c^2$. This establishes the role of the metric tensor in relativistic gravity: it is the analog of the Newtonian *potential.*

The metric has some simple properties that one can infer from Eq. (16). First, since exchanging dx^α and dx^β in this equation can be accomplished by relabeling the indices, there cannot be any difference between $g_{\alpha\beta}$ and $g_{\beta\alpha}$: the 4×4 matrix of components $g_{\alpha\beta}$ is *symmetric*. This means there are 10 independent components. Second, since one has complete freedom to change the coordinates, there are essentially four degrees of arbitrariness among the 10 components: a given curved spacetime can be described by a variety of metric tensors, all related by coordinate transformations. There are essentially $10-4=6$ geometrically independent functions that one can choose in order to determine the spacetime.

1.2.3.3 Local Flatness of Spacetime and the Local Freely Falling Frames. The freely falling observers are a special class of coordinate systems that make spacetime look as much like SR as possible in the region of one event. This idea is very similar to the observation that any smooth surface is nearly flat if we look at only a small region. The *local flatness theorem* states that we can choose any point as the origin of a locally flat (or in spacetime, freely falling) coordinate system and adjust the coordinates in such a way that if we make a Taylor expansion of the metric components about this point, the first departure from flatness will be at *second order* in the coordinates. This means that the coordinates can be chosen to make the first derivatives of the metric vanish at any desired point. Since the acceleration of gravity also vanishes in a freely falling frame, the local flatness theorem suggests that *the acceleration of gravity resides in the first derivatives of the metric tensor components* at the point. This is consistent with the relation we saw earlier between the metric and the Newtonian potential.

1.2.3.4 Curvature and Tidal Forces. The *curvature* of the spacetime is a function of the metric tensor. The relation is not immediately straightforward, since even in the flat (Minkowski) spacetime of SR, one can choose a funny coordinate system and make the metric components look very complicated. The local flatness theorem tells us that the curvature is not defined by the first derivatives of the metric, since these can be made to vanish. Therefore, the curvature information must reside in the second derivatives of the metric components. Now, if the acceleration of gravity is given by the first derivatives, then the true gravitational forces—the tidal forces—are given by the gradients of the acceleration of gravity, which are the second derivatives of the metric. Therefore, we conclude that *the tidal forces are represented mathematically by the curvature of spacetime.*

The fundamental measure of curvature is the *Riemann curvature tensor,* denoted by $R^\alpha{}_{\mu\beta\nu}$. It is an object with four indices, essentially because it must be a function of the second derivatives of the metric, which have four indices: $\partial^2 g_{\alpha\beta}/\partial x^\mu \partial x^\nu$. There are a number of symmetries among the indices, so that, among its $4^4=256$ components, only 20 are algebraically independent. This is far fewer than the number of independent second de rivatives of the metric tensor components ($10^2=100$) because most of the second derivatives can be adjusted or even set equal to zero by appropriate coordinate choices. The 20 Riemann components represent the irreducible, coordinate-free geometrical information about the curvature. It is a theorem that the spacetime is flat (Minkowskian) if and only if the Riemann tensor vanishes everywhere.

One can derive from this tensor another called the *Ricci curvature tensor* $R^{\alpha\beta}$ by taking a trace. (It turns out that there is only one independent trace of the Riemann tensor, so that the Ricci tensor is essentially unique). The Ricci tensor is a symmetric tensor, with 10 independent components. It has two indices. One can likewise take its trace to get an object with no indices: this is called the *Ricci scalar* R.

A further two-index tensor is the so-called *Einstein tensor* $G^{\alpha\beta}$, which is formed by subtracting one-half of the product of the Ricci scalar and the metric tensor from the Ricci tensor. Its derivatives in a locally flat coordinate system satisfy a remarkable identity, called the *Bianchi identity*: for any metric, the Einstein tensor is divergence-free. (The divergence of a symmetric two-index tensor is defined as the trace of its first derivative, the trace being taken on the derivative index and one of the tensor indices.) This identity is central to Einstein's theory of gravity, as we will see in the next section. Notice also that there is one other divergence-free two-index tensor: the metric tensor itself, whose first derivatives all vanish in a locally flat coordinate system.

1.2.4 Sources of Gravity: How Matter Creates the Geometry

1.2.4.1 The Stress–Energy Tensor. In Newtonian gravity, the source of gravity is simple: the density of mass. It creates the field (the Newtonian potential ϕ) through Newton's field equation, Eq. (11). Because of the interconvertibility of mass and energy, we would expect the density of total mass–energy to be the source. This is, however, incompatible with SR for two reasons. First, in SR, mass is a form of energy, and energy is not a scalar: it is only one component of the energy–momentum four-vector. Second, in a relativistic theory, the notion of a density is not frame independent. The Lorentz contraction means that volumes and therefore densities depend on the observer.

These two transformations of mass–energy density (one acting on *mass–energy*, the other on *density*) mean that the mass–energy density is actually only one component of a two-index tensor. The other components of this tensor include the momentum density and the *stress tensor*. Just as SR links momentum and energy in a single four-vector, so too does it link stress and energy–momentum density into a single four-tensor with two indices. The unified tensor is called the *stress–energy tensor*. It is denoted by $T^{\alpha\beta}$. The mass density is measured by T^{tt}, the density of x-momentum by T^{tx}, and the stresses by the spatial components.

Energy and momentum are conserved in ordinary physics, and by the EEP this must be true in a local freely falling frame. For energy, for example, the conservation law says that the rate of change of energy in any volume equals the total net rate at which energy enters the volume across its sides. This implies that the (four-)divergence of the stress–energy tensor vanishes.

If mass density creates gravity in Newton's theory, then it is natural to expect the stress–energy tensor to be the source for a relativistic theory of gravity. A simple counting argument reinforces this idea. The stress–energy tensor can be shown to be symmetric on its two indices, so it has 10 independent components. This matches the 10 components of the metric tensor that describe the gravitational field: 10 unknowns $g_{\alpha\beta}$ determined by the 10 sources $T^{\alpha\beta}$.

However, this simple argument is too hasty: we saw above that there are effectively only six components of the metric that can be determined by the physics, since there are four degrees of coordinate freedom. Would such a theory be overdetermined? The answer is no, because there are as well four identities among the components of the stress–energy tensor: the laws of conservation of energy and momentum. So the counting is indeed encouraging: there are as many independent "sources" of gravity as there are "fields."

1.2.4.2 Einstein's Field Equations. To turn the counting argument into a full theory of gravity, Einstein had to find the appropriate differential equations that would allow the fields to be found in terms of the sources. He made what seemed to be the simplest choice.

We shall see below that there are more complicated alternatives.

One wants a generalization of Eq. (11), which has the form of a differential equation involving second derivatives of the potential set equal to the mass density as a source. The analog of the potential in a geometrical theory is, as we have seen, the metric tensor. So we need an equation involving second derivatives of the metric. The natural tensorial object involving second derivatives is the curvature tensor. If we take the hint of the preceding section and assume that the source will be the stress–energy tensor, then what we want is to equate the stress–energy tensor to a two-index curvature tensor that, like the stress–energy tensor, is divergenceless. As we pointed out earlier, there is such a tensor: the Einstein tensor. Einstein's choice was, then, to adopt the following form of the field equations:

$$\text{Einstein tensor} = \kappa \times \text{stress–energy tensor} ,$$

where κ is a constant of proportionality that is not fixed by the argument so far.

We fix κ by demanding that the solution of the field equations when the density is low and the velocities of the sources are small should have geodesics that are the paths of freely falling particles in the Newtonian gravitational field of the same sources. This gives $\kappa = 8\pi G/c^4$. In mathematical notation, the field equations of GR are

$$G^{\alpha\beta} = (8\pi G/c^4) T^{\alpha\beta} . \tag{17}$$

These equations are determined only by the correspondence with Newtonian gravity: there are no free parameters. Therefore, experimental constraints on GR can be very strict. One new consequence of Einstein's field equations after another has been calculated: the perihelion shift of Mercury's orbit (Sec. 2.4.4); the gravitational deflection of light (Sec. 2.4.3); the energy radiated in gravitational waves by a binary star system (Sec. 2.4.4); the existence of black holes (Sec. 2.4.2); the Big Bang and its consequences (Sec. 2.4.5). Each one could have proved the undoing of the theory. Yet in each case, there has been excellent quantitative agreement with the predictions of GR.

Because the Einstein equations are exceedingly nonlinear in the metric tensor, it has not been easy to find solutions of the field equations. Some exact solutions are known, which fortunately correspond to some of the most interesting simple cases: the field outside an isolated neutron star, the field of a black hole, and the metric of the homogeneous universe as a whole. In other cases, approximations can be made to good effect, such as when looking for small corrections to Newtonian gravity or for gravitational waves. And increasingly, as computers improve, relativists are attempting to solve more complicated systems numerically.

1.2.5 Other Theories of Gravity. General relativity is not the only geometrical theory of gravity possible. By the Einstein equivalence principle (EEP), the spacetime metric is the only field that directly affects geodesics or the behavior of stress–energy. Nevertheless, there could be other gravitational fields in the universe. Most alternative metric theories introduce such auxiliary fields; they could be scalar fields, vector fields, tensor fields, and so on. These fields may mediate the manner in which matter generates the spacetime metric, but they do not act back directly on the matter. Theories of gravity in which auxiliary fields act directly on matter are called *nonmetric* theories and typically violate the EEP. Experimental tests of that principle, described in Sec. 3.1, place tight constraints on such theories.

The prototypical example of an alternative metric theory of gravity is the Brans–Dicke theory, in which a scalar field exists in addition to the metric. This field plays the role of allowing the gravitational "constant" to vary in space and time. The differences in the predictions for observable effects between Brans–Dicke theory and GR depend on how strongly coupled the scalar field is to the metric—the weaker the coupling, the smaller the differences.

When one focuses on the weak-field, slow-motion regime that is appropriate to the Solar System (the so-called post-Newtonian limit because it includes the first corrections to Newtonian gravity) one finds that, in a broad class of metric theories, the metric looks the same, except for the numerical values of coefficients in front of various terms. A framework for studying metric theories in general has been developed, called the parametrized post-Newtonian (PPN) framework, in which parameters take the place of the numerical coefficients, parameters whose values depend on the theory under study. We shall encounter the use of some of these parameters in Sec. 3.2.1.

1.2.6 A Cosmological Term in Einstein's Equations. When we derived the form of Einstein's equations, Eq. (17) above, we reasoned that we needed a curvature tensor that had two indices and was divergenceless, and so we followed Einstein and used the Einstein tensor. But we remarked in Sec. 1.2.3.4 that there is another divergenceless tensor, the metric tensor itself. So it is possible to amend Einstein's equations to the following form:

$$\text{Einstein tensor} + \Lambda \times \text{metric tensor} = \kappa \times \text{stress–energy tensor}, \qquad (18)$$

which satisfies all the properties we needed for consistency and which will reduce to Newton's field equation in the appropriate limit provided the constant Λ is sufficiently small. Einstein introduced this modification into his theory when he found that his original equations did not admit static cosmologies, because the astronomical prejudices of his day held that the Universe was static and unchanging. Einstein found that he could choose a value of Λ that would indeed allow a static cosmological solution. He called Λ the *cosmological constant.*

There was no experimental evidence for Λ in Einstein's time, and when the expansion of the Universe was established a decade or so later, Einstein disavowed the cosmological term, calling it one of his biggest blunders. This is understandable: had he stuck to the original form of the equations, he would have predicted the expansion of the Universe and the associated Big Bang long before there was astronomical evidence for it.

Today there is a different view of Λ. If we carry the cosmological term over to the right-hand side of the equation, it then plays the role of an effective stress–energy tensor of the form

$$T^{\text{cosmol}}_{\alpha\beta} = -\Lambda g_{\alpha\beta}. \qquad (19)$$

Because $g_{tt} < 0$, this means that Λ is an effective energy density, constant everywhere. Provided Λ is much smaller than the mean energy density of the solar system, its effects will not have been noticeable. The values discussed today are much smaller. Interestingly, since the stresses are given by the spatial parts of Eq. (19), we find that the effective pressure is $-\Lambda$: if the energy density is positive, the pressure is negative.

Strange as this may look for ordinary matter, it seems almost inevitable in some schemes for quantizing gravity. When a classical field is quantized, there are renormalization terms that affect the residual energy density of the field (see Birrell and Davies, 1982). If one quantizes the vacuum gravitational field, the stress–energy tensor that survives renormalization will have to be proportional to the metric tensor, since there are no other tensors around, and no preferred frames. (This effect has an electromagnetic analog, called the *Casimir effect.*) It could happen, of course, that the cosmological term turns out to be zero; but there is no reason for this to be inevitable, and there is an expectation among many cosmologists today that the term may be comparable to the smoothed-out energy density of the present Universe.

2. SOME CONSEQUENCES OF EINSTEIN'S FIELD EQUATIONS

2.1 Momentum and Stress Also Make Gravity

The fact that all components of the stress–energy tensor contribute to gravity has important consequences.

2.1.1 Gravitomagnetism. In the Solar System, Einstein's equations will give the Newtonian potential in g_{tt}, using the mass density (tt component of the stress–energy tensor) as the source (Sec. 1.2.3.2). But the momentum density is also a source, so that *moving* bodies create new parts of the gravitational field. These couple to the velocities of particles, so they are called *gravitomagnetic effects.*

An important example is rotation. The angular momentum density of the Earth generates a metric term whose value is proportional to the angular momentum and which falls off as $1/r^2$, just as the electromagnetic potential of a rotating conductor does.

This term has a number of consequences. A free particle falling straight down will acquire a small motion in the same sense as the Earth's rotation. This is sometimes called the "dragging of inertial frames" or the *Lense–Thirring effect,* after its discovers. For the same reason, the orbital period of a satellite orbiting from west to east is slightly less than that of one going in the opposite direction. A spinning gyroscope in orbit will couple to this effect in much the same way that the spin of an electron in an atom couples to the magnetic moment of the nucleus, producing a precession of the spin.

These effects are weak compared to the dominant Newtonian orbital effects and hence hard to measure, for two reasons. First, the angular momentum density is small compared to the mass density, basically by a factor of v/c, which for the Earth's rotational motion is about 1.5×10^{-6}; the gravitomagnetic metric terms are therefore smaller than ϕ by this factor. But the effect is smaller still because, like magnetic effects, it only couples to the speed of the orbiting body, not simply to its mass. This introduces yet another factor of v/c. Such effects that are predicted by Einstein's equations but are of order $(v/c)^2$ smaller than the Newtonian effects are called *post-Newtonian* effects. Measuring them is one way of testing the validity of GR (Sec. 3.4.1).

2.1.2 Gravitational Collapse. In the same way, the stresses inside a body also make a contribution to gravity. These have an even smaller effect in nonrelativistic bodies like the Earth, being down by order $(v/c)^4$. But in a relativistic star, like the neutron stars we will describe in Sec. 2.4.1 below, they can be important. The dominant stress inside a star is the ordinary pressure of the fluid. In a neutron star, pressure and density are comparable, in the sense that $p/c^2 \sim \rho$. Such a large pressure has the effect of *increasing* the effective gravitational field inside the star. The result in GR is that there is actually a limit on how compact and relativistic a star can be, regardless of what it is made of: no star of mass M and radius R can have $GM/Rc^2 > 2.25$.

This leads to a very interesting conclusion. Suppose a star is right at the limiting size, and then it is perturbed, to make its radius marginally smaller. It cannot restore itself to equilibrium, and so it will collapse. Once it begins to collapse, it cannot stabilize itself at a smaller radius, for this would violate the inequality. This is called *gravitational collapse*: the unstoppable collapse of a star. The result of such collapse is a *black hole.*

2.2 Black-Hole Theory

2.2.1 Black Holes in the Eighteenth Century. Probably the most dramatic prediction of Einstein's equations is the existence of black holes. It may seem surprising, therefore, that essentially the same concept was discussed in the context of Newtonian gravity two centuries ago!

Black holes are regions of space in which gravity is so strong that light is trapped. The boundary of this region is the *horizon*: no light emitted from inside the horizon can reach the outside. The idea that light could be trapped by gravity occurred to eighteenth-century physicists as well. The first to suggest it was the amateur scientist John Michell (1724–1793), who in 1784 reasoned that, since light traveled at a finite speed, it would in principle be possible for an astronomical body to exist whose escape velocity was greater than the speed of light. Similar conclusions were drawn by Pierre Laplace in 1796.

Since the escape velocity is $(2GM/R)^{1/2}$, it follows that a body will trap light in Newtonian gravity if $2GM/Rc^2 > 1$. This is, remarkably, exactly the condition for the formation of a black hole in Einstein's theory as well. [Michell's suggestion was no fluke of speculation: it was Michell who suggested to his friend Henry Cavendish (1731–1810) that Cavendish should perform the famous experiment to measure the value of G that now bears his name.]

In the Newtonian picture, the trapping star is dark, because light cannot reach us from it, but its gravitational field is unchanged, and it can be discovered and identified by its gravitational effects. The same is true for the relativistic black hole.

2.2.2 Black Holes in General Relativity. The modifications needed to turn the Newtonian picture into a black hole in GR arise because of the special role played by the speed of light in relativity. In the Newtonian picture, light would still leave the surface of the trapping body, but it would slow down progressively and eventually turn around and fall back to the surface. Light emitted somewhat further out would escape, passing at some point the previous photon where it turns around. In relativity, all photons travel at the same speed. If a photon leaves the surface of the body, it cannot turn around later while other photons pass it, still moving outwards. Instead, there is a *horizon*: any photons outside the horizon can escape to infinity, while those inside are trapped.

Moreover, in the Newtonian picture, an interested astronaut could still in principle explore the dark star, getting away on a sufficiently powerful rocket. In relativity, nothing can go faster than light, so anyone or anything that crosses inside the horizon is trapped there forever.

There are no markers at the horizon, no signs saying "Point of no return". The horizon is defined as the boundary between what is trapped and what is not, but this boundary may not be known until the whole dynamics of the collapse that formed the black hole has occurred. The horizon is generally a place in the vacuum gravitational field, locally flat, in every way locally unremarkable.

2.2.3 Singularities Inside the Hole. We saw in Sec. 2.1.2 that a star with a radius smaller than 9/8 of the horizon size of a black hole of the same mass as the star cannot support itself against gravity. This means that the mass that has collapsed to form the black hole cannot find an equilibrium radius inside the hole: the material must continue to move inwards. The details of what happens to it are conjectural at present, but there is a set of *singularity theorems*, proved within GR by the mathematical physicists Roger Penrose and Stephen Hawking (see Hawking and Ellis, 1973), that show that matter obeying rather weak conditions (such as that its energy density should be positive) will always generate some sort of singularity inside the horizon. The nature of this singularity is, in general, poorly understood. Quantizing gravity (or even the matter fields) may change or eliminate the singularity, but it is hard to see how quantum effects could get outside the horizon and change the external aspect of the hole of macroscopic size.

It is also not clear whether gravitational collapse can lead to a singularity that is not inside the horizon. Such an event would prove much more damaging to notions of causality: singularities inside the horizon are confined, but those outside might make unpredictable effects on their surroundings. Such *naked singularities* are an active subject of research today. Penrose has formulated the *cosmic censorship hypothesis*, which asserts that naked singularities do not form. There is no proof of it at present.

2.2.4 Black Holes Have No Hair. Although the inside of a black hole may be messy, the external gravitational field is extraordinarily simple. A series of "no hair" theorems by Hawking, Brandon Carter, and others (see Wald, 1984) has shown that black holes, once formed, quickly radiate away everything possible and settle into a stationary state characterized entirely by values of the conventional conserved quantities of physics: total energy (the mass of the hole), total angular momentum, electric charge, and magnetic monopole moment (should monopoles exist). These properties of the hole are all measurable externally: the mass from orbital periods of satellites, the angular momentum from the Lense–Thirring effect (Sec. 2.1.1), and the charge from electrostatic attraction.

Higher multiple moments of the electromagnetic or gravitational field that might have characterized the collapsing star are carried away from the hole in a burst of radiation that accompanies its formation. The total number of baryons and leptons that formed the hole is not measurable from outside, because the nuclear forces have short range.

The metric of the spherical uncharged black hole was the first exact solution found for Einstein's equations, derived by Karl Schwarzschild (1873–1916) in 1916. It was not completely understood until the 1960s, after work by Martin Kruskal, Peter Szekeres, John Wheeler, and others. (See Misner *et al.*, 1973, for references.) The rotating hole is described by the Kerr metric. The term "black hole" was coined by Wheeler in the 1960s.

2.2.5 Black-Hole Thermodynamics. Forming a black hole entails a considerable loss of information: by the "no hair" theorems, most of what goes down the hole is lost forever. It is not surprising, then, that one can assign an *entropy* to the black hole. In fact, the whole of thermodynamics can be generalized to include black holes, and *black-hole thermodynamics* is one of the most beautiful parts of black hole theory (see Thorne *et al.*, 1986). The entropy of the hole is proportional to the surface area of its horizon. A theorem of Hawking establishes that this area cannot decrease with time (Hawking and Ellis, 1973).

There is a corresponding temperature, which is proportional to the surface gravity of the hole.

This temperature is the most remarkable black-hole property of all. In black-hole thermodynamics, it plays a formal role in determining the energy (mass) change associated with a change in the entropy (surface area) of a black hole: $dM=TdS$. But in ordinary thermodynamics, objects also exhibit their temperature by emitting blackbody radiation. Despite the fact that black holes trap all photons, they also give off a *thermal radiation* whose spectrum is exactly that of a blackbody of the thermodynamic temperature. This is called the *Hawking radiation* (Hawking, 1974).

Hawking's demonstration of this radiation relies on quantum mechanics, but it requires only the quantum field theory of the electromagnetic field near the hole, not any quantum theory of gravity. The Hawking temperature is inversely proportional to the mass of the hole, and for a hole that has the mass of the Sun, it is entirely negligible. This means that the radiation is likely to be exceedingly difficult to observe. Its existence is accepted, however, partly because well-established techniques of quantum field theory predict it, and partly because it allows black-hole thermodynamics to fit so beautifully into standard thermodynamics.

Black holes have other macroscopic properties as well (Thorne *et al.*, 1986). For example, the horizon has a finite electrical conductivity. This comes essentially from the "no hair" theorems as well: if a charge is lowered near the horizon, it will have to look from a distance as if it is smeared uniformly over the horizon; otherwise there would be an electric dipole moment. The horizon therefore effectively conducts charge along its surface.

2.2.6 Wormholes. The simplest black-hole solution, the one found by Schwarzschild, describes a stationary black hole, i.e., one that has existed for all time. It has an interesting topology: it actually involves *two* "exterior" spaces connected by a throat, or wormhole. Although the gravitational field outside the hole in both exterior regions is static, the throat is not. It opens up to a maximum size and then closes off in a finite proper time. In fact, it closes off so fast that a particle falling into the hole would not have time to get through it: the wormhole is not a channel for communication between the two exteriors. Moreover, a black hole formed by the collapse of a star has a simpler topology, with no wormhole, and only one exterior region.

Nevertheless, wormholes have intriguing properties. If physicists could manipulate quantum fields to create and maintain a region of negative energy (as happens in the Casimir effect referred to in Sec. 1.2.6), then they could in principle maintain a wormhole open long enough for a particle to travel through it. If the two ends of the wormhole are open in the same space, then a particle could circle through the throat many times. If, in addition, the ends of the wormhole were made to move relative to one another, then, as Thorne (1991) has shown, the time dilation effect of special relativity could be arranged to allow the particle to travel backwards in time.

The realization that GR allows such behavior, even under what present technology suggests are implausible conditions, has created considerable interest. If such *closed timelike curves* exist, they raise questions about causality and especially the consistency of initial-value formulations of the law of physics, and they have to be taken into account in formulations of quantum gravity. The study of these rather exotic conditions may in the future shed new light on fundamental physics.

2.3 Gravitational Waves

2.3.1 The Necessity of Gravitational Waves. Gravitational waves (GWs) are present in any relativistic theory of gravity. When fields are weak and motions slow, the relativistic equations must reduce to Newton's field equation, Eq. (11). This involves the differential operator ∇^2. If fields are weak but motions may be rapid, then one expects the theory to be relativistically invariant. The operator ∇^2 will be replaced by its relativistic generalization

$$-\frac{1}{c^2}\frac{\partial^2}{\partial t^2}+\nabla^2 .$$

This is the wave operator, with the characteristic wave speed c. We should expect wave effects in relativistic gravity, propagating at the speed of light. Different theories of gravity will differ in the details of the waves, but GWs will be present in all of them.

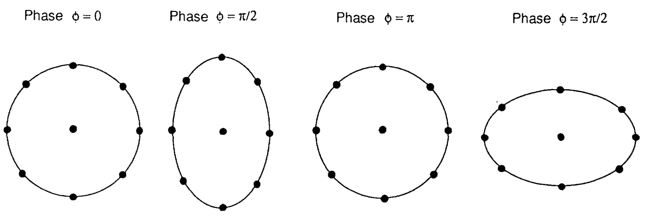
In GR, the waves bear a striking mathematical resemblance to electromagnetic waves. They are transverse, have two independent polarizations, and fall off in amplitude as $1/r$. Electromagnetic waves do not carry monopole radiation: for slow-motion sources they are dominated by dipole emission. Gravitational waves in Einstein's theory do not carry either monopole or dipole radiation, but are dominated by quadrupole emission (Sec. 2.3.3).

2.3.2 The Interaction of Gravitational Waves with Matter. Waves can only be detected through their time-dependent tidal forces. If a wave passes a single particle, one can always choose comoving coordinates, so that the particle remains at a fixed coordinate position. By the EEP, the particle will not feel anything locally from the wave: bowls of soup will not spill, pocket calculators will work normally. The particle will only be able to detect the wave if it looks at other things sufficiently far away for the tidal effects of gravity to be noticeable.

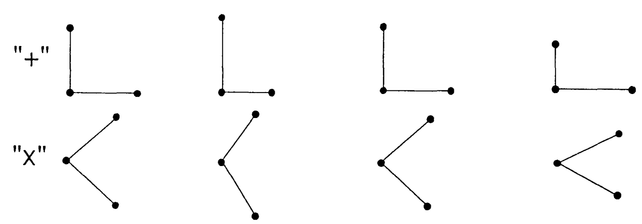
The absence of single-particle effects of GWs led to much misunderstanding in the early development of GR. The intuition developed in electromagnetism, where single charged particles can detect electromagnetic waves, was not helpful. Many relativists, including at times Einstein himself, believed that GWs were a mathematical illusion. Work in the 1950s and 1960s by Hermann Bondi, Richard Isaacson, Penrose, Joseph Weber, and many others showed that to detect GWs one needs at least two particles, but that the waves are very real, transferring energy and angular momentum away from their sources to their detectors. [See Misner *et al.* (1973) or Schutz (1985) for more details.]

The simplest way to detect a GW is to monitor the proper distance between two nearby free particles, particles that have no external forces on them. The distance can be monitored, for example, by measuring the round-trip light-travel time between the particles. A GW can affect this distance. Gravitational waves are transverse, and so if the wave moves in the z direction, then only distances in the x-y plane will be affected.

The pattern of distance changes produced by a given wave is shown in Fig. 1. The dots represent a ring of free particles. The circles and ellipses are not physical connections: they only illustrate the pattern of the placement of the particles. The first ring is the undisturbed position: a circular ring of particles. The second diagram shows the effect of a GW on proper distances. It has lengthened the x axis of the circle and shortened the y axis by the same fraction, preserving the area of the ring. When the wave reaches its opposite phase (final diagram), the effects on the axes are reversed. At the bottom of the diagram are



Polarization of a Gravitational Wave



Response of a three-mass gravitational wave "detector" in two orientations

FIG. 1. Illustration of the action of a GW on a ring of free particles transverse to the direction of propagation.

shown the lines joining certain particles to the center of the ring. The top lines are for the particles at 12 o'clock and 3 o'clock (particles oriented in the "+" configuration relative to the ellipse's principal axes). Their lines remain perpendicular but change their relative length. The bottom lines are for the particles at 1:30 and 4:30 (particles oriented in the "×" orientation relative to the ellipse's principal axes). Their lines remain the same length but the angle between them changes.

Nothing is preferred about the x axis in this diagram. The entire ellipse can be rotated about the z axis to give possible patterns. A rotation of 90° effectively carries the pattern back into itself, which is characteristic of a tensor (spin-2) wave. The second independent polarization is obtained by a rotation of 45°.

Because tidal effects grow linearly with distance, *the shape of the ellipse in Fig. 1 is a property only of the wave, independent of the size of the ring.* The relative change in the axes is, therefore, a measure of the amplitude of the wave itself. It is conventionally called h, and can be defined from Fig. 1 as

$$h := 2(\delta l)_{\max}/l \,, \tag{20}$$

where l is the length of the semimajor axis of the ellipse. (The factor of 2 is conventional.) The relative distortions shown in the figure are, of course, exaggerated in order to make them easy to see. Modern GW detectors are being built to detect amplitudes as small as 10^{-22}. We shall consider the technical challenges of this in Sec. 4.2.

This tiny amplitude means that the effect of matter on the gravitational wave will also be of this order; the wave will lose or scatter only a fraction of order 10^{-22} of its energy as it passes through a detector. By extension, this means that the waves that arrive at our detectors have lost little of their original form: they carry information from their sources uncorrupted by scattering or absorption. In this they are a unique carrier of information in astronomy; even the neutrinos detected from the supernova event in 1987 (SN1987A) were from a thermal distribution that had scattered many times before leaving the collapsed core (Sec. 2.4.1.4). Traveling at the speed of light, gravitational waves follow geodesics through the Universe; they can be gravitationally lensed, but scattering and absorption are negligible.

2.3.3 Wave Emission: The Quadrupole Formula. Sources of gravitational waves respect the conservation laws for energy and momentum that are built into Einstein's equations. For weak GWs, these have a similar effect to that produced by the conservation of charge in electromagnetism, which ensures that there are no monopole electromagnetic waves: the lowest order of radiation is dipole. In GR, the law of conservation of energy similarly ensures there is no spherical gravitational radiation. Any oscillating spherical mass leaves its exterior gravitational field undisturbed in GR (just as in Newtonian gravity), and so it does not radiate GWs. Conservation of momentum has the same effect on dipole radiation: there is no dipole gravitational radiation.

From a fundamental point of view, charge conservation (and its consequence, the absence of monopole radiation) in electromagnetism follows from the gauge invariance of the theory. (See SYMMETRY AND CONSERVATION LAWS.) In GR, energy–momentum conservation (and the absence of monopole and dipole radiation) follow from the general coordinate invariance of the theory.

At quadrupole order, the formulas for the radiation emitted by a slow-motion system are remarkably similar to those for electric quadrupole radiation in electromagnetism. (For highly relativistic, fast-motion systems, the formulas below can only be used approximately.) We define the quadrupole moment tensor of the mass distribution:

$$I_{jk}(t) = \int \rho(t,\mathbf{r})\, x_j x_k\, d^3x \,, \tag{21}$$

where ρ is the mass density (rest mass dominates in a nonrelativistic system), and where we follow the usual convention of employing Latin indices for purely spatial values (1,2,3). This equation can only be used in a Cartesian spatial coordinate system. The trace-free or reduced quadrupole moment is derived from this by

$$\rlap{-}I_{jk} := I_{jk} - \tfrac{1}{3}\,\delta_{jk} I \,, \tag{22}$$

where I is the trace of I_{jk}.

The amplitude of the radiation at a distance r from the source is roughly

$$h \sim (4G/c^4)\,(\ddot{\rlap{-}I}/r) \,, \tag{23}$$

where $\ddot{I}$ stands for the second time derivative of a typical component of the quadrupole moment. If the motions that are responsible for the time derivatives are driven by the internal gravitational fields of the source, which is the case for all the realistic sources of GWs that we will consider later, then there is a convenient upper bound on this amplitude, given by

$$h \leqslant (GM/rc^4)\phi_{\text{internal}} , \tag{24}$$

where ϕ_{internal} is the typical size of the Newtonian gravitational potential within the source (Schutz, 1984).

Although the local conservation laws of energy and momentum eliminate the monopole and dipole radiation, it does not follow that GWs remove no energy or angular momentum from the source. Unlike electromagnetism, which is a linear theory, GR is nonlinear, and GWs can act as sources for gravity. So when they leave the system, there is a gradual decrease in its energy. This is compensated by a well-defined energy flux carried by the waves (Isaacson, 1968). Energy from this flux can be transferred to other systems, such as GW detectors. The GW luminosity (Landau and Lifshitz, 1962) is probably the most useful of the quadrupole formulas:

$$L_{\text{GW}} = \frac{G}{5c^5} \left\langle \sum_{j=1}^{3} \sum_{k=1}^{3} |\dddot{I}_{jk}|^2 \right\rangle , \tag{25}$$

where the angle brackets denote an average over one period of the motion of the source. Notice that this depends on the square of a third time derivative, just as the analogous formula for electric quadrupole radiation does. It is therefore very sensitive to the size of the velocities inside the source. As a source becomes more relativistic, the power radiated goes up very rapidly, as $(v/c)^6$.

2.4 Applications of General Relativity

For its first 50 years, GR was mainly the property of mathematicians and theoretical physicists who valued it for its intellectual challenge and its aesthetic beauty. It seemed to have little practical relevance to the rest of physics. But astounding discoveries in astronomy, beginning with the realization in 1963 that quasars have enormous luminosities, attracted physicists to the challenge of explaining the new phenomena, and they found that they needed to use GR as an everyday tool in making models of astronomical phenomena. In this section we describe some of the ways that GR is used. For more details of many of these phenomena, the reader is referred to the article on ASTROPHYSICS.

2.4.1 Relativistic Stars (Pulsars) and Gravitational Collapse

2.4.1.1 Stellar Evolution. An ordinary star nearing the end of its nuclear-burning lifetime undergoes many changes as it switches from its primary fuel (hydrogen) to short-lived secondary sources of energy (helium, then carbon, and so on). When it finally exhausts its nuclear fuel, it can no longer generate energy to replace that which it radiates from its surface, with the result that gas pressure can no longer hold the star up against gravity. The star then has only two options: it can rely on *degeneracy pressure* (the quantum-mechanical resistance of identical fermions to being squeezed into too small a volume), or it can collapse to a black hole. Which option it takes depends on its mass.

2.4.1.2 White Dwarfs. If the mass of the star when it reaches this point is less than about 1.4 times the mass of the Sun, then it can end its days quietly, supported by electron degeneracy pressure. It is called a *white dwarf*, and has a radius roughly that of the Earth, about 10^4 km.

However, Chandrasekhar (1939) showed that electron degeneracy cannot support more than about $1.4M_{\odot}$. The burnt-out core of a star that is larger than this will inevitably grow to exceed this size, and then it must gravitationally collapse. During the collapse, which lasts less than a tenth of a second, essentially all electrons and protons combine to form neutrons. This process is called *neutronization*. When the density is high enough for neutron degeneracy pressure to become effective, the collapse will halt, provided again that the star is not too massive. This *neutron star* has the density of a typical atomic nucleus, so that a $1M_{\odot}$ star has a radius of about 10 km.

2.4.1.3 Neutron Stars. We have met neutron stars (NSs) in Sec. 1.1.2.1. The upper mass limit of NSs is sensitive to poorly understood high-density nuclear physics, and to the details of the relativistic theory of gravity. It is probably between $2M_{\odot}$ and $3M_{\odot}$ in GR (Hartle, 1978).

The result of halting the collapse is a bounce; a shock travels outwards through the rest of the envelope of the star, blowing it away in an explosion called a *supernova*. Since the collapsing core originally had a rest mass of $1.4M_\odot$, one expects the supernova to leave behind a NS of about that rest mass or a little more. Because the gravitational redshift reduces all energies as measured from far away, and because the strong equivalence principle (Sec. 3.2.3) ensures that all energies contribute to gravity, it follows that the gravitational mass of the star as measured by orbits in its gravitational field will be some 10% or so less than its rest mass.

2.4.1.4 Black Holes. Collapse to a NS is likely to be complicated by a number of factors. One is rotation. If the collapsing core has as much angular momentum as the Sun (which is a slow rotator), centrifugal effects will halt the collapse before neutron-star densities. Smaller amounts of rotation may therefore have significant dynamical effects. Work is currently in progress to model rotating collapse on computers.

Another complication is neutrino physics. The collapse generates many neutrinos, first from the neutronization reaction $p+e\rightarrow n+\nu_e$, but more copiously from the thermal equilibrium reaction $\gamma+\gamma\leftrightarrow\nu+\bar{\nu}$ that develops as the collapse halts. These appear to exert a crucial pressure to power the shock outwards. The neutrinos detected from the nearby supernova event in 1987 (called SN1987A—see ASTROPHYSICS) came primarily from the thermal distribution.

Whatever the complications, it seems that on occasion the shock does not blow away the whole star, and enough further matter falls on the collapsed core to push it over the upper mass limit. It must then collapse further, and it forms a black hole (BH). In the next section we will see that there is good evidence for a number of $10M_\odot$ BHs in our Galaxy.

2.4.1.5 Pulsars. When a NS is formed, it is likely to be rotating. By what seems like a great stroke of luck, we are able to observe this rotation in hundreds of cases. During the collapse, not only is the rotation speed amplified, but so is the magnetic field of the star. It happens that the magnetic and rotation axes do not line up; in fact, they seem to prefer to be perpendicular to each other. The result is that rotation carries the magnetic poles around. Charged particles spiral around the magnetic field lines and crash into the star at its magnetic poles, in a colossal version of our terrestrial auroral displays. The result is a beam of radiation that emerges from the poles and is spun by the star's rotation in the same way a lighthouse beam turns. If we happen to sit in the direction of the beam, we see the radiation (radio, optical, and x-ray) turning on and off. This is a *pulsar*.

Pulsar periods must be longer than the orbital period at the surface of a NS, which is about 0.5–1 ms. In fact, the fastest known pulsar has a 1.6-ms period. However, all pulsars that we know are young (for example, those that can be identified with supernova explosions whose remnant clouds of gas are still visible) are rather slow rotators. For example, the pulsar in the Crab nebula spins "only" 30 times per second. We now believe that this is typical of new NSs, and that the really rapid rotators have been spun up by accreting gas from a companion star in a binary system (Sec. 2.4.2).

Pulsars in binaries are not uncommon, but they are hard to find because the orbital motion keeps changing their apparent pulse period. However, binary pulsars are prized discoveries, because by monitoring the Doppler shifts of the period one gets dynamical information about the system. In a few cases, we get enough information to determine the masses of the individual stars, as we describe in Sec. 3.3. Interestingly, all six neutron stars with well-determined masses are within 10% of $1.4M_\odot$.

2.4.2 Black Holes in X-Ray Binaries and in Galactic Centers

2.4.2.1 X-Ray Binaries. When gravity overwhelms neutron degeneracy, the star must collapse. Even though high-density nuclear physics is poorly understood, simple constraints (such as that the speed of sound in nuclear matter must be less than the speed of light) are enough to guarantee that nuclear physics cannot support more than about $3M_\odot$ at these densities (Hartle, 1978). This implies that a compact object with a significantly larger mass, such as $7M_\odot$ or $10M_\odot$, must be a BH. Since BHs do not emit observable radiation themselves, practically the only way we can identify holes of this size is by their effects in binary systems.

When NSs or BHs orbit ordinary stars, mass can sometimes flow from the companion onto the compact star. The angular momentum of the infalling gas forces it into a disk around the star, and friction in the disk leads to a more or less steady accretion of matter onto the compact object. As we noted above, NSs can be spun up by this process. Black holes also spin up, but this may not be observable. But the hot accretion disk is itself a source of observable radiation: x rays.

One of the big surprises of the early 1970s was the discovery, by x-ray satellite observatories, that our Galaxy has dozens of such binary x-ray sources. If the companion can be identified by optical observations and its mass estimated from its spectrum, then the mass of the compact object can be estimated. In this way, we now have three or four fairly secure identifications of BHs. The best identification, in a system called V404-Cyg, has a minimum mass of $8M_\odot$ (Casares *et al.*, 1992).

This certainly underestimates the number of BHs in the Galaxy. Most mass determinations are uncertain by 50% or so, and, given the uncertainty in the upper mass limit of NSs, there are a number of binaries where we are unable to be sure about the nature of the compact object. Therefore, while we are confident that about 10% of the stars in the Galaxy are white dwarfs and 1% are NSs, the fraction that are BHs is very uncertain. X-ray binary observations suggest a plausible lower limit of about one in 10^4.

2.4.2.2 Galactic Black Holes. Giant BHs seem to be relatively more common than this: it is possible that every normal galaxy has in its center a BH of mass between $10^4M_\odot$ and $10^{10}M_\odot$. These would probably have been formed at about the same time as the galaxy itself formed, either from a dense gas cloud in the center or from the collective collapse of a swarm of NSs and small BHs formed near the center. Recall that the density of a $10^8M_\odot$ cloud of gas when it forms a BH is only the density of water.

For general information about galaxies, the reader is referred to the article on GALAXIES AND COSMOLOGY. The evidence for BHs in the centers of galaxies is manifold, and in many ways better than that for individual x-ray binary BHs. The strongest evidence is velocity information. By measuring the Doppler shifts of spectral features in many wave bands, astronomers have accumulated evidence for rotation, collapse, and/or expansion with velocities of typically hundreds of km/s inside volumes no larger than a parsec (3×10^{16} m, which is a typical distance between individual stars in the neighborhood of the Sun). Using the order-of-magnitude relation $GM/R=v^2$ gives masses of the order we have quoted (Rees, 1990). There do not seem to be any mechanisms that would allow such concentrations of mass to remain stable for long without collapsing to BHs. The inference is that the collapse has already occurred in most cases, and we are seeing a small amount of gas swirling around in the resulting gravitational field.
